The plan shown in Fig. 2 shows the location of all the machine tools. Each rectangle represents the tool thereon designated. The area of the rectangle is proportionate to the actual floor space occupied. The symbols in Table 1, column 3, give the location of all the tools. The letters *E* and *W* refer to the east and west sides of the building. The numbers refer to the columns at the sides of the building. Thus vertical boring mill No. 2598 is located by *W*-9—column 9 on the west side of the building; planer No. 2314 is located at column 5 on the east side, designated by *E*-5.

The charges against the machine-tool department are divided as follows: (1) Variable charges; (2) fixed charges—(a) salaries, (b) interest and depreciation on auxiliary apparatus; (3) interest and depreciation on machine tools; (4) cost of power; (5) shipping charge.

Variable charges consist of the items given in Table 2. The amount of each of these charges is given for the total building. This value is divided among the machine-tool, assembling and testing departments as indicated by the percentages next to the amount in dollars.

Wherever the percentage 43, 38 or 19 is used, the division is made according to the percentage of total floor space. Other percentages are used where this division is not suitable. For example, patterns are charged 50 per cent. to machine tool and 50 per cent to assembling, none being charged to test. New dies and formers are charged entirely to assembling or winding. Repairs to tools are charged 90 per cent. to machine tool and 10 per cent. to assembling and winding.

All the charges in Table 2 cover six months' operation. The number of working hours per year, based on 54 hours per week, is 52 × 54 = 2,808 hours per year. From this table the variable charge per hour per square foot is derived as follows:

Total variable charges (six months)	$63,920
Number of hours (six months)	1,404
Number of square feet (machine-tool department)	35,900
Charge per hour ($63,920 ÷ 1,404)	$45.50
Charge per hour per square foot ($45.50 ÷ 35,900)	$0.00127

The variable charges are divided among the following items as indicated by the percentages:

	Per Cent.
Repairs and renewals to tools	26.0
Nonproductive sections	20.0
Defective workmanship	14.0
Defective design	12.2
Stores	7.4
Defective material	5.3
Miscellaneous	3.5
Repairs to electrical plant	3.0
Repairs to mechanical plant	2.8
Patterns	2.7
Repairs and renewals to buildings, etc	2.5
Lost material	0.6
	100.0

* Designation used for machine tools is as follows—VBM., vertical boring mill; DR, drilling machine; RD, radial drilling machine; HBM, horizontal boring mill; SLTR, slotter; SLMM, slot-milling machine; DHMM, double-head milling machine.

The variable charge per hour of a machine tool is obtained by multiplying $0.00127 by the total floor space of the machine in question. This value is given in Table 1, column 8.

Fixed charges are divided into two parts—(1) wages and salaries and (2) interest and depreciation on auxiliary apparatus.

TABLE 2. SUMMARY SHOWING DISTRIBUTION OF VARIABLE CHARGES

	Total	Machine Tool	Per Cent.	Assembling and Winding	Per Cent.	Test	Per Cent.
Repairs and Renewals:							
Office buildings, factory, heaters and ventilators, sanitary plants, fire appliances, miscellaneous apparatus, bench and shelving, fences, gates, guards, roadway and tracks, other....	$3,431	$1,480	43	$1,300	38	$650	19
Tools....	18,489	16,640	90	1,849	10	....	....
Electric plant....	3,296	1,976	60	330	10	990	30
Mechanical plant....	3,967	1,710	43	1,510	38	755	19
Patterns:							
New, repairs to, change in....	3,498	1,749	50	1,749	50	....	....
New dies and forms....	143	....	..	143	....	....	....
Metals, polish and plate....	83	....	..	83	....	....	....
From nonproductive section....	29,950	12,900	43	11,460	38	5,700	19
Stores....	8,890	4,890	55	4,000	45	....	....
Defective design....	18,200	7,850	43	6,900	38	3,450	19
Defective material....	6,140	3,380	55	2,760	45	....	....
Defective workmanship....	16,270	8,950	55	7,320	45	....	....
Lost material....	80	45	55	35	45	....	....
Undistributed freight and haulage; demurrage; insurance; sick and injured employees; relief department; printing and stationery; lubricants; other manufacturing supplies; coke, gas, except plant; water, except power house use; undistributed factory expense; miscellaneous travel expense..	5,470	2,350	43	2,080	38	1,040	19
Total....	117,907	63,920		41,459		12,585	
Shipping....	47,054	20,200	43	17,900	38	8,950	19

Table 3 contains a summary of the salaries for six months' operation, amounting to $33,032, from which the charge per hour per square foot is obtained as follows:

Total salaries (six months)....	$33,032
Number of hours....	1,404
Number of square feet....	35,900
Charge per hour ($33,032 ÷ 1,404)....	$23.60
Charge per hour per square foot ($23.60 ÷ 35,900)....	$0.00066

This value multiplied by the total floor space per machine tool gives the charges listed under "Salaries," Table 1, column 9. The salaries are divided as follows:

	Per Cent.
Foremen....	20.5
Engineering....	18.4
Handling material....	17.6
Factory clerks....	13.6
Crane and elevator men....	7.0
Boiler and engine room....	7.0
Timekeepers....	6.3
Janitors and watchmen....	4.1
Operating heads and superintendents....	3.0
Inspection....	2.5
	100.0

Interest and depreciation on auxiliary apparatus include interest and depreciation on cranes, heating system, wiring, etc., listed in Table 4. The interest is taken at 6 per cent. and depreciation at 10 per cent. of a reducing balance, as explained previously.

Since most of the apparatus has been installed from 10 to 15 years, the depreciation will be from 3 to 4 per cent. on the original value (see the curve of Fig. 1); hence if we take 10 per cent of the original investment, we cover both interest and depreciation. The method of figuring the charge per hour per square foot for interest and depreciation is as follows:

Total investment in auxiliary apparatus....	$36,555
10 per cent. of investment ($36,555)....	3,655
Number of hours per year....	2,808
Square feet of floor space....	35,900
Charge per hour ($3,655 ÷ 2,808)....	$1.30
Charge per hour per square foot ($1.30 ÷ 35,900)....	$0.000036

This value multiplied by the total floor space is listed in Table 1, column 10.

Interest on a machine tool is taken at 6 per cent. The investment includes the cost of the machine and all accessories. Depreciation is taken at 10 per cent. of a reducing balance, as already explained. A method of keeping a record of the details of each machine tool will be outlined later. The power required to run each machine tool is based upon tests made with a recording meter on both motor-driven and line-shaft-driven machines. An average kilowatt per hour consumption of power was determined. The charge per kilowatt hour was one cent. The cost of power is a small percentage of the other charges. Table 1, column 4, gives this charge.

The shipping charge is also a variable charge, given in Table 2, and is divided according to floor space. The charge per hour per square foot is figured out in the following manner:

Total shipping charge (six months)....	$20,200
Charge per hour ($20,200 ÷ 1,404)....	14.40
Charge per hour per square foot ($14.40 ÷ 35,900)....	$0.0004

This charge multiplied by the total floor space of a machine tool is listed under "Shipping," Table 1, column 15.

The charges have been separated, as explained, to show their relative importance. It is also possible to work out easily the total charges against any machine during any period of time by finding the charge per square foot per hour and multiplying this by the total floor space occupied by the machine in question. The following percentages show the relative importance of the charges given in Table 1:

	Vertical Boring Mills	Drilling Machines	Horizontal Boring Mills	Lathes	Planers	Miscellaneous	Portable
Variable....	45.5	48.7	47.0	46.0	48.0	44.5	44.5
Salaries....	25.0	27.3	26.3	25.9	27.0	26.0	24.5
Shipping....	14.3	15.5	14.8	14.2	15.0	14.1	14.0
Interest....	7.6	3.3	6.1	7.8	4.6	8.1	7.8
Depreciation....	5.2	3.0	4.2	4.0	3.2	5.2	7.0
Auxiliary apparatus	1.4	1.2	1.3	1.1	1.4	1.0	1.1
Power....	1.0	1.0	0.3	1.0	0.8	1.1	1.1
	100.0	100.0	100.0	100.0	100.0	100.0	100.0

The total charge against the machine-tool department per hour is $96.06.

For convenience and ready reference the following record kept for each machine tool has been found convenient:

1. Type of tool—Niles vertical boring mill N-1415.
2. Location—E-29.
3. Size—60 in.
4. Date installed—1900.
5. Floor space—Occupied by tool, 110 sq.ft.; supplemental space, 119 sq.ft.; total chargeable to tool, 229 sq.ft.
6. Cost of tool—$2,100.
7. Cost of accessories—foundation, $175; motor; control; attachments, $179; line shaft, $88.
8. Motor, horsepower.
9. Average load—1 kw. per hour.
10. Hourly charges—variable charges, 29c.; shipping charges, 9c.; fixed charges, salaries, 15c.; auxiliary apparatus, 1c.; interest on tool, 5c.; depreciation on tool, 2c.; power, 1c.; total, 62c.

Just as the charges have been divided in the machine-tool department among the various tools, the charges in the assembly section can be divided among the various workmen employed in this department. If one does benchwork, the space occupied by his bench is directly chargeable to him; if he does laying-out work on a surface plate, the space occupied by the surface plate is directly chargeable to him. A gang working on a bedplate assembling large machinery should be charged with the space occupied by the bedplate. The basis of obtaining these charges can be obtained from the charge per hour per square foot. These charges are as follows for the assembly and winding department adjoining the machine-tool department previously discussed: (1) Variable charges;

(2) salaries; (3) shipping; (4) interest and depreciation on auxiliary apparatus.

TABLE 3. SUMMARY OF NONPRODUCTIVE WAGES AND SALARIES

	Total	Machine Tool	Per Cent.	Assembling and Winding	Per Cent.	Test	Per Cent.
Wages:							
Time keepers	$3,222	$1,777	55	$1,445	45	....	....
Manager works, office clerks, factory clerks, errand boys	10,520	4,520	43	4,000	38	$2,000	19
General foreman, assistant foreman, foremen	12,400	6,800	55	5,600	45	....	....
Fire brigade	43	19	43	15	38	8	19
Watchmen, janitors, porters	3,236	1,390	43	1,230	38	616	19
Crane and elevator men and heaters	5,450	2,340	43	2,070	38	1,040	19
Inspection and test	3,615	904	25	904	25	1,808	50
Tool, mold, die and pattern rooms	29	17	55	12	45	....	....
Handling material in factory not otherwise specified	13,610	5,850	43	5,170	38	2,580	19
Superintendent salaries	1,805	905	50	720	40	180	10
Drafting salaries and expenses, engineering salaries and expenses	14,330	6,150	43	5,450	38	2,730	19
Boiler and engine-room, wages	5,900	2,360	40	1,180	20	2,360	40
Total	74,160	33,032		27,796		13,322	

These items are similar to those given under the machine-tool section and are also listed in Table 2. The charge per hour is found in a like manner, as follows:

Variable charges (six months)	$41,459
Salaries	27,796
Shipping	17,900
Total	$87,155
Number of hours (6 months)	1,404
Charge per hour ($87,155 ÷ 1,404)	$62

For auxiliary apparatus (see Table 4) the charges are found as here shown:

Investment	$53,072
10 per cent. of investment (interest and depreciation)	5,307
Hours per year	2,808
Charge per hour ($5,307 ÷ 2,808)	1.79
Total charge per hour	63.90
Charge per hour per square foot ($63.90 ÷ 15,700)	$0.004
Square feet of floor space	31,400

The assembly section should be divided among the various workmen or gangs just as the machine-tool department was divided among the various tools. Both the space actually required by the workman to do his work and his share of space required for storage, aisles, etc., should be charged to him as supplemental floor space, as was done in dividing total space among the various tools in the previous discussion. Thus if a winder requires a space 10x10 ft., or 100 sq.ft., to do his work, and supplemental space chargeable to him is 75 sq.ft., the hourly charge to be added to his wages will be $0.002 × 175 = $0.35. A gang assembling large machinery, or a bedplate 25x50 ft., or 1,250 sq.ft. and chargeable with 1,000 sq.ft. supplemental space should be charged $0.002 × 2,250 = $4.50 per hour.

TABLE 4. CHARGES FOR AUXILIARY APPARATUS

Portion of power-house cost	$19,000
Fans and heating	7,985
Electric wiring	7,200
Lamps: Arc	750
Incandescent	250
Cranes	40,888
Total	$76,073
Divided as follows:	
Machine tool	$32,600
Assembly	28,900
Test	14,500
Charges Against Machine-Tool Division:	
Portion of total	$32,600
Dividing tables	2,283
Grinders	500
Miscellaneous	1,172
Total	$36,555
Charges Against Assembly Division:	
Portion of total	$28,900
Jib cranes	2,187
Dividing tables	2,283
Grinders	500
Testing devices	700
Hydraulic press	8,700
Scales	576
Surface plates	6,960
Miscellaneous	2,266
Total	$53,072

The testing department can be divided into sections laid out for testing various types of machines. Space can be definitely allotted to each individual section, as was done in subdividing space among the various machine tools. As before, the total charge consists of the following variable, shipping and salary charges divided per square foot of floor space, in addition to the interest and depreciation on the cost of testing equipment installed for each individual section:

Variable charges (six months)	$12,585
Shipping charges	8,950
Salaries	13,322
Total	$34,857
Number of hours (six months)	1,404
Charge per hour ($34,857 ÷ 1,404)	$24.80
Auxiliary apparatus:	
Investment (see Table 4)	14,500
10 per cent. of investment (interest and depreciation	1,450
Charge per hour ($1,450 ÷ 2,808)	$0.52
Total charge per hour	$25.32
Total floor space	15,700
Charge per hour per square foot of floor space	$0.0016

The charge against a testing section occupying a space 30x60 ft. and charged with a supplemental space of 2,000 sq.ft., or a total of 3,800 sq.ft., will be $0.0016 × 3,800 =$6.10 per hour for the total charges. If investment in testing equipment is $2,500, interest and depreciation will be at 10 per cent., $250 per year, or $250 ÷ 2,808 = $0.089. Average power required for testing is 5 kw. per hour, so the cost of power is $0.05 per hour. The total charge against this individual testing section is therefore $6.10 + $0.089 + $0.05 = $6.24 per hour, outside of the wages of those conducting the test.

The previous analysis shows how the charges against the different departments of a large manufacturing organization can be divided among the various machine tools as machine-hour rates or among the various workmen in an assembly or testing section. In addition to giving accurate costs, figures of this kind are extremely valuable to the shop superintendent, since they show what each element of his organization is costing him per hour. They show in dollars and cents what even a small delay to any one man means, show where efficiency of operation is mostly needed to avoid greatest loss by delays, and show the great importance of economy in space.

In deciding whether or not certain tools shall be made to reduce the setting-up time on machine tools, or whether tools shall be made to facilitate and reduce assembly time, the hourly rates as here figured will be the determining factor.

Over-Safetyized Machines

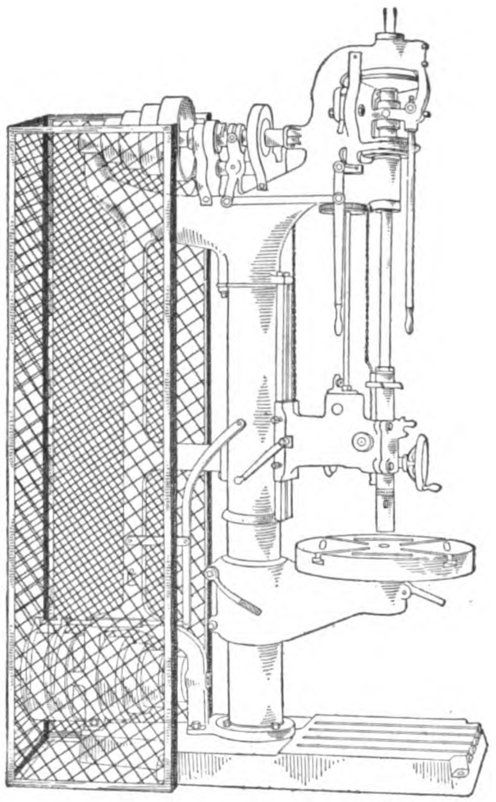
By H. B. McDermid

"Safety First" has become a national slogan, but like many other reforms, initiated because of a real need for a change for the better and so taken up in a wave of popularity, the movement is in danger of going too far and so perhaps defeating its legitimate object. It seems to have become a habit to see how much can be put upon a machine in the way of devices to protect the operator from the results of his own gross carelessness, in some instances; and too often the safeguards (?) serve no real purpose, but are instead a menace to the man running the machine.

An instance of this sort was noticed recently in a small machine shop and power plant in an oil-storage yard. The place contained two high-speed vertical engines each

direct connected to a generator of about 25 kw., a small unit, familiar to everyone nowadays. These engines had previously been amply protected by a heavy pipe railing around the moving parts. There were also a pipe machine and a drill press of a standard type; another small engine belted to an overhead line shaft, for driving the last two machines, completed the equipment.

It was said that a state factory inspector's visit caused the changes; if so, he ought to be ashamed of himself,



OVER-SAFETYIZED MACHINE

or the state which demanded such provisions. The engines, already protected by a railing so designed that a careless man could not injure himself, were further covered by a netting made of $\frac{1}{8}$-in. wire, with a mesh about 1 in. square, to such an extent that a man intentionally seeking to injure himself could not get near the moving parts. The belts of the pipe machine were thoroughly covered with similar cages of like netting, but it remained for the drilling machine to take the prize. Its belts were covered, as shown by the illustration, in a manner that was foolhardy dangerous.

The cone-pulley belt was a 3-in. double-ply belt, difficult at best to throw off the pulleys while not running, as any mechanic knows. Yet a cage had been built covering the full length along the shafts of the pulleys, as least 7 ft. high and clearing the large diameters by less than 2 in. No opening had been left anywhere on three sides, the frame was solid and bolted to the floor, making the changing of the belt a very difficult operation when not running, and several times more dangerous when running, than ever before. Just enough opening had been left on the side toward the table to encourage a reckless man to try to change the belt while running. The whole device was merely a trap to a man of ordinary ability, and a valid excuse for quantities of lost time to a timid or lazy operator.

It would seem that there ought to be a quick-acting remedy for such cases. If state laws are responsible, they should be repealed or modified till a better condition can be secured. If the personal equation of the state's inspection is responsible, then care should be used to secure sensible and experienced men. If the condition is the result of a safety-first fad by some company officer, the case is even worse, because the cure is harder to find.

Whatever the cause, it should be removed and methods adopted which make for real safety for an ordinarily careful and skillful man, instead of those which make a machine safe in the hands of a recklessly ignorant or otherwise unreliable man.

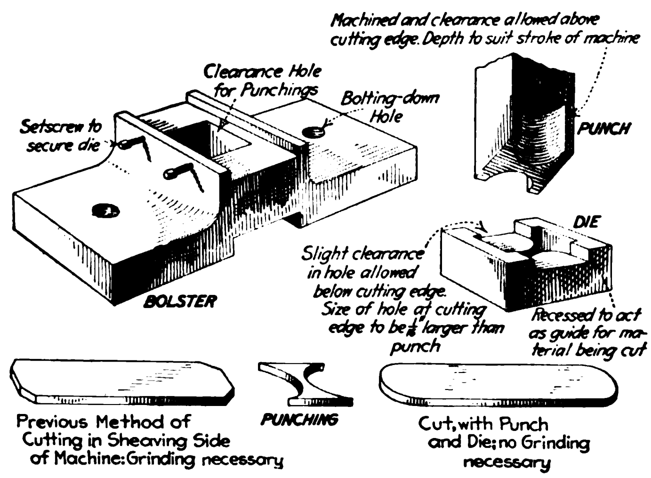
Saving Costs in Shearing and Punching Flat Bars

By A. Patterson

I recently had occasion to be in a shop cutting flat bars into short lengths and trimming the ends in the shearing side of a punch and shearing machine. The ends were finally ground circular in shape on a grinding machine. The cost involved was $2.86 per 100. The material was $2\frac{1}{4}$x$\frac{1}{2}$ flat mild steel.

To reduce the cost, I had a punch and die made with a bolster to fit the punching side of the machine. The illustration gives an idea of the arrangement.

A gage was afterward attached to the bolster so that the bar could be cut accurately into lengths without



SAVING COSTS IN SHEARING AND PUNCHING

marking off. The ends were nicely rounded off when cut and required no dressing. The price of the job was reduced to 12c. per 100, a saving of 2.74 per 100.

The die was recessed to the depth and width of the flat bar to insure the material being fed square into the machine. The punch was made wider than the material, as it was feared that the corners at the extreme points of the radius would be difficult to temper and likely to chip and break.

The recess in the bottom of the bolster was to permit raking out the punchings; but the machine the bolster was used on, the hole for the punchings was large enough to allow the $2\frac{1}{4}$-in. section to pass through.

As a large number of this article is made in the course of a year, the tool has been a profitable one. A number of dies similar to the one shown have been made from old shear blades for square punches, as I find the square-section die shows no tendency to break, whereas the round dies usually supplied with punching machines break very frequently.

Alignment Charts for Design of Flat Plates--I

By Axel K. Pedersen

SYNOPSIS—A series of nine charts simplifying the usually complex problem of the design of flat plates. Seven take up common cases of circular, elliptical, square and rectangular plates for different conditions of loading and supporting. Another covers the ideal case of a stayed surface, and the last a surface stayed according to the recommendation of the A. S. M. E. boiler code.

The application of mathematical analysis in developing the theory of flat plates forms one of the most interesting chapters in the history of the theory of elasticity. From a mathematical point of view, the results obtained are quite satisfactory; the hypothesis adopted for developing the theory, however, circumscribes the problem too closely, not taking into account all the factors which, from a practical point of view, enter into the subject. Also the application of the mathematical theory results in formulas far too complicated for practical use.

The state of stress of a flat plate is a very complicated one, and in order to obtain practical formulas in close agreement with experiments the method of research seems to be the only one possible. The experiments conducted by Professor Bach continuously over a long period of years form the fundamentals upon which the practical design of flat plates confidently may be based. All the experiments conclusively prove that the strength of a flat plate is directly proportional to the square of the thickness of the plate and a more or less complex function of the other dimensions of the plate. Certain coefficients introduced bring the formulas in accordance with the experimental data.

In the *American Machinist,* Vol. 43, page 21, in my article "The Graphical Design of Shear and Press Frames," the different behavior of ductile and brittle materials relative to Hooke's law—the law of proportionality between stresses and strains—was discussed. While the bending stress for a plate made of steel may be definitely determined at any load, the bending stress for cast-iron plates is an apparent one only, and the factor of safety in this case must be determined by taking the dimensions of the section into account, the ultimate bending stress not being a constant figure but depending upon the dimensions of the section.

For detailed information the article in the *American Machinist* on the design of shear and press frames is referred to, the relation, experimentally determined, between the apparent ultimate strength and the tensile strength of the material only being given here in the following formula:

$$S_u = \sqrt{\frac{E_1}{E_0}}\, S_t$$

S_u = Apparent ultimate bending stress in pounds per square inch;

S_t = Tensile strength of the cast iron in pounds per square inch;

E_1 = Distance in inches from the "neutral axis," or center of gravity of the whole section, to the extreme fibers in tension;

E_0 = Distance in inches from the neutral axis to the center of gravity of that portion of the section which is located between the neutral axis and the extreme fibers in tension.

In the case of flat plates

$$E_0 = \tfrac{1}{2}\, E_1$$

Introducing this value in the formula, we obtain

$$S_u = S_t \sqrt{2}$$

or

$$S_u = 1.41\ S_t$$

The experimental coefficients vary according to the material used. It is interesting to observe that in each case the ratio of the experimental coefficients for cast iron to that of steel is approximately 1.41. If therefore in all cases for cast iron the ultimate tensile strength instead of the ultimate bending strength is used, the same formulas may be employed both for steel and for cast iron, because the ultimate bending stress is reduced in the same ratio as the coefficient is reduced.

The method of support is of great importance when calculating the strength of flat plates; in each case the conditions of support must be carefully analyzed, and the result obtained by assuming ideal conditions relative to support must be accordingly modified.

The charts accompanying this article cover all the important cases likely to be met with in practice. Eight practical cases and one ideal case are covered by the charts: Chart 1, elliptical plate, uniformly loaded, supported or fixed; Chart 2, elliptical plate, concentrated load W at the center, plate supported at edge; Chart 3, circular plate, total load W uniformly distributed on circular area of diameter D, plate supported at edge; Chart 4, rectangular plate, uniformly loaded, supported or fixed; Chart 5, rectangular plate, uniformly loaded, fixed along edges A and supported along edges B; Chart 6, rectangualr plate, concentrated load W at center, plate supported at edge; Chart 7, square plate, uniformly loaded, plate supported at four corners; Chart 8, flat stayed surface, uniformly loaded, ideal case; Chart 9, flat stayed surface, uniformly loaded, according to recommendation of the A. S. M. E. Boiler Code Committee.

As to Chart 9, it is interesting to compare the results obtained from this chart with the results obtained from Chart 8, which gives the ideal case of a flat stayed surface. The influence of the circumstances in regard to the method in which the stays are fitted to the plates is evident.

The formulas for developing Charts 1 to 8 are of the general form

$$S = CF\frac{P}{T^2}$$

where

P = Load in pounds per square inch;

T = Thickness of the plate in inches;

Explanation. This chart connects five variables and may be used in various ways. Any three scales or axes when used together must have consecutive subscripts. The method of using the chart to determine the thickness of the plate is as follows: From the point on the M_1 scale representing the unit pressure, trace to the point on the M_2 scale representing the allowable unit stress and note the intersection of the line so traced on the M_3 axis. Connect this intersection with the point on the M_4 scale representing the width of the plate and note the intersection of this line on the M_5 axis. Through this point trace a line from the point on the M_6 scale representing the proper ratio K to the M_7 scale. At the point of intersection on the M_7 scale read the required thickness of the plate.

The example indicated on the key diagram has given: A = 10", B = 11.1", P = 2000 lb. per sq.in., material cast iron of ultimate strength of 20,000 lb. per sq.in. Factor of safety is 5. The plate is fixed along the edges. The allowable stress is $\frac{20000}{5}$ = 4000 lb. per sq.in. The ratio $K = \frac{A}{B} = 0.9$. Solving on the chart as indicated above gives the thickness of the plate T, as 3.35"

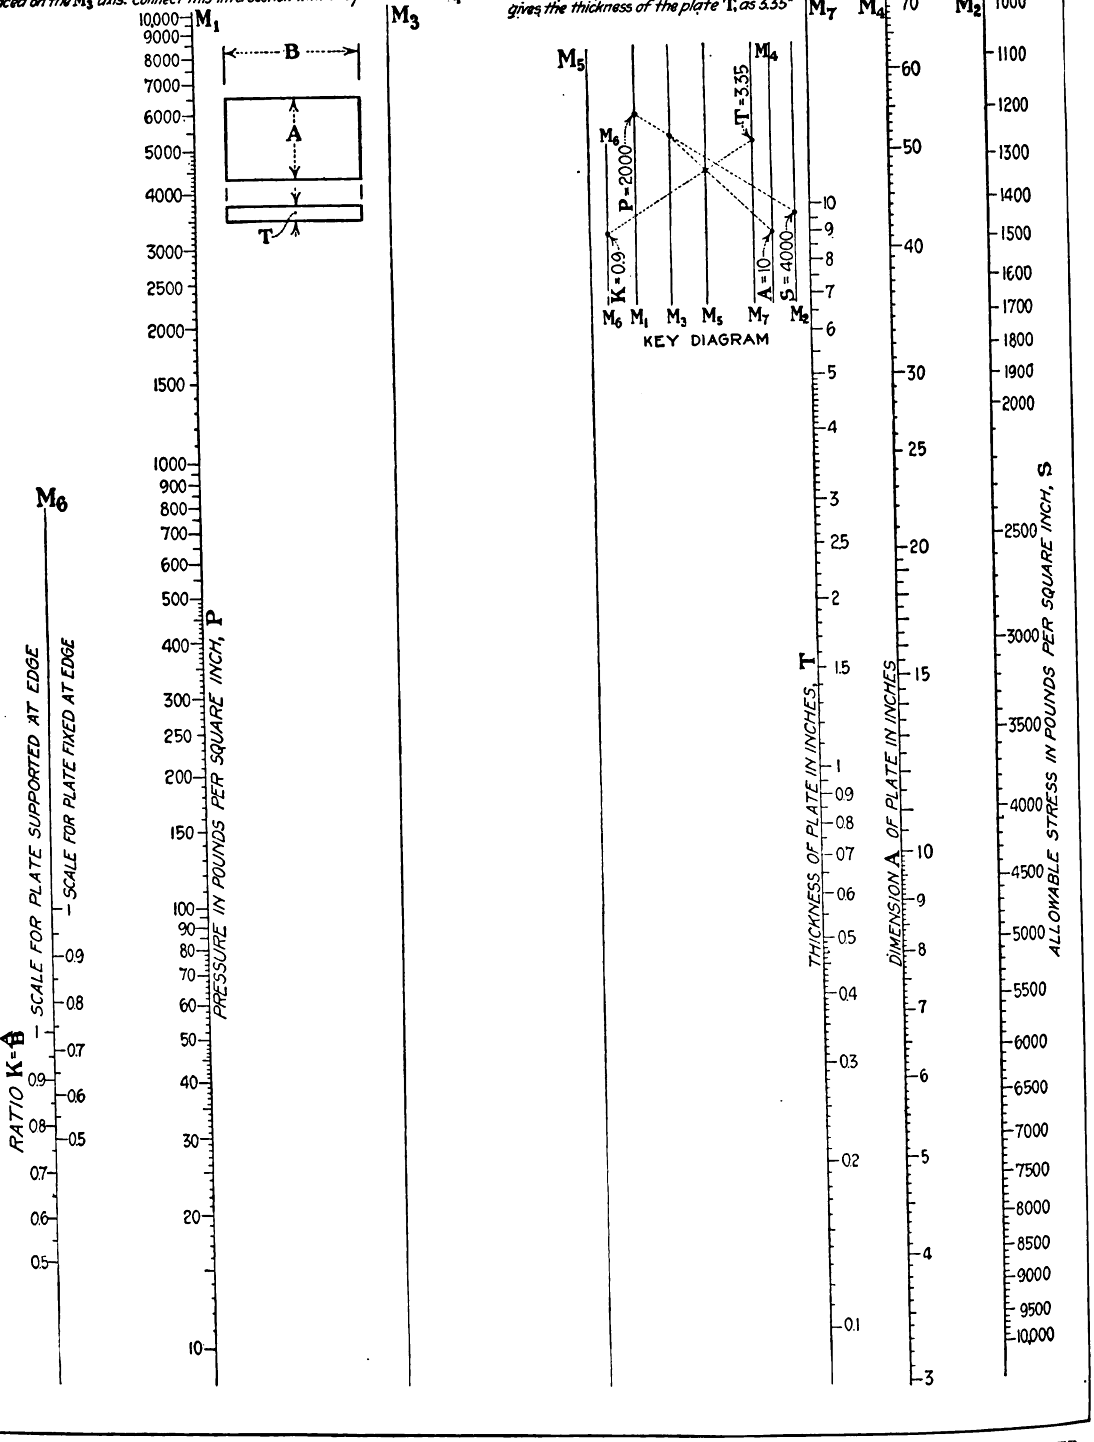


CHART 1. ALIGNMENT CHART FOR DESIGN OF FLAT ELLIPTICAL PLATES, UNIFORMLY LOADED AND EITHER SUPPORTED OR FIXED AT THE EDGE—BY AXEL K. PEDERSEN

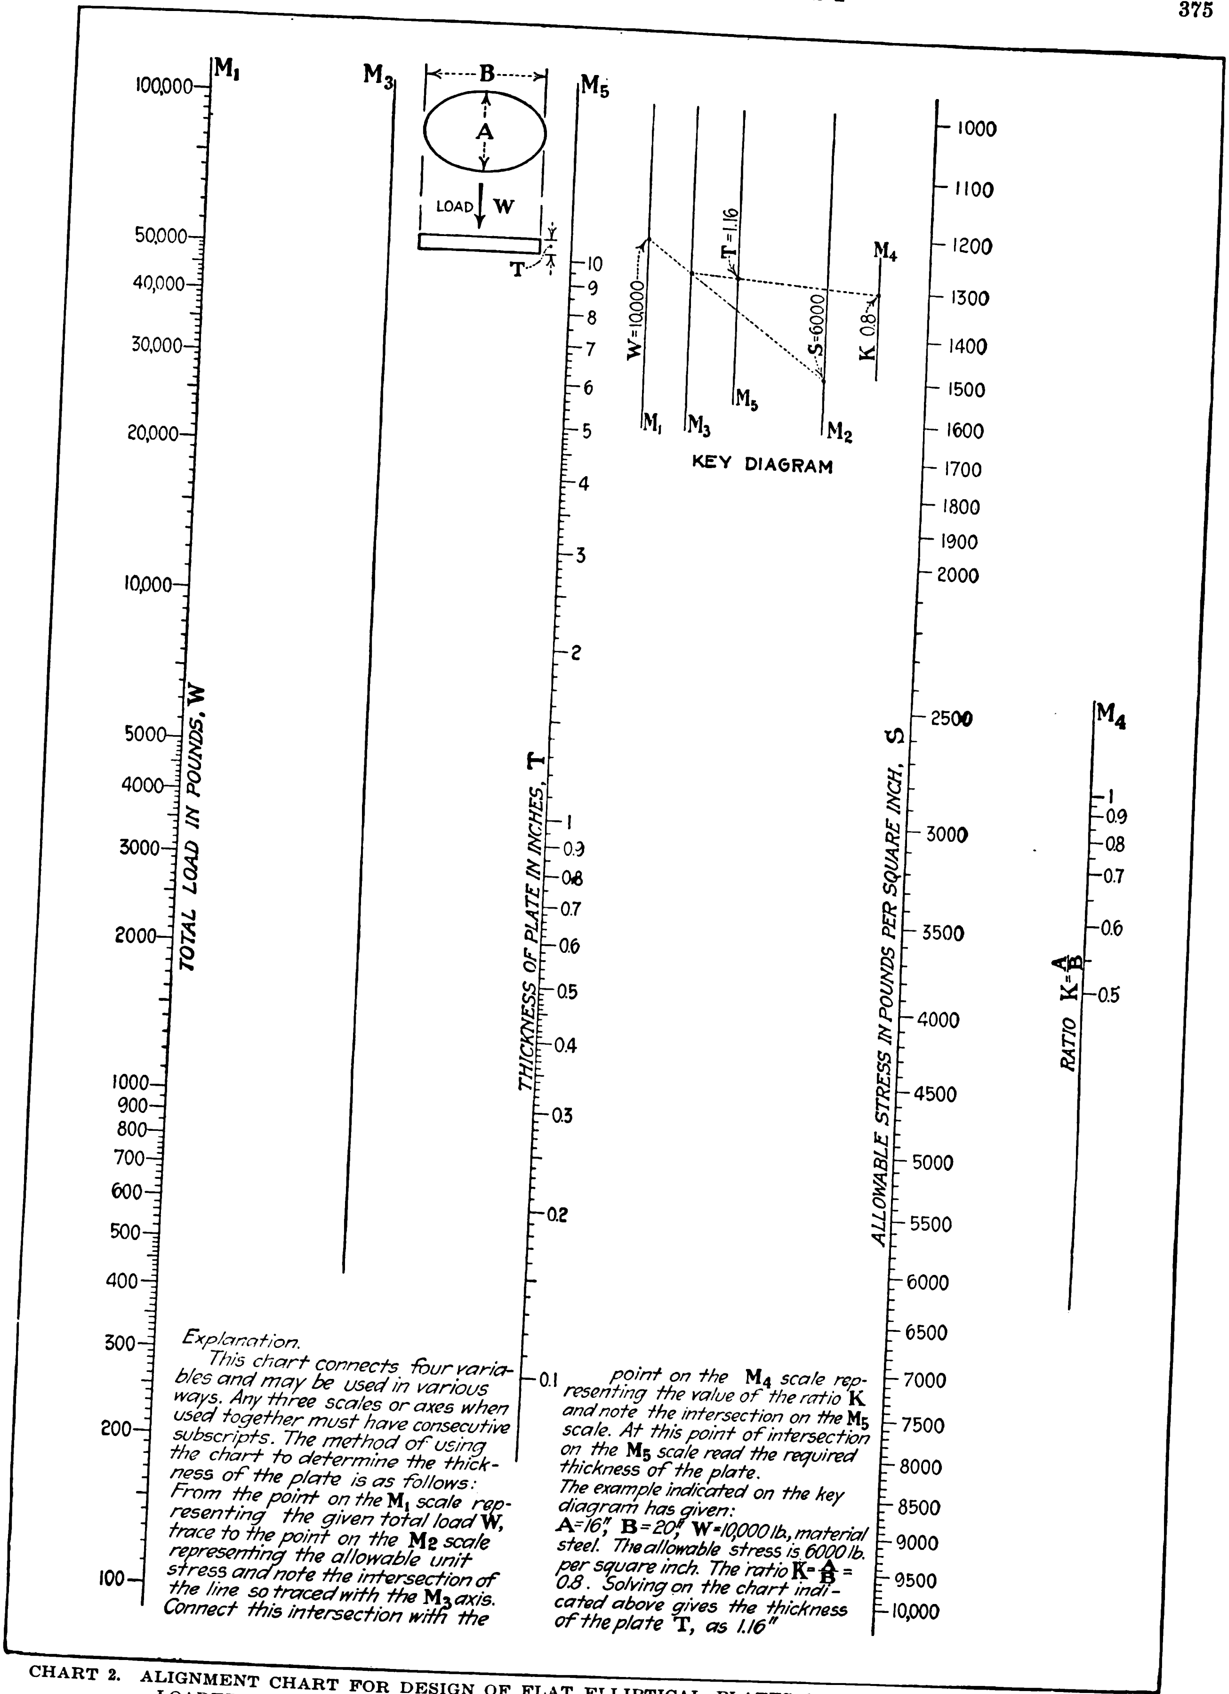

Explanation.

This chart connects four variables and may be used in various ways. Any three scales or axes when used together must have consecutive subscripts. The method of using the chart to determine the thickness of the plate is as follows: From the point on the M_1 scale representing the given total load W, trace to the point on the M_2 scale representing the allowable unit stress and note the intersection of the line so traced with the M_3 axis. Connect this intersection with the point on the M_4 scale representing the value of the ratio K and note the intersection on the M_5 scale. At this point of intersection on the M_5 scale read the required thickness of the plate.

The example indicated on the key diagram has given: A=16", B=20", W=10,000 lb., material steel. The allowable stress is 6000 lb. per square inch. The ratio $K=\frac{A}{B}=0.8$. Solving on the chart indicated above gives the thickness of the plate T, as 1.16"

CHART 2. ALIGNMENT CHART FOR DESIGN OF FLAT ELLIPTICAL PLATES SUPPORTED AT THE EDGE AND LOADED WITH A CONCENTRATED LOAD AT THE CENTER—BY AXEL K. PEDERSEN

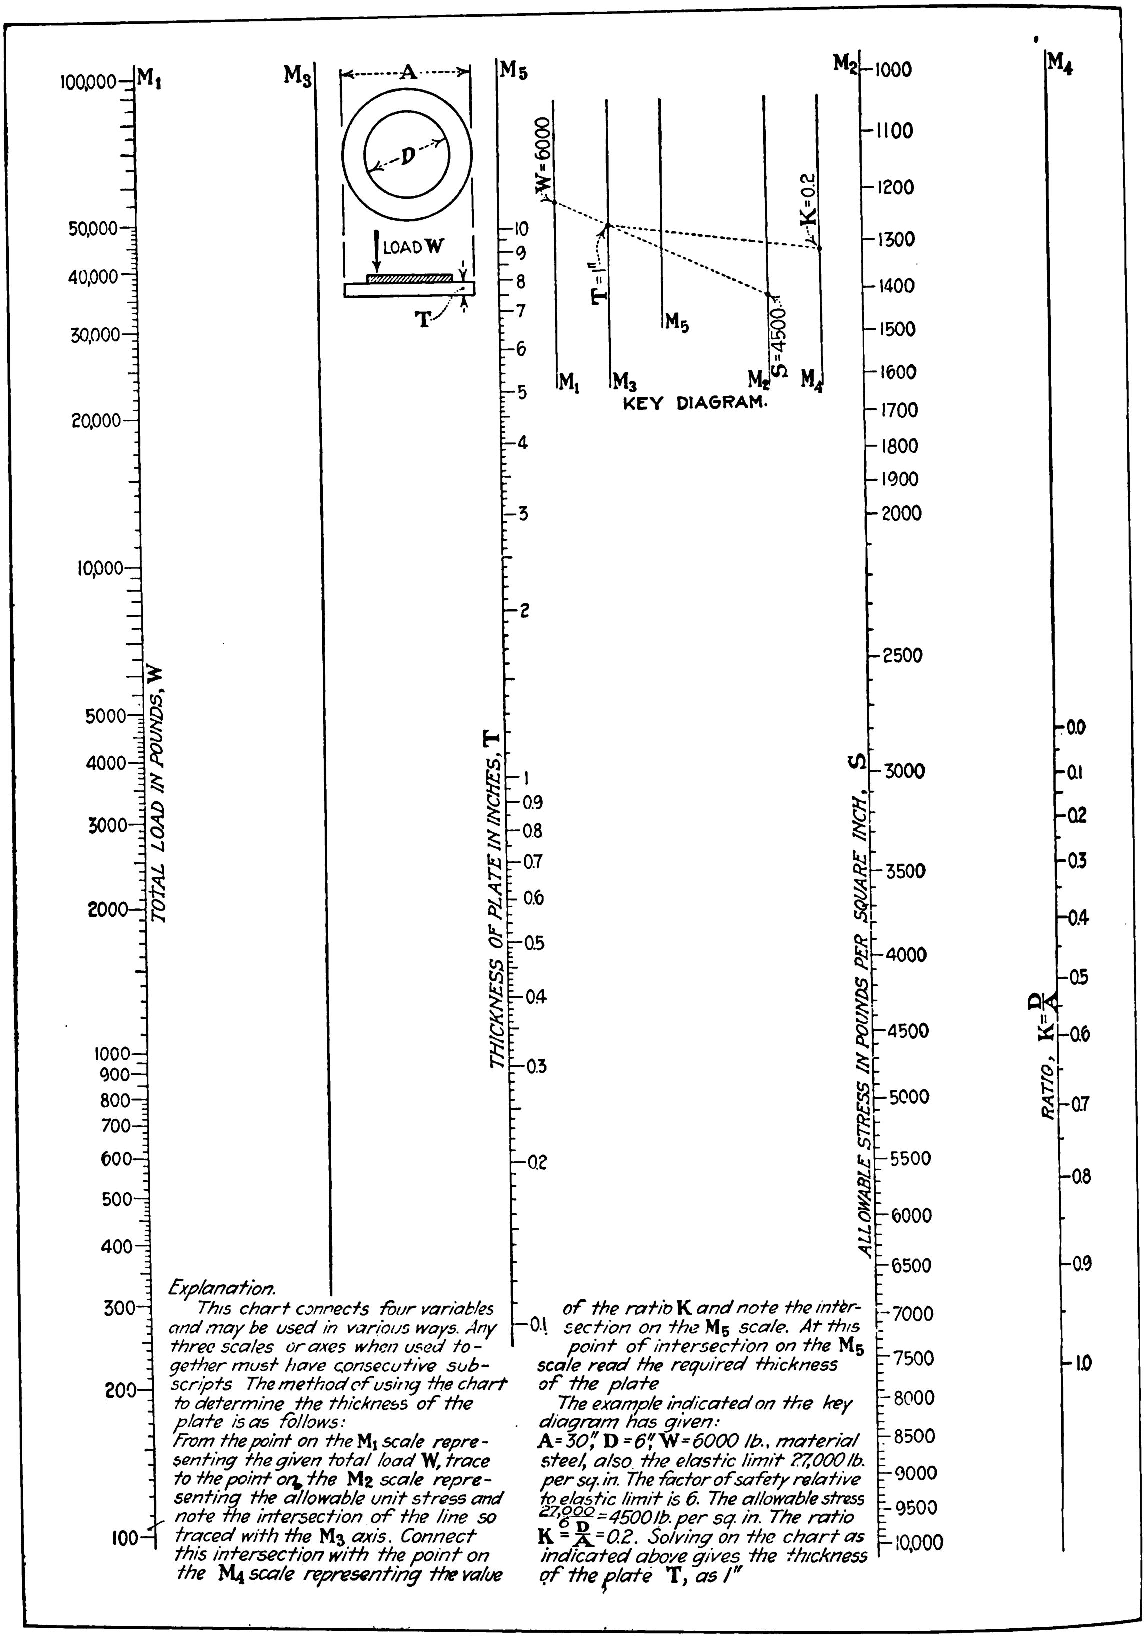

CHART 8. ALIGNMENT CHART FOR DESIGN OF FLAT CIRCULAR PLATE SUPPORTED AT EDGE WITH TOTAL LOAD UNIFORMLY DISTRIBUTED ON A CONCENTRIC, CIRCULAR AREA—BY AXEL K. PEDERSEN

Explanation. This chart connects five variables and may be used in various ways. Any three scales or axes when used together must have consecutive subscripts. The method of using the chart to determine the thickness of the plate is as follows:

From the point on the M_1 scale representing the given unit pressure, trace to the point on the M_2 scale representing the allowable unit stress and note the intersection of the line so traced with the M_3 axis. Connect this intersection with the point on the M_4 scale representing the short diameter of the plate and note the intersection on the M_5 axis. Through this intersection trace from the point on the M_6 scale representing the ratio K to the M_7 scale. At this point of intersection on the M_7 scale read the required thickness of the plate. — The example indicated on the key diagram has given: A = 12"; B = 17"; P = 150 lb. per sq. in.; material, cast iron of an ultimate strength of 20,000 lb. per sq. in.; factor of safety 10. The allowable stress $= \frac{20000}{10} = 2000$ lb. per sq. in. The ratio $K = \frac{A}{B} = 0.706$. Solving on the chart as previously indicated, gives the thickness of the plate T as 1.6"

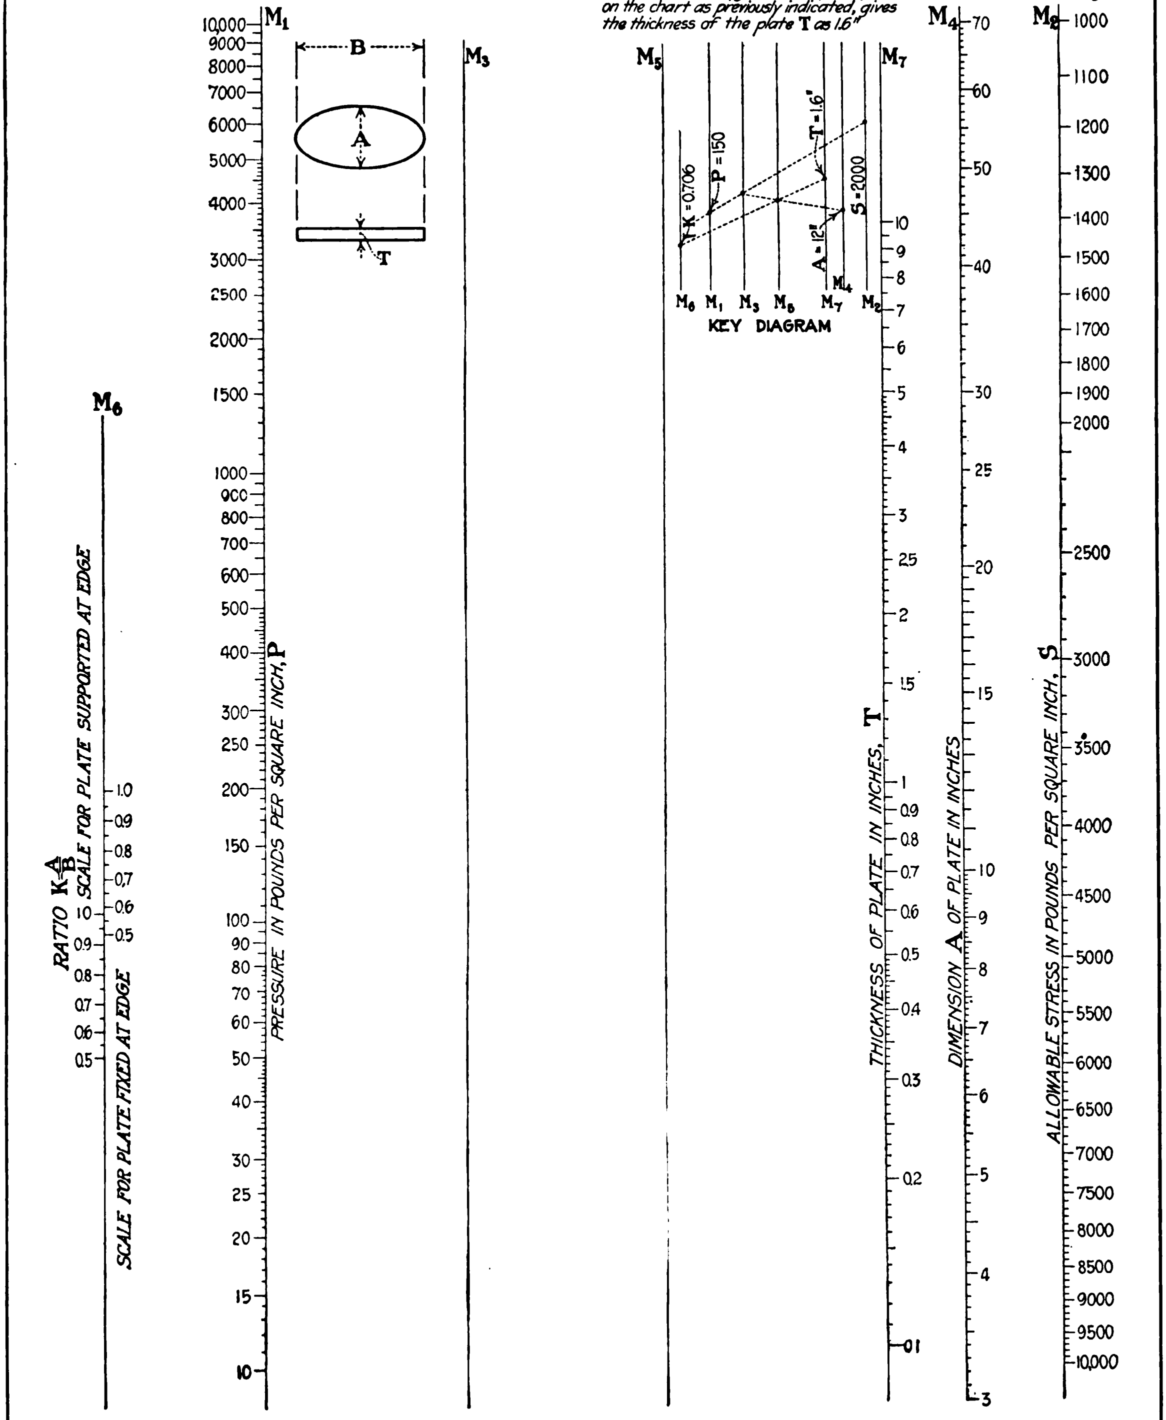

CHART 4. ALIGNMENT CHART FOR DESIGN OF FLAT RECTANGULAR PLATES UNIFORMLY LOADED AND EITHER SUPPORTED OR FIXED AT THE EDGES—BY AXEL K. PEDERSEN

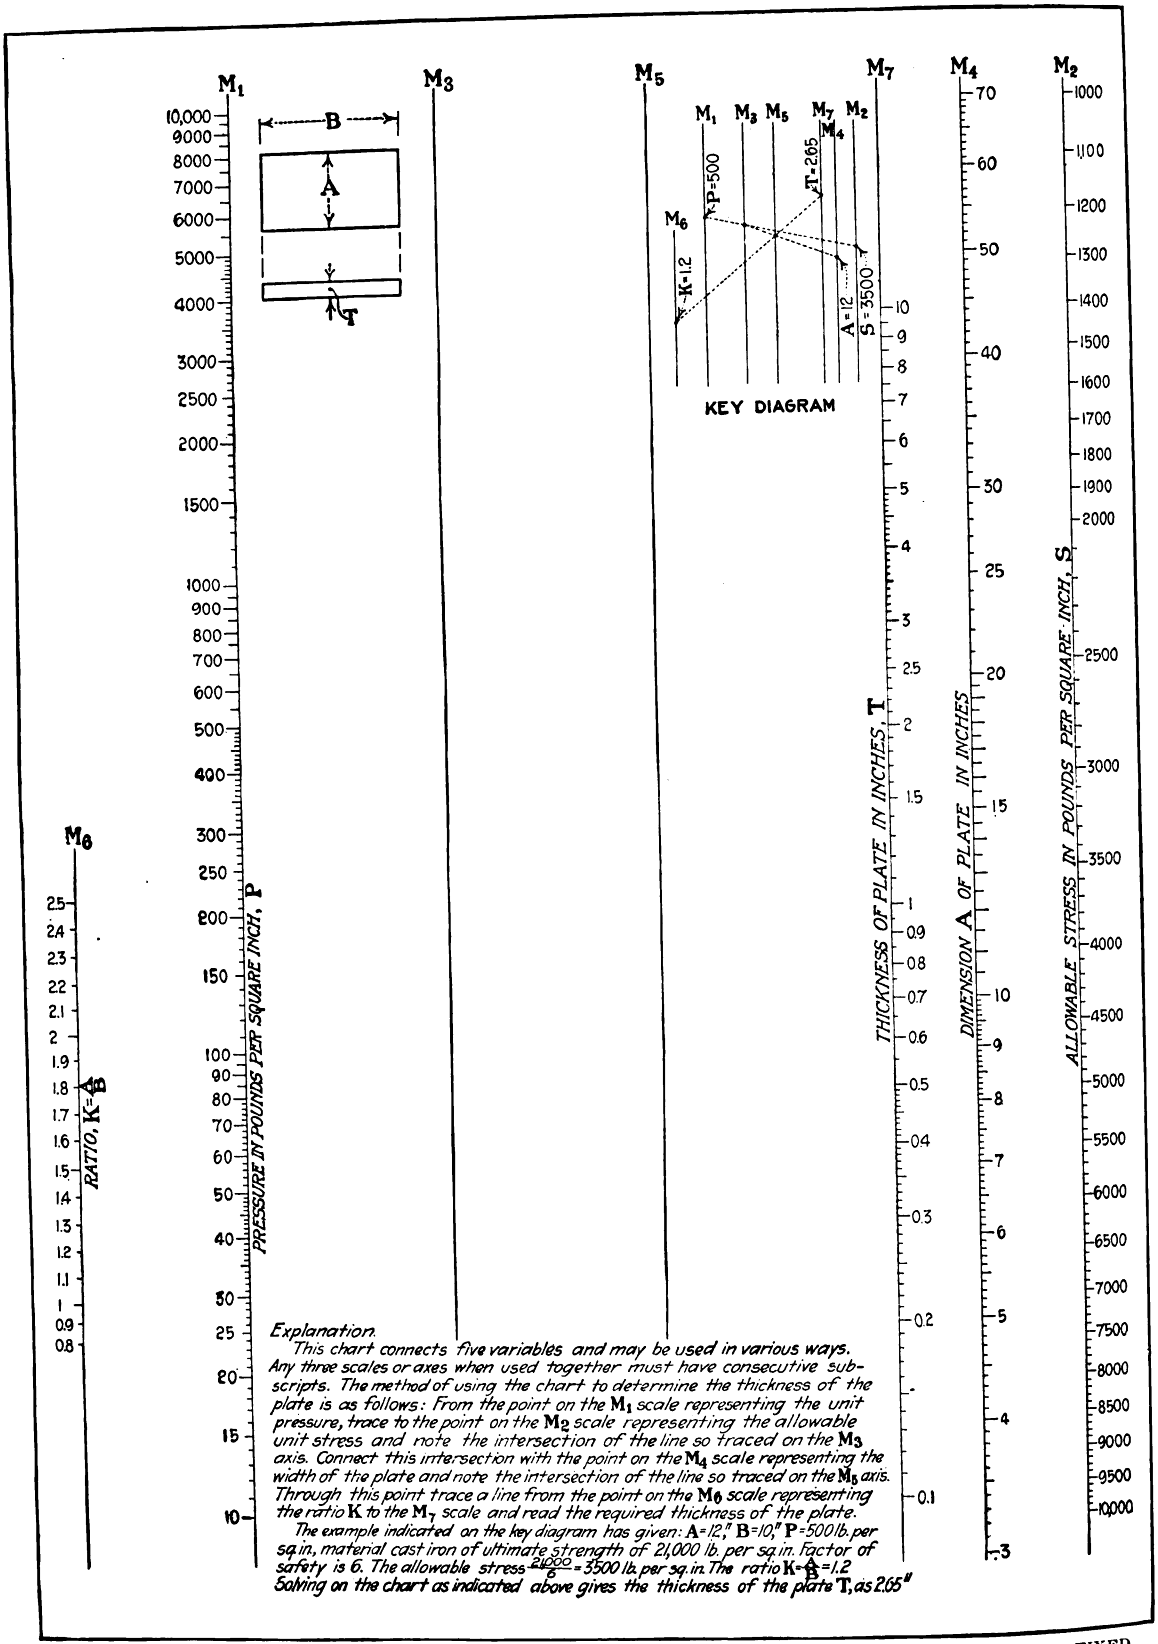

CHART 5. ALIGNMENT CHART FOR DESIGN OF FLAT RECTANGULAR PLATES UNIFORMLY LOADED, FIXED ALONG SHORTER EDGES, SUPPORTED ALONG LONGER EDGES—BY AXEL K. PEDERSEN

F = Function of the dimensions of the plate and can be determined as a function of the ratio K;

K = Ratio between certain dimensions of the plate as explained on the charts in each case;

C = Experimentally determined coefficients;

S = Allowable stress in pounds per square inch.

The factor of safety is determined for steel as follows:

$$f = \frac{S_e}{S}$$

and for cast iron

$$f = \frac{S_t}{S}$$

S_e is the elastic limit of steel, and S_t the ultimate tensile strength of cast iron in accordance with the fact that for brittle materials the factor of safety must be determined by taking the ultimate strength into account.

The formula for developing Chart 9 is as follows:

$$P = \frac{M\,(T+1)^2}{A^2 - 6}$$

where

T = Thickness of the plate in sixteenths of an inch;

A = Pitch of the stays, in inches;

M = Constant according to circumstances as given in instructions for using M_2 axis on Chart 9;

P = Working pressure in pounds per square inch.

The procedure is rendered very easy by numbering the various scales consecutively M_1, M_2, M_3, etc., straight lines being drawn from proper points between two consecutive scales locating a point on the third consecutive scale or axis, which then again is used in connection with the two next consecutive scales. It will be noticed that the charts may be used in various ways according to data given; care, however, must be taken always to use any three sets of scales simultaneously, only if they bear consecutive numbers.

Several of the charts contain a double scale for the ratio K, which must be used in accordance with the conditions as to support, as especially noted in each case on the charts.

(To be continued)

Reducing Cost of Chain

By Dan Patch

Back in 1909, when the estimating division was formed at the Boston Navy Yard, one of the first things noticed was the extremely high prices at which standard stud-link chain cables were issued to the ships. An investigation was made of the three subdivisions of cost—namely, material, labor and overhead—and the curves of Fig. 1 were plotted. The thing which first caught the eye was the high cost of the material entering into the manufacture of the chain.

On looking into this it was found that the Navy Yard was buying the best of iron in sizes other than that for the chain wanted, blooming these bars and rerolling in a not too modern rolling plant and charging all this labor and expense to the material cost. When this practice was objected to, the estimating division was informed that this treatment was necessary to get the "superior quality" of Government-made cables. This sounded like the reason for soap floating given by a guide when he was showing a party through a big soap works: "It floats, madam, because of its superior quality."

At the time there was no answer to this statement, but a little later a neighboring shipyard received permission to have a chain cable which was to be installed in a recently completed merchant vessel tested in our

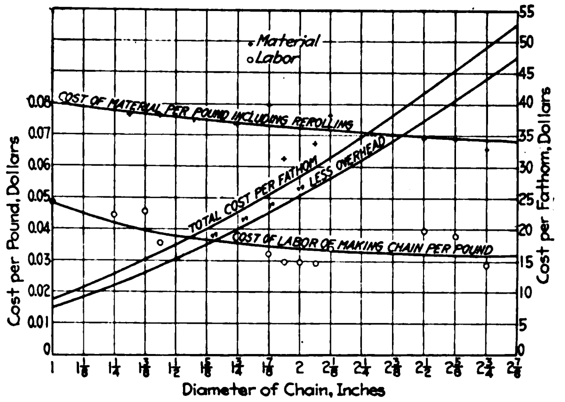

FIG. 1. TOTAL AND MATERIAL COST OF STUD-LINK CHAIN PRIOR TO 1909

pit. A representative of the estimating division was detailed to be present at the test and found that the results were very close to those of our "superior-quality" chain.

To make a long story short, in spite of opposition, officers having the efficiency of the service at heart finally abolished the rolling mill and eliminated one unnecessary operation in the manufacture of the chain.

The next item in the chain cost which was noted was the manufacture of the studs. These studs were shaped somewhat as in Fig. 2 and were drop-forged. The dot-and-dash lines indicate the location of the link with regard to the studs. After leaving the drop-forge shop the studs were sent to a machine shop in another building, where they were first planed, set up in gangs and

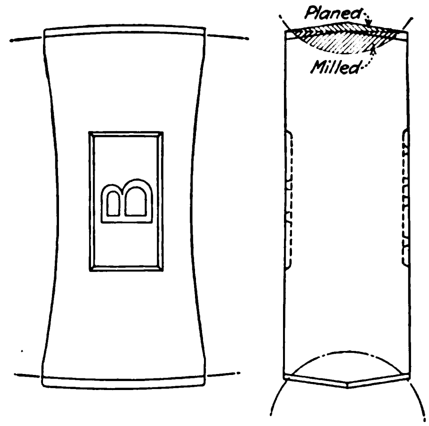

FIG. 2. DETAIL OF A STUD FOR STUD-LINK CHAIN

then milled in a miller with a revolving table, on which they were so dogged as to give the proper longitudinal radius for the particular chain with which they were destined to be used. After the machining process was completed they were sent to a third building to be put into the chain.

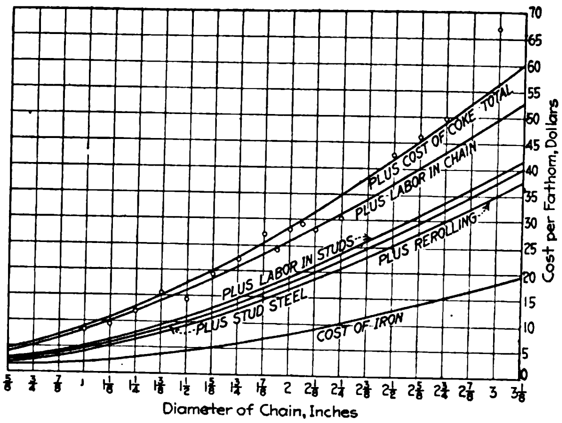

FIG. 3. ANALYSIS OF STUD-LINK CHAIN COST PER FATHOM PRIOR TO 1909

It was suggested that the studs be drop-forged on edge, so that the draft of the die would give the proper radius. The objections raised to this were that the dies would be apt to crack on account of the fine corners and that the letters "U S" and "B" would not appear on the sides of the link. The first objection was believed to be overestimated and the second groundless, as the "U S" and "B" could just as well come on the edges as on the sides. The stunt was tried on one of the smaller sizes. It worked all right, so that this method was extended to the other sizes, eliminating a process which, though a delight to the eye and apparently very efficiently carried on due to the gang set-up, was nevertheless unnecessary.

Along with this reduction in the number of operations was an increase in output due to a study of rest and work periods and shop methods which reduced the direct-labor cost on the making operation.

The costs are shown graphically analyzed in Figs. 3 and 4. Approximately the material had advanced about 4 per cent. of its value, or about 1 per cent. on the cost of chain. The labor costs, direct and indirect, had been reduced 40 per cent. by the elimination of processes and 13 per cent. by increased output. These percentages are based on labor costs of 27 per cent. and 9 per cent. respectively on the total costs of the chain. This reduction in costs brought work to the yard which undoubtedly would otherwise have gone to outside plants or abroad—namely, the manufacture of the fender chains for the Panama Canal.

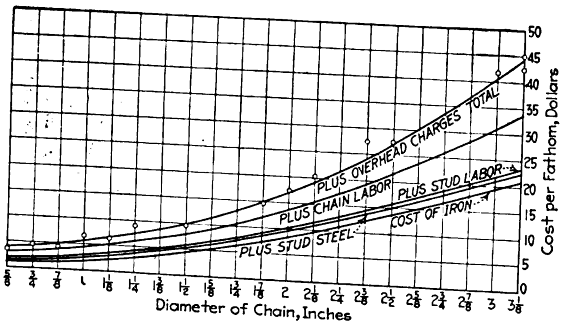

FIG. 4. ANALYSIS OF STUD-LINK CHAIN COST PER FATHOM, 1912

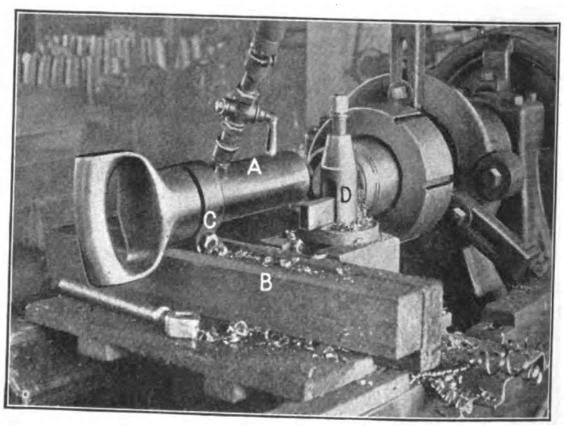
The credit for these changes is largely due to the younger officers of the Construction Corps, who have received special technical training. Such industrial officers should serve long terms without change of yard in order that they may formulate and build up a managing policy. On the contrary, they are constantly shifted, and political interference from without and friction within the service make their lives anything but pleasant. It will be surprising if there are not many resignations from the Construction Corps to take up more congenial positions in civil life.

Turning Bases of Shells and Riveting Base Plates

The illustration shows a method (employed in one of the Canadian shell shops where 4.5-in. high-explosive shells are manufactured) of riveting in the base plates of the shells at the same time that a cut is being run across the base of the shell. An ordinary air hammer *A* is used to close the metal around the base plate, which is of the threaded type.

The wooden blocking *B* on the carriage is of such height that the air hammer can be rested on it, the clamp *C* acting as a pivot. The threaded type of base plate is



RIVETING AND TURNING BASE PLATES

of a thickness that makes it project beyond the surface of the base of the shell. While the tool in the tool post *D*, at the back of the lathe, is facing off the extra metal on the base plate, the air hammer at the front rivets the base plate in.

This method of doing the job combines what would otherwise be two distinct operations. Running the two concurrently saves considerable time.

While on the subject of base-plate riveting, it may be mentioned that in another works, where they are making 18-pounder high-explosive shells with the new type of riveted base plate, an ordinary air hammer closes the base of the shell over on to the base plate in ½ min. from floor to floor.

The outfit used consists of a 12x12 timber set, end up, in the concrete floor. It is of such height as to be convenient for the operator holding and operating the hammer. The end of the timber has a hole in it large enough to take the shell and deep enough to allow the shell to go down about three-fourths of its length. A steel ring fits over the base end of the shell, to act as a guide for the riveting tool in the air hammer.

Letters from Practical Men

Irregular Grinding Jobs

There are four factors to be considered in "getting by" on operations of the irregular type, where there is no machine or jig well suited for the work. These factors are, first, the piece itself; second, the machine that is to handle the work; third, a good supply of ingenuity; and, fourth and by no means least, a man with an appetite for the irregular job—an "optimo-mechanic."

Mr. Van Deventer in his recent eulogy of the drill press as a *multum in parvo* machine for general shop work took a shy at the drafting-room force and suggested the use of a mallet as a useful antidote for a certain obstinacy peculiar to the profession. It might also be said of some operatives that, when the knock-down-and-drag-out method seems imprudent, a clever word-sponging will animate the fellow on the job until he says, "I'll do it, or my name is McGinnis."

Four jobs are here described, all grinding operations. The machine is a small universal tool grinder—a Norton No. 2. A careful study of the illustrations will help one understand these various jobs, and a few words in connection will insure a good idea of the methods used.

In Fig. 1 is shown an extraordinary set-up. Four square-end mandrels were required to be ground clean to a shoulder and perfectly true with the cylindrical portion. It will be seen from the shape of the mandrels that it was impossible to use the cup-wheel method. The top (false) platen of the grinder was lifted off and clamped at right angles to the table, the overhanging end of the platen being supported by an ironwork table conveniently placed, with a steel plate leveled for the traverse and $\frac{5}{16}$ steel balls for the platen to ride upon. All this material was within easy reach of the machine, and it was only a few minutes before this grinding job was put on a manufacturing basis. The arbors in question were for holding automobile transmission gears in which the holes were broached.

The second task was to grind four sections of a circle, with two center points for rotating. The radii were to be exactly alike—or in other words, two sections of two circles of exact diameters, with their centers offset from each other and with the piece itself, when assembled to operate upon a third center. Despite all this description the only way to grasp the idea is to look at the piece as it was arranged for grinding.

It will be observed that the piece, which was a hardened-steel plate, had a relatively large hole in which a bushing was inserted with a small hole carefully drilled and reamed for position on the milling machine. The bushing was also splined, and a key was set in, which located it in the plate. Thus arranged, the plate was placed on the surface plate, which in turn was held in the universal head and properly set for the grinding operation against the cup wheel. The radius grinding was accomplished by rotating the work by hand about the small stud in the surface plate, which served as an arbor. The opposite sections were ground to the required diameter, the plate simply reversed with the bushing, and the other two sections then ground.

The third operation was to grind a radius (inside) many times larger than the wheel used. This was accomplished simply by setting the table traverse at an angle from the wheel spindle, so that a position was reached in which by passing the work across the corner of the wheel the required curve was obtained. This method will serve for curves of limited arc. A curve 5 in. long with a 30-in. radius can be ground with a 7-in. wheel—a curve so nearly a perfect circle that it would be difficult to detect any error. The illustration, Fig. 3, shows a former for shrapnel turning being thus ground.

The fourth case illustrates how the inconvenience of not having a regular form-grinding attachment for circular formed cutters may be overcome. All that was needed besides the regular equipment was a sufficiently large faceplate attached to a spindle, and this in turn held in a bronze quill with an adjustable nut on the end of the spindle for the end thrust. The faceplate was notched lightly on the quarters, a flat strip of spring-tempered steel attached to the regular tooth support and set for tension against the rim of the faceplate. Simple holders, as shown, adapted to the specially shaped cutters were made, and the cutters were then ground mechanically correct—exactly "like the cutters you buy."

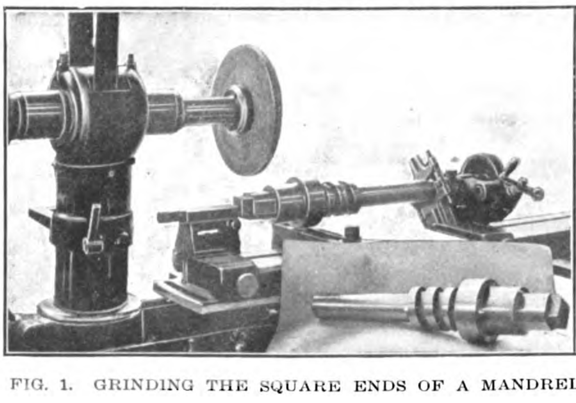


FIG. 1. GRINDING THE SQUARE ENDS OF A MANDREL

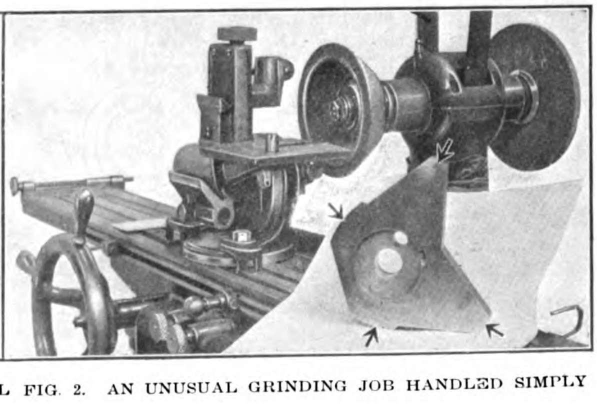

FIG. 2. AN UNUSUAL GRINDING JOB HANDLED SIMPLY

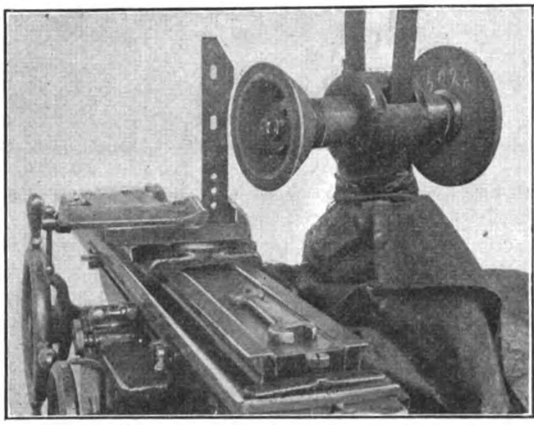

FIG. 3. GRINDING A LARGE RADIUS WITH A SMALL WHEEL

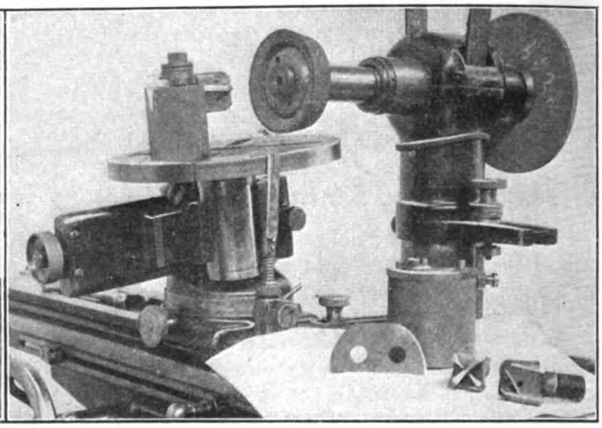

FIG. 4. GRINDING FORMED CUTTERS WITH SIMPLE FIXTURES

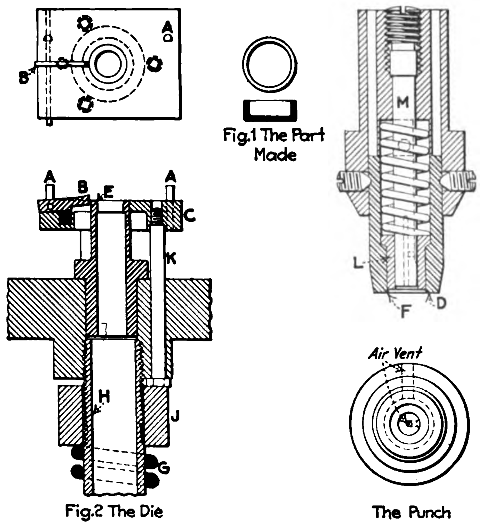
Incidentally, the new type of four-lip drill, shown in Fig. 4, is stocky and a great cutter. Two lips are carried across it, the same as in an ordinary drill, and the other two cut nearly to the center. This particular drill is flat on the end, with a 0.4-in. radius on the corners. The ends, sides and corners were accurately ground on the fixture shown, including the relieving. The finger support for the lip is removed to give an unobstructed view of the cutter.

These operations are not shown as presenting the last word in manufacturing the particular parts, but hint how to get along until the proper machine arrives.

Springfield, Vt. O. S. MARSHALL.

Blanking and Forming Die

The die in Fig. 2 was designed for blanking and forming the cup shown in Fig. 1 and has proved satisfactory for small work. The dimensions of the cup are as follows:



BLANKING AND FORMING DIE

lows: Inside diameter, $\frac{3}{8}$ in.; depth, $\frac{1}{8}$ in.; thickness of metal, $\frac{1}{32}$ in.

The stock used for making the part is $\frac{3}{4}$ in. in width. It is guided by the pins *A*, while the spring lever *B* acts as a pilot. The spring pad *C* holds the metal firmly against the lower surface of the punch *D* while the shearing is being done. The outside diameter of the piece *E* and the corresponding hole at *F* in the punch act as cutting surfaces.

The spring *G*, for supporting the pad, is located beneath the die bed, as shown, and is placed around the pipe *H*, which is screwed into the die bed. At the lower end of the pipe is a nut for adjusting the tension of the spring.

The sleeve *J* acts as a bearing surface for the pins *K*. There are three of these pins used in this die. The piece *E* is of tool steel, hardened and ground, and acts as a punch in shearing, while the inside diameter acts as a die in the forming.

The punch is designed to fit a standard press. The sleeve *L* fits into the piece *F*, which is of tool steel hardened and ground. This sleeve locates the blank and holds it firmly until the descent of the forming punch *M*, which is held in position by means of a shoulder on the upper end and by a setscrew. On the return stroke the sleeve releases the finished cup so that the work falls through the clearance hole in *E*.

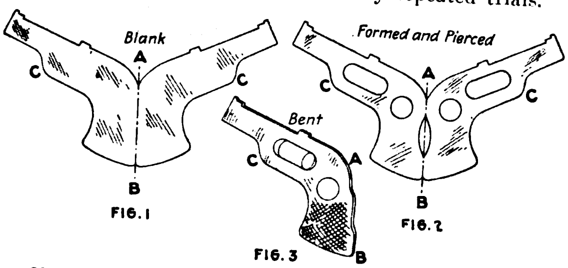
Bridgeport, Conn. MALCOLM PETERSON.

Overcoming a Difficulty in Forming Dies

In making the dies for a sheet-metal toy pistol, we ran against several snags, and the solution of our problems may be of interest and value to other readers. The pistol is modeled after the Smith & Wesson hammerless, with the case made in one piece. It is blanked, formed and pierced, the sides spread open and then bent through the handle on the line *AB*, shown in the illustrations, Figs. 1 and 2.

The trouble arose from the fact that the line *AB* is straight in the flat but forms a double curve in the finished case. There is an open space from *B* to *C* in the finished case for the works, but it is only $\frac{1}{2}$ in. wide, while the grips are $\frac{7}{8}$ in. This leaves only room for a bending punch $\frac{1}{2}$ in. thick in the fourth operation, which operation must be a simple bend, for any drawing of the metal would distort the sides, which are already formed.

It was necessary in the first forming operation to put enough metal along the line AB to make the double curve covering a space ½ in. wide. This result was accomplished by putting a hump in the forming die, between the handles. The right height to give just the proper amount of metal was found by repeated trials.



OVERCOMING A DIFFICULTY IN FORMING DIES

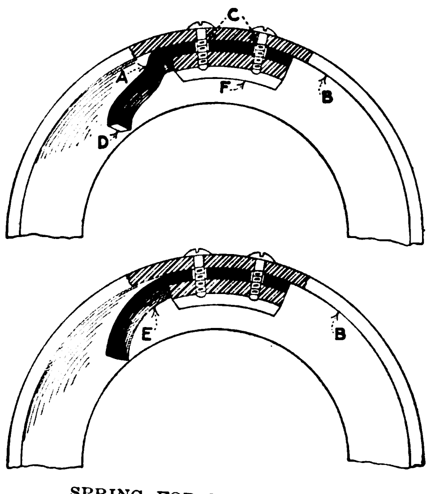
The bending operation reverses this hump and gives the proper curve to AB without affecting the shape of the grips.

The metal tears down somewhat at A in the first forming, and the two edges fold over one another in the bend. We could not avoid this without a long thin point in the blanking die, which would not give any service. As the lap is ironed down smooth in the fifth operation, it is not objectionable.

Bridgeport, Conn. W. B. GREENLEAF.

Designing Small Springs To Avoid Breakage

The spring shown full size is made of steel 0.020 in. thick, ⅛ in. wide and about ⅞ in. long. There are three springs in each multiple lens piece for microscopes and they are continually breaking, causing much annoyance



SPRING FOR MICROSCOPES

and expense where a number of instruments are in constant use.

The point D snaps into a notch and serves to hold one of the lenses in position for use. The spring is secured to the surface B by two screws through the holes C threading into the plate F. The strain is thrown into a very short section at A, which is the weakest part of the whole spring.

If the spring is formed as shown at E, then the movement of the point D, will cause the spring to bear against the surface B, which will remove the strain from A and distribute it along between the binding screws and the working point D.

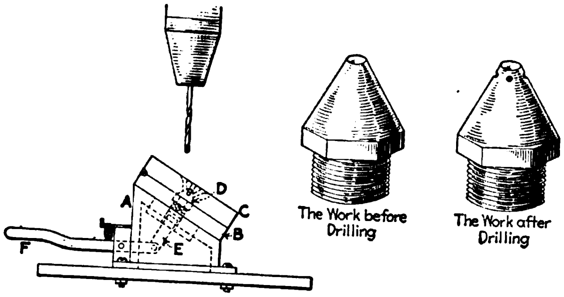
There is nothing about the lens piece or the adjustment of the spring that really calls for the offset at A, and a spring like E will be a decided improvement. The principle involved can be applied to similar cases and to any size of spring.

Rochester, Minn. GEORGE G. LITTLE.

Drilling Holes in Gas Burner

The accompanying sketch shows a revolving jig for drilling the four holes in a gas-stove spud, for an adjustable orifice. The spud is made of brass and finished in one operation on an automatic machine, except for the four holes, which are drilled in the jig.

The jig consists of a cast-iron base A upon which the parts B and C turn. Parts B and C are hinged at G, the



REVOLVING JIG FOR DRILLING HOLES AT AN ANGLE

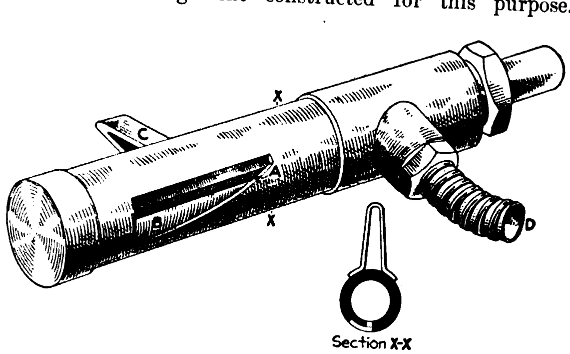
cover C being lifted up to place and remove the work at D. The lever F works the plunger E to kick the spud out after it is drilled.

The drilling is done through the hardened cover C through the holes in the top of the cover, a No. 50 Morse twist drill being used. With this jig the four holes can be drilled at the rate of 325 spuds per hour.

Rockford, Ill. H. J. McCLAFFERTY.

Combined Feed Pipe and Valve

In cases where it is advisable to flow cutting solution in the form of a sheet, it is desirable to control the width of stream and flow at the same point. The illustration shows an arrangement constructed for this purpose.



COMBINED FEED PIPE AND VALVE

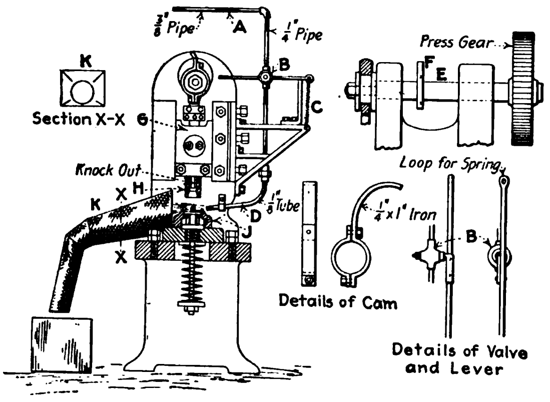
The solution is delivered through a narrow slot *A* in a brass tube, and the flow is regulated by a taper opening *B* in a sleeve that fits over the tube. As the sleeve is rotated by means of the handle *C* soldered to it, the taper side of the opening cuts down the length of the slot in the tube and hence the width of the lubricant stream. This sleeve must be carefully fitted over the tube so that it will not leak.

The whole device is supported by the customary rod, which is threaded into the tee of a pipe. The solution is fed through the flexible metal hose *D* into the side of the T-pipe. This arrangement allows considerable flexibility in flowing the cutting solution on the right place.

Bridgeport, Conn. W. BURR BENNETT.

Blowing Work Out of Dies

Some months ago we had occasion to manufacture quite a number of small copper and other metal caps ranging from ½ to 1 in. in diameter and from ½ to 1⅛ in. long. They were made on a single-action vertical punch press



BLOWING WORK OUT OF DIES

with combination blanking and drawing dies. The action of these dies was perfectly satisfactory, but the problem arose as to a more economical and safer method of removing the finished cap from the die without running the risk of having the ram come down meanwhile. We also wished to prevent the waste of time taken in removing chips of metal and occasionally such dust and dirt as might accidentally adhere to the oiled sheets of stock, as it was our idea to keep the press running continuously.

The air compressor used was a small 3x3-in. single action of vertical type belted directly from the line shaft and running at a speed of 350 r.p.m. The tank was only a little larger than the ordinary commercial household hot-water tank. This gave us a very limited supply of air, especially as it was already being used to clean off chips from drill presses and other machines, and to force oil up from a tank on the ground floor to the floor above to be used at the different assembling benches.

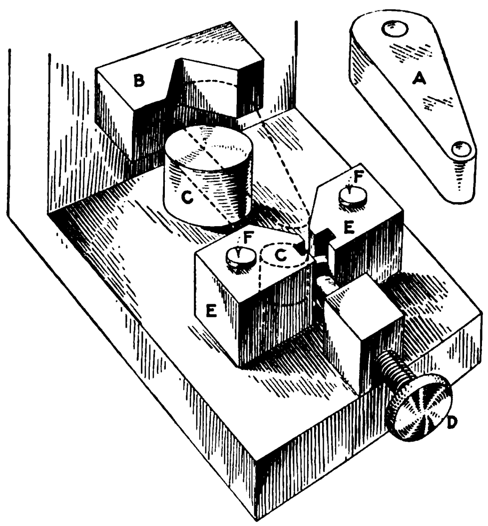
We at first rigged up the press with a continuous flow of air at about 80 lb. pressure through a ⅛-in. pipe. That soon exhausted the supply, so we planned and rigged up an intermittent air supply in the following manner: On the press used, the main shaft rotated between two bearings with the cam on the outside of the front housing, exposing about 8 in. of the shaft. On this section a trip was placed and so timed that at each revolution of the shaft, just as the punch was ascending from the die, a valve was opened letting the full pressure of the air blow across the die for a second or two only, the valve being closed again by a spring after the high part of the trip passed the handle on the valve. On the other side of the die was placed a funnel-shaped chute to catch the caps as they were formed and blown from the die. Passing through this, they were carried through a pipe to a barrel or box placed on the floor by the side of the press.

The illustration fully explains the device. The air line *A* comes from the tank; *B* is the valve; *C* a spring to close the valve; *D* a copper tube to be bent as required to bring air in proper relation to the die; *E* the main shaft of the press; *F* represents the cam for opening the valve; *G* is the press ram; *H* the punch; *J* the die and *K* the funnel-shaped carrier and pipe leading to the box.

Buffalo, N. Y. HERBERT J. RANDALL.

Locating Round Ends of Levers

The illustration shows a good device for locating in a drill jig work similar to *A*. The holes are located concentric with the rounded ends, which is always desirable. The work is set on one end in a suitable fixed V-block,



LOCATING ROUNDED ENDS OF LEVERS

as *B*, and upon the bottom on studs *C*. The screw *D* is then tightened, which in turn forces the movable V-blocks *EE*. These V-blocks pivot on studs *FF*. B. MACK.

Dayton, Ohio.

Tinning Tempered Steel

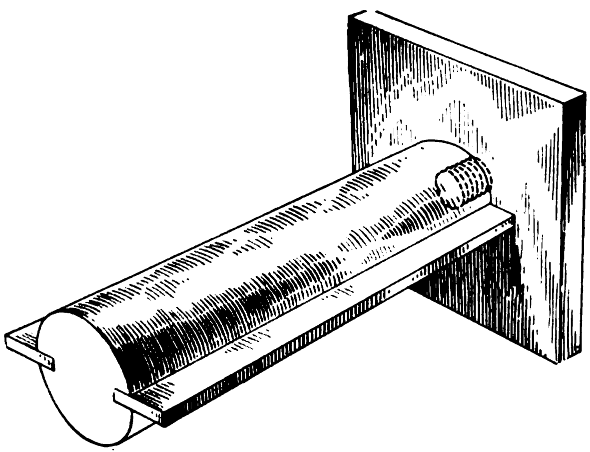
Steel articles that have been tempered or blued and show a light color, either straw or blue, cannot be tinned without first removing the thin film of oxide which gives color to the hardened and tempered steel. A bath of dilute hydrochloric acid is necessary to remove this thin film of oxide. It will require only a few seconds' immersion to do so, after which the object should be dipped into the lead and tin bath while wet; lace it immediately in the melted bath, as quick as it comes from the acid, and the lead and tin alloy will immediately coat the surface and form a foundation for soldering.—"Brass World."

Discussion of Previous Question

Around Small-Shop Babbitt Fires

I read your article in Vol. 43, on page 1017, dealing with babbitting and was particularly interested, because that is an important part of the work in our repair shop. We have a cheap and easy way of babbitting our standard bearings. While not new, it may be of interest to those having similar work to do.

Having a number of bearings running from 1 15/16 in. to 4 15/16 in. in size, to be babbitted regularly, we made a mandrel, as shown in the sketch. The scrap pile was appealed to, and a piece of cast iron about 8 in. square and 1 in. thick was found. A 1¾-in. hole was bored out



MANDREL FOR BABBITTING STANDARD BEARINGS

and threaded in its center. Mandrels for each size of bearing were then turned, leaving them about 2 in. longer than the bearings and, as we did not want to do much scraping, a few thousandths oversize in diameter.

One end was turned and threaded to screw down flush into the cast-iron plate. The mandrels were then put into the shaper and slotted along two opposite sides, and flat pieces were tightly driven in, as shown. The thickness of the pieces varied according to the amount of liners wanted for that size of bearing.

In babbitting, the base plate is laid flat, the proper-sized mandrel is screwed into it, and the bearing and cap are bolted on with their regular bolts, the side strips fitting into the planed-out part of the bearing and automatically centering it around the mandrel. A little of the asbestos and cylinder-oil mixture is put around the bottom and in the oil holes, to prevent leaking, and also around the top, so that a riser can be poured. The babbitt is then poured into the open end. As soon as it sets, the bearing and cap are taken off, and the surplus metal is removed with a piece of iron heated in the forge. The resulting bearing is smooth; and as the bearings are always planed the same, they are always in line and the same height from the sole plate, without any measuring on the part of the man doing the pouring.

We use this hot-iron method to remove surplus babbitt from nearly all our babbitting jobs. It is quicker and safer, for unless extreme care is taken, the babbitt in the bearing is likely to be loosened by chipping. In melting off the babbitt, care must be taken to hold the bearing in such a position that the melting metal will run away from, and not into, the bearing proper.

It has been our experience that sometimes a little more care and thought in cutting the oil grooves in a bearing are more important than the grade of babbitt used. In a number of instances, after a few experiments with different ways of cutting the grooves and finding the most suitable lubricant, we were able to get as good, or even better, results with a much cheaper grade of babbitt, which is quite an item in these days of high-priced copper and tin.

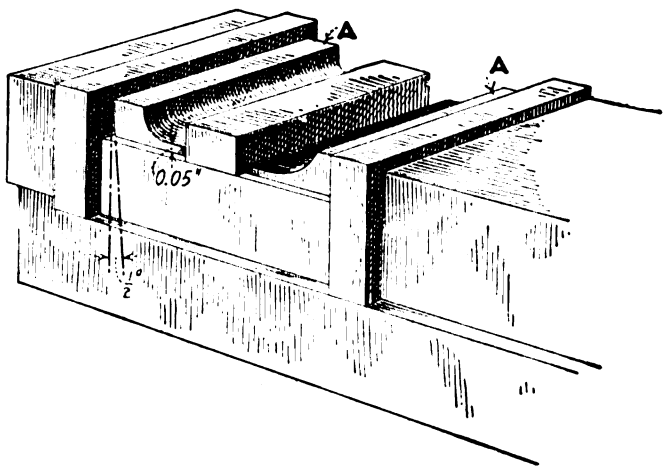
Milling Attachment for Thin Cutter Blades

On page 1175, Vol. 43, Mr. Fruhner describes a fixture which looks very good. I have been up against the same proposition and find that two simple strips shown at *A*



MILLING ATTACHMENT FOR THIN CUTTER BLADES

answer the same purpose very satisfactorily when used in an ordinary milling vise. Blades as thin as 1/16 in. thick may be milled with them.

The strips may be made of ¼ or 3/16 in. thick tool steel, spring tempered, with the edges which come in contact with the vise jaws made on a slight angle. This arrangement tends to force the work solidly against the parallel.

Chart To Determine Maximum Unit Repeated Stresses

We have noticed with much interest Professor Kommers' diagram for use with the exponential formula for strength of metals under repeated stress. Professor Kommers' diagram is, in many respects, a decided improvement over the diagram given by us in the paper on

"The Failure of Materials Under Repeated Stress" (American Society for Testing Materials, 1915).

In this connection it seems proper to call attention to the fact that the values of B given in that paper and quoted by Professor Kommers were given as tentative values. Recently the writers have discovered an error in the derivation of the value of B from the test data.[1] Having corrected this error and having given further consideration to available test data, we now suggest the following values for B:

Material	Values of B
Structural steel and soft machinery steel....	250,000
Cold-rolled steel shafting....................	400,000
Steel, 0.45% carbon..........................	350,000
Wrought iron	250,000
Spring steel	400,000 to 600,000
Hard steel wire................................	600,000
Cast iron (gray)...............................	100,000
Cast aluminum	80,000
Hard-drawn copper wire.........................	140,000

In view of the small number of test data available for some of the materials the values herewith should be regarded as tentative. It is our opinion that in no case should working stresses be taken as greater than one-half the stresses for fatigue failure as given by the exponential formulas, using the foregoing values of the constant B, while in many cases the working stresses should be lower than one-half the fatigue-failure stress. Of course, in no case should working stress be taken greater than the safe static stress.

Two Small-Shop Items

The contributions of John H. Van Deventer are most interesting reading for me and must be more so to the owner of the small shop, who is too often looked upon as a sort of "stick in the mud" by all of us who "know something."

Quite recently I visited a small shop. The whole of its machinery consisted of two old engine lathes, a milling machine, made when milling machines were young, and a drill press of the same period.

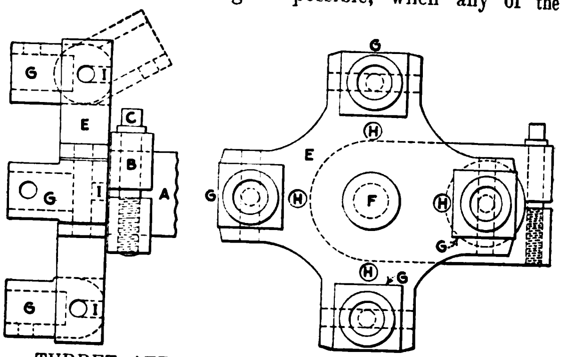
This shop was exceptionally busy on munitions—small details for aëroplanes. The work was ideal stuff for the automatic. Many of us, I fear, if similarly placed, would have started in by getting into communication with some makers of automatics. After telling them what we thought of their delivery dates, we should probably have finished up by not getting the automatics and by making no attempt to get on with the details. The proprietor of this little shop had no time to waste. He just went ahead, and the way those old engine lathes were eating up the bars would have surprised the automatic and its maker.

The illustration shows the home-made turret attachment used on the engine lathes. The turret is attached to the sleeve A of the tailstock by means of the bar B and the screw C. To this bar the swing plate E is attached by means of the pin F. On plate E the four tool holders G are pinned and arranged, as the proprietor said, to swing "clear of everything."

The tools are located by means of a pin carried on bar B, engaging with the holes H. In the center hole of the sleeve is a spring plunger that engages with the hole I at the back of the tool holder, keeping this in position while in use.

For the work on hand, a drill, a reamer, a recessing tool and a tap were in use, while in the tool post a forming tool and parting tool were carried. While I could not help but admire the speed with which these methods produced the small parts, I think what appealed to me most was the "swinging clear of everything" of the tools not in use.

The proprietor of this same shop had recently installed electricity for lighting purposes. He had placed an old barrel in the loft, to which the disused gas pipe was attached, thus making it possible, when any of the machines required lubricant for their cutting tools, just to "turn on the gas."



TURRET ATTACHMENT FOR LATHE TAILSTOCK

No trouble was experienced with this system, the boy at the drill press taking a sort of delight in looking after the supply to the barrel. The only untoward incident occurred when someone "turned on the gas" in the proprietor's little office, which unfortunately for some of his correspondence and drawings, still had its gas jet. One accident of this sort was quite enough to convince the proprietor that it was advisable to make a second one impossible by blanking off the pipe entirely.

Somehow, while admiring these methods, the thought passed through my mind that one of the boys of this shop might one day make his way to a modern shop, with its drip cans and pans. Perhaps he will compare it with the old man's gas-pipe system and think how terribly the modern shop is out of it. Possibly he might go into a really modern shop, with its lubricant system complete with pipes and pumps and with costs worked out to the fraction of a cent; but even then it would not cause him any surprise, as quite naturally he would think someone had stolen the old man's ideas and also his system of bringing lubricant to the cutting tools.

Belfast, Ireland. G. P. TERRY.

Best Way To Do Certain Things

On page 165 Mr. Jacker has commented on the method proposed by Professor Sweet for attaching a lever to a shaft. Mr. Jacker suggests replacing with a taper pin the nut originally recommended by Professor Sweet.

To my mind the nut is much easier to fit up in the first place. On interchangeable work especially, the taper pin calls for expensive jigs and extremely careful work. The lever and shaft may be assembled and drilled in place, but then they are no longer interchangeable. After the thing has been fitted up once and taken apart a few

[1]In the paper before the American Society for Testing Materials the last sentence on page 452 (1915 Proceedings, Part II) should read: "It (B) is twice the value of the ordinate," etc. The mistake was ours, not the editor's. The values of B given in the illustrative problems solved in that article will be affected by this error, but the methods of solution will not be affected.

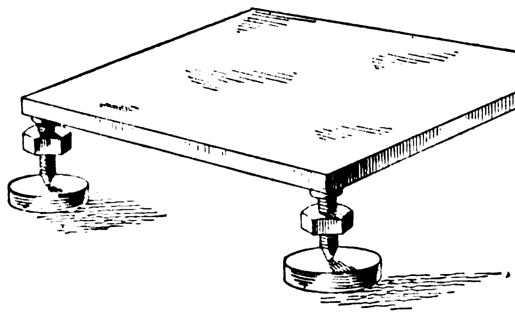
times, the crank will be worn or stretched enough so that the pin holes will not match when the crank is driven on snugly.

When it comes to a job such as a gasoline-engine flywheel, great is my respect for the designer who bolts his wheel to a flange on the crankshaft. Especially on boat engines this job of removing a flywheel has to be done under unfavorable circumstances with limited tools, and no system of keying on either a straight or a taper shaft will let go so promptly as a flanged, bolted joint. It will even defy sea water, which converts the fixing of any other joint I ever saw into one of the meanest jobs the repair man has to handle. H. W. JOHNSON.

Poughkeepsie, N. Y.

A Bench Plate with Legs

A. E. Holaday, on page 1130, Vol. 43, illustrates a bench plate with legs, in which the threaded holes pass right through the plate and the bolt heads of the adjusting screws serve as the surfaces in contact with the bench. The plate here shown corrects these two seeming disad-



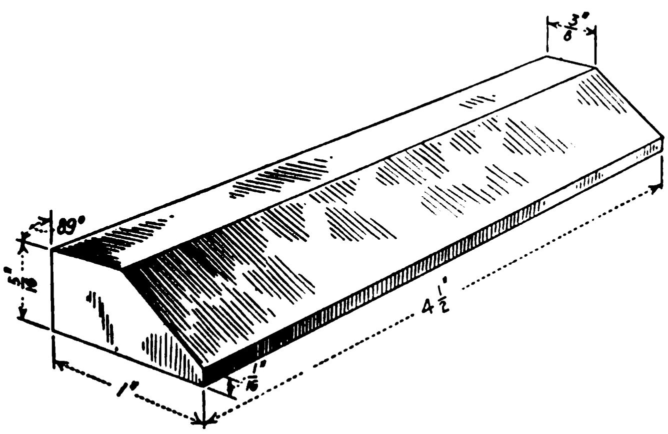
A BENCH PLATE WITH LEGS

vantages. Chips and dirt will find their way into holes that run wholly through the plate, and the adjustment will be more readily made when the hexagons on the adjusting screws are raised somewhat from the table.

London, England. G. S. BOWLING.

The Small-Shop Planer

On page 841 of Vol. 43 Mr. Van Deventer mentions a kink used in holding work against the solid jaw in the milling, planer and the shaper chuck with a piece



CENTERS FOR HOLDING THIN WORK IN A VISE

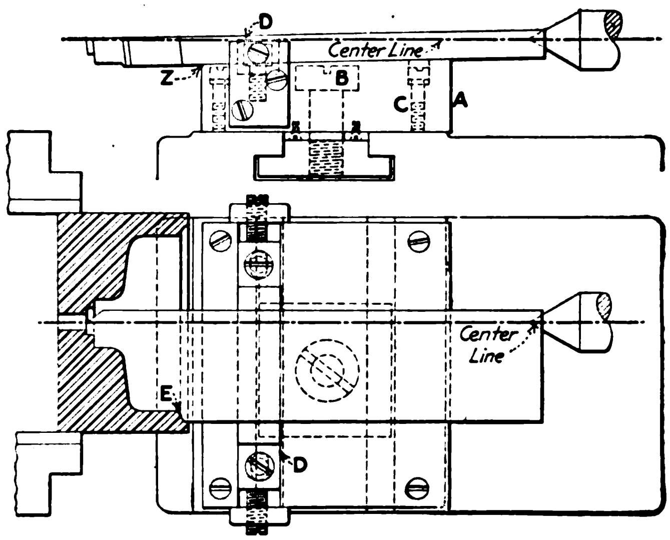
of round stock. Pieces like the one illustrated, called "centers," are a great improvement over the round pieces. They are made of tool steel hardened and ground.

I am doing a good deal of shaper work in making dies and don't see how I could get along without the pair I have, not alone for holding work against the solid jaw, but on lots of other work, particularly thin pieces. One on each side of the work fills the bill here and in many other places. Grinding the face which goes against the jaw, a little past square tends to force the work against the parallels. AXEL HALVORSEN.

Albany, Ind.

Face-Forming Tool for a Lathe

With reference to Gustave A. Remacle's article, page 1127, Vol. 43, I think this is purely a technical idea. If put to a practical test, it would be likely to fall down.



FACE-FORMING TOOL FOR A LATHE

After the tool has been made and hardened, the tempering would have to be carefully studied, as *Z* in the reproduced illustration would be subjected to a great pressure and would probably break or bend. Owing to the great cutting surface, the tool would be found to spring and chatter. This class of tool is all right for roughing out; but for finishing, it is nearly useless.

If your contributor requires a tool for such a die, it would be advisable to make a reamer or D-bit, which could be done without much trouble.

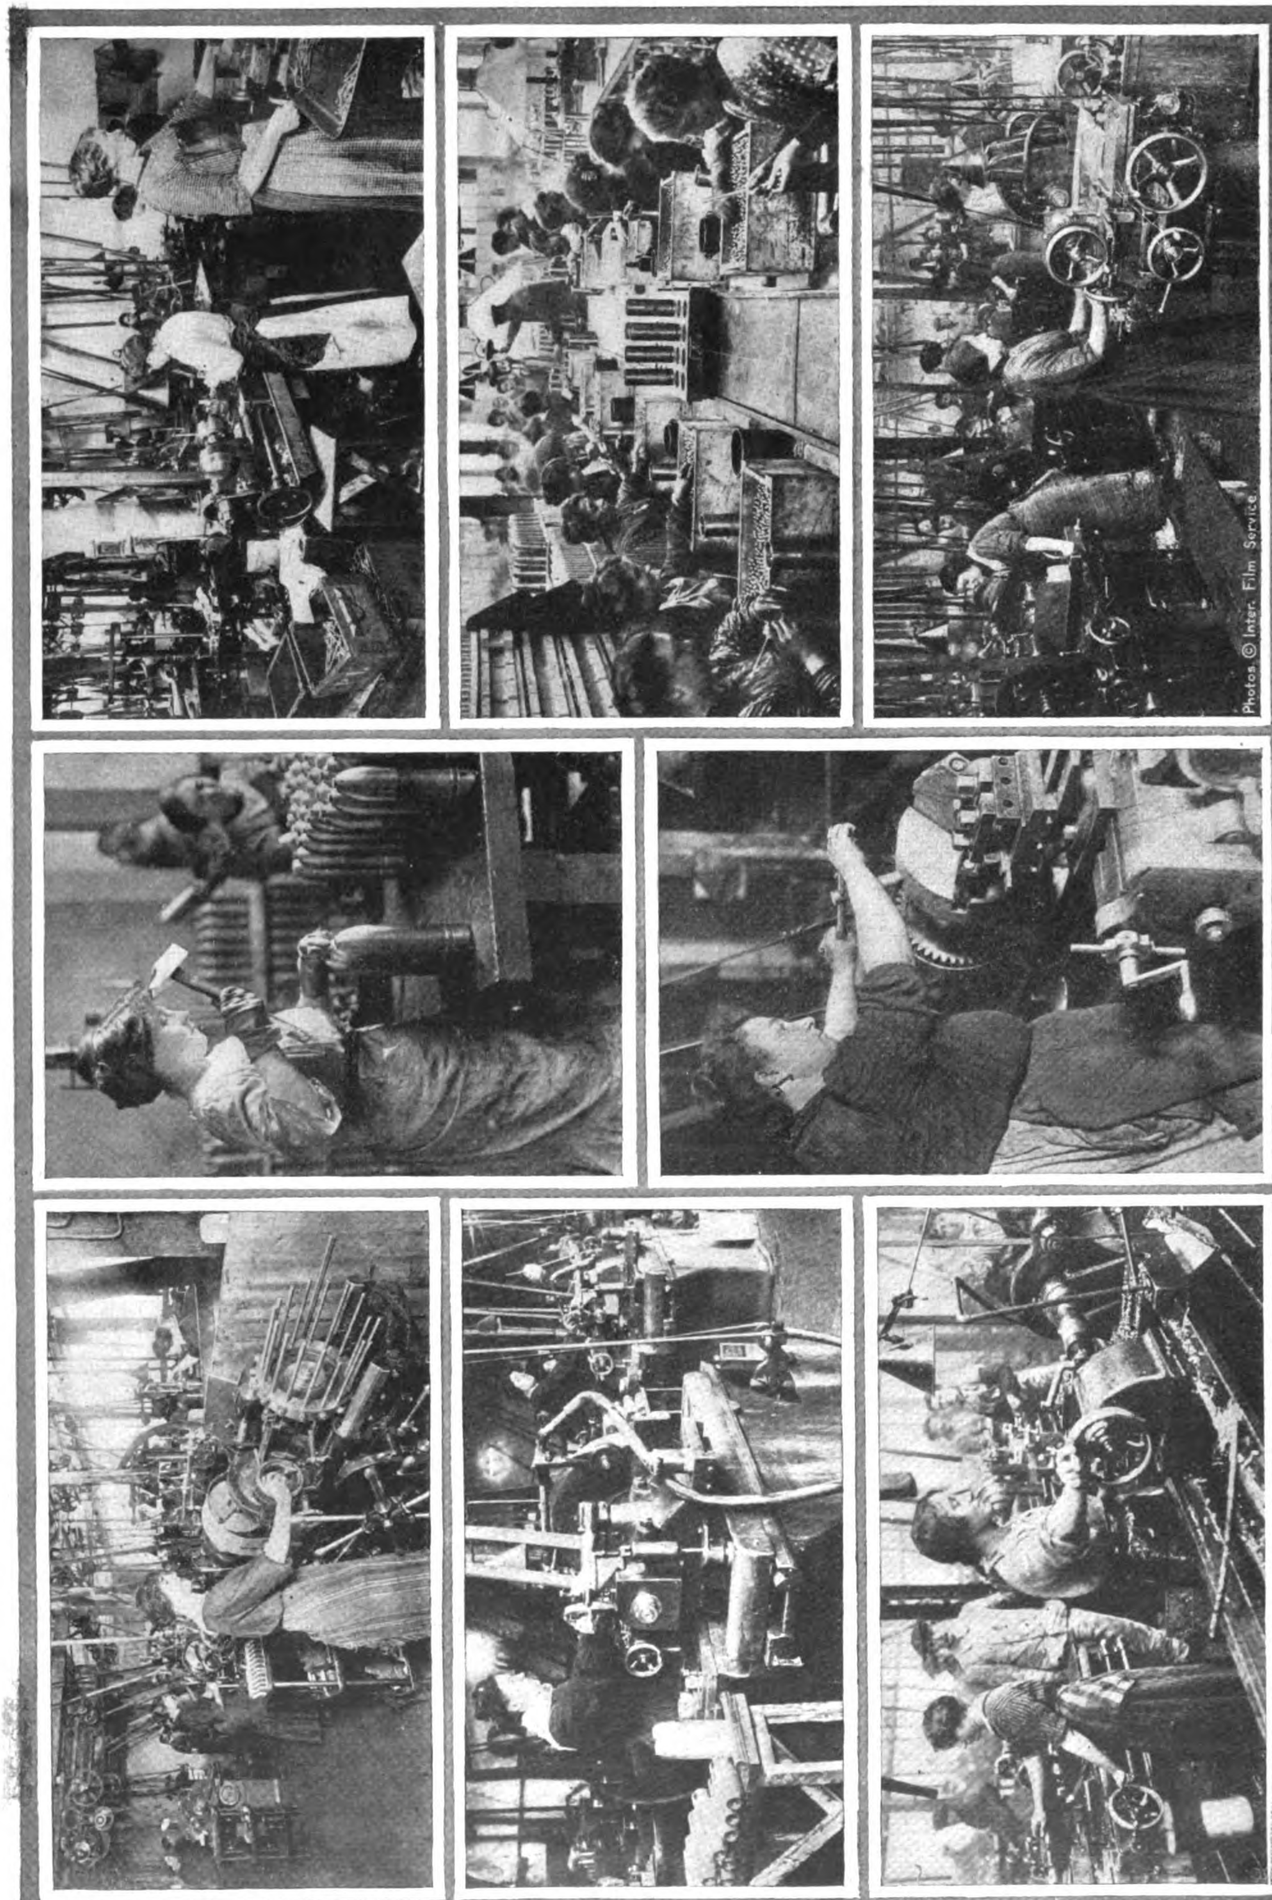
Chingford, England. W. H. HUTCHINS.

Humoring a Small Lathe

Your correspondent, A. S. Day, on page 912 brought up an interesting subject. I believe that the cutoff tool is one of the most unsuccessful tools which the engine-lathe operator has, unless it is used upside down and the lathe reversed.

I have seen a lathe operator cutting up in a 14-in lathe a steel bar $1\frac{1}{2}$ in. in diameter by 18 in. long into disks about 1 in. thick. One end of the bar was held in the chuck; the other end ran on the center. I doubt if the ordinary cutoff tool could have been made to go right along the bar without some digging in and some broken tools. It seems to be the general practice in motor shops around London to cut off with upside-down tools. What would they do with a lathe having only forward speeds?

Wembly, England. J. H. DAVIS.



Women Machine-Tool Operators and Bench Workers in a French Munition Plant.

Editorials

Women Munition Workers in French Shops

The illustrations reproduced on the opposite page show conclusively how universal the employment of women has become in French munition shops. It will be noticed that their employment is not restricted to machines and operations that in the past have been considered suitable for women. Here they are shown operating cutting-off machines, rough-turning lathes, wet grinders and screw machines, as well as performing a number of manual operations such as loading, inspecting and stamping.

One point is emphasized by an inspection of the costumes worn by these operators. Apparently standardization in this matter has not yet been attempted, although it will probably come with time.

The shop from which these illustrations are reproduced is a part of the celebrated Panhard-Levasser works.

Racial Traits and Feelings in South America

"Pardon me, but I cannot give you anything." This expression, or its close equivalent, is the courteous everyday refusal to beggars in South America. Not only are the words polite, but the sentiment that they convey is genuine. Through this everyday occurrence is exhibited the strongest racial trait of South Americans. In contrast the brusque, "Beat it," hurled over one's shoulder at a northern panhandler exhibits a racial trait of the Anglo-Saxon.

To North Americans such extreme courtesy may appear hypocritical, but it is not. It springs from an inborn sense of the rights and privileges of others, and in its gracious thoughtfulness for another's feelings is a fine practical application of the Golden Rule. In South America there is no such thing as "cussing out" a subordinate; there is no discourtesy on the part of servants. Short-changing in the transactions of daily life is unknown. As a rule, financial obligations are scrupulously met. In this respect the subscription records of the *American Machinist* show that South American accounts are uniformly paid. Would that the same could be said of domestic accounts!

These things, while perhaps small in themselves, are traits and characteristics that every northern business man should understand and value at their true worth, if he hopes to do business in the great markets that are opening to the south of the Panama Canal.

It is more than likely that the average North American forms his opinions of South Americans by his knowledge of Mexicans. This twisted viewpoint is aided and abetted by our magazines and daily newspapers, which one often believes are deliberately fed with misrepresentations. Racially the Mexican is a mixture of Spanish and vicious Indian. In contrast Brazil, the largest country of South America, is racially Portuguese, Negro and Indian, but Indian of a far different type than that met with in Mexico. The rest of South America is racially Spanish and Indian. The population, taken as a whole, is far different from that in Mexico in almost every way that is touched in business connections.

Broadly speaking, there is no color line in South America. In Brazil, where the negro blood is most plentiful, many of the most important positions are held by pure negroes. For illustration, the president of the Bahia Water-Works Co., an able engineer and a man of affairs, is a negro—and he is no exception.

This population, which is just on the eve of tremendous advancement in the use of manufactured products, occupies the richest section of the entire world. The Amazon River basin has twice the area, and La Plata basin one and one-third times the area, of the Mississippi. The national resources are untouched and are magnificent in extent.

An Argentine statesman recently said that his country today is in the same position that the United States was in 1805. What tremendous things will happen there in the next 50 years!

Life is easier in South America than here, because of the great fertility and productiveness of the land, because wants are simpler and because of racial habits. But this leisure is not misused. The average man who would be approached by a salesman from North America is better educated than his caller. Not only would he have a thorough knowledge of his own business, but he would have accomplishments in languages, literature, art and music that would far outshine and outdistance the man from the north, with his purely business viewpoint. Such facts are well worth consideration whenever plans are being formed to enter South American markets.

The feelings of South Americans toward the United States have been as much misjudged as their racial traits have been misrepresented. It is true that, in the past, South American countries believed that the United States was a huge aggressor, interested mainly in stretching her boundaries and absorbing portions of the weaker countries to the southward. The latest incident to foster this feeling was the landing of the naval contingent at Vera Cruz. But when these troops were withdrawn and President Wilson affirmed and reaffirmed the position of the United States—that not one square foot of Mexican soil was wanted or would be taken—the sentiment in South America changed again. Today the feeling for us is one of extreme cordiality. Our much discussed Monroe doctrine is looked upon as the great safeguard of the entire western hemisphere and a principle that should be supported by the nations of the south as well as by the United States. In fact, in Rio de Janeiro there is a beautifully constructed building known as the "Monroe Palace." It was built to honor President Monroe and commemorate the establishment of the American doctrine that bears his name. At the present time there are running in South America serial novels in which Brazil, Argentina and Chile are pictured as joining with the United States in defending this doctrine against European aggression.

The business men of South America now realize that they have made a mistake in past years by not establishing closer business relations with their northern neighbors. This feeling has been accentuated by the situation developed from the European War. Without doubt, at no previous time in our history has the feeling in South America been so cordial and favorable toward the United States as it is today. Obviously, this is the time to lay the foundation for foreign trade that shall endure for decades to come.

Another source of misrepresentation has been in regard to the quality of goods demanded by South Americans. It has often been thought that they would purchase only cheaply made, inferiorly finished products. This is not true. It is an interesting fact that very little plated jewelry is sold in South America. However, people buy plentifully, within the limit of their means, genuine jewelry of excellent design and superior workmanship. In the region of more practical things—up to 20 years ago a Connecticut firm had practically a monopoly of the cutlery trade of the rubber districts of the upper Amazon. At about that time German goods began to enter, selling for a much lower price than the North American, but inferior in quality. In a short time the American products were driven out. But about 10 years ago the tide turned, and within another 5 years the German products had disappeared. The trade of the Connecticut firm is now firmly reëstablished. The turnover was due entirely to the superior quality of the Yankee products.

The lack of real information in regard to South America, her people, their traits, feelings and business likings, is perhaps due partly to the provincialism of North America. This is a well-worn statement, but it has not lost the force of truth. Now, if ever, is the time when facts, not beliefs, and plans, not schemes, must be relied upon if American manufacturers are to obtain and retain their proper share of the business in South American markets.

Preparedness for Manufacture Instead of for War Itself

We hear much in some quarters about the raising and equipping of a huge army at short notice, should we be threatened with an invasion. But those who talk in this way know nothing of the problem of securing arms and accouterments for such an army; they do not realize the time required to manufacture arms and ammunition.

They read of the huge order for munitions that have been placed in this country and read of different shops that are turning out from 3,000 to 10,000 shells per day and of cartridges by the million. They think of our large automobile and other shops and fondly imagine them turned into huge munition factories, and a sense of security comes over them. They say we are the greatest country on earth, with the greatest resources; why worry?

But they do not know that in reality we are supplying only a small percentage of the ammunition being used by the warring nations. They do not know the time required to begin turning out rifles, fuses and other munitions.

We are informed that very few rifles have yet been delivered of the millions which are under contract. And this in spite of the fact that some of the contractors were already in the business and large manufacturers of arms. Even mechanics do not realize the immense amount of preparation required to manufacture rifles; they do not appreciate the hundreds of operations that go to make up a modern rifle, the hundreds of jigs and of gages and the training of men or women for inspection and assembly.

Fixtures and gages play an important part in the making of rifles, and unfortunately they require a long time to design and manufacture. And even with the design made and blueprints to work from, it is no easy task to secure enough tool makers capable of this sort of work to turn these pieces out accurately and quickly, as mechanics of this class are none too plentiful in ordinary times.

As we have pointed out before, an excellent form of preparedness is in the making of as many sets of fixtures and gages as may be necessary to enable rifles to be turned out quickly in a dozen or more shops. Preparedness of this kind could hardly be used for offensive purposes and would yet be extremely effective in the effect on possible invaders.

With enough rifles on hand for the first few weeks—and although another 250,000 would do no harm—we are not as deficient in that respect as some would have us believe. And with fixtures and gages, not overlooking drop-forging dies and similar tools, additional arms could be quickly manufactured, preferably in interior towns and cities.

Preparedness to manufacture quickly is not only cheaper, but is more effective than many of the plans proposed. Such action, coupled with world-wide publicity that all preparations have been made, will do much to prevent invasion and also nullify even the most elaborate spy system in existence. Playing the game with the cards in the open is always the best in the long run.

The Cup That Energizes

In practically all the shell shops of Canada work goes on day after day and night after night with no let-up. The hungry guns on the battle front must be fed, and those who make the fodder must not rest. In many of the shops Christmas and New Year's day were the only holidays in the twelvemonth past. Night work for even a single night is trying. How much more so is it when carried on night after night, week after week and month after month!

In one of the larger Canadian shell shops the management has set up coffee stalls at convenient points throughout the plant. Here the men can get a hot cup of good coffee for two cents. There is only one restriction—a man can go and get a cup whenever he likes, day or night, except at four o'clock in the morning. This is the hour, so the doctors tell us, when a man's vitality is at its lowest. In the works referred to it is compulsory for the men to drink, at the firm's expense, a cup of hot coffee at this hour. The scheme has been in operation but a short time, but the results have justified the expense. A tired man, after drinking a cup of hot coffee, returns to his work with renewed vigor.

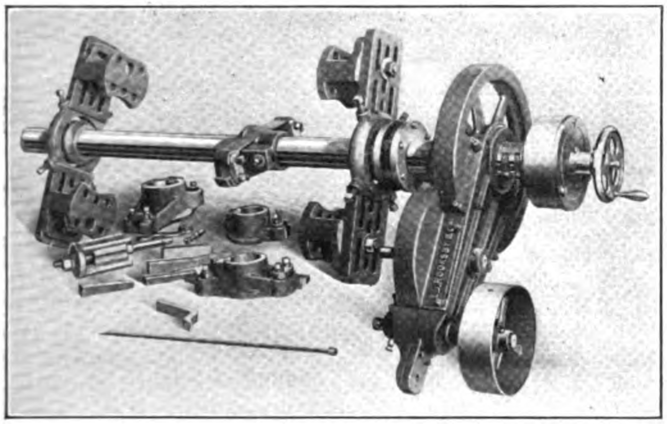
The increase in production after 4 a.m., since the coffee stands were started, has not yet been tabulated and compared with the production previous to their installation, but it is sufficiently marked to be noticeable.

Shop Equipment News

Cylinder Boring Bar

In the construction of the portable locomotive-cylinder boring bar shown, designed for reboring locomotive cylinders and valve-chamber bushings, special attention has been given to the safeguarding of all gears and moving parts.

The tool can be used with one or both cylinder heads removed. The crosshead blocks are bolted to the cylinder with the cylinder-head studs; and the bar revolves in the sleeves, supported and centered by setscrews in the crossheads.



CYLINDER BORING BAR

When boring with only one head removed, the expanding chuck and pin, having five sets of taper gibs to fit in stuffing-boxes of various diameters, are used to support the crank end of the bar.

The power is applied to the bar by means of a back-geared driving power having a two-speed quick-change gear drive. This form of drive is calculated to be of particular advantage where the same bar is used to rebore cylinders and valve-chamber bushings of various sizes. The quick-change is accomplished by simply pulling out a slip pin, shifting the primary pinion out of gear and driving by the intermediate shaft.

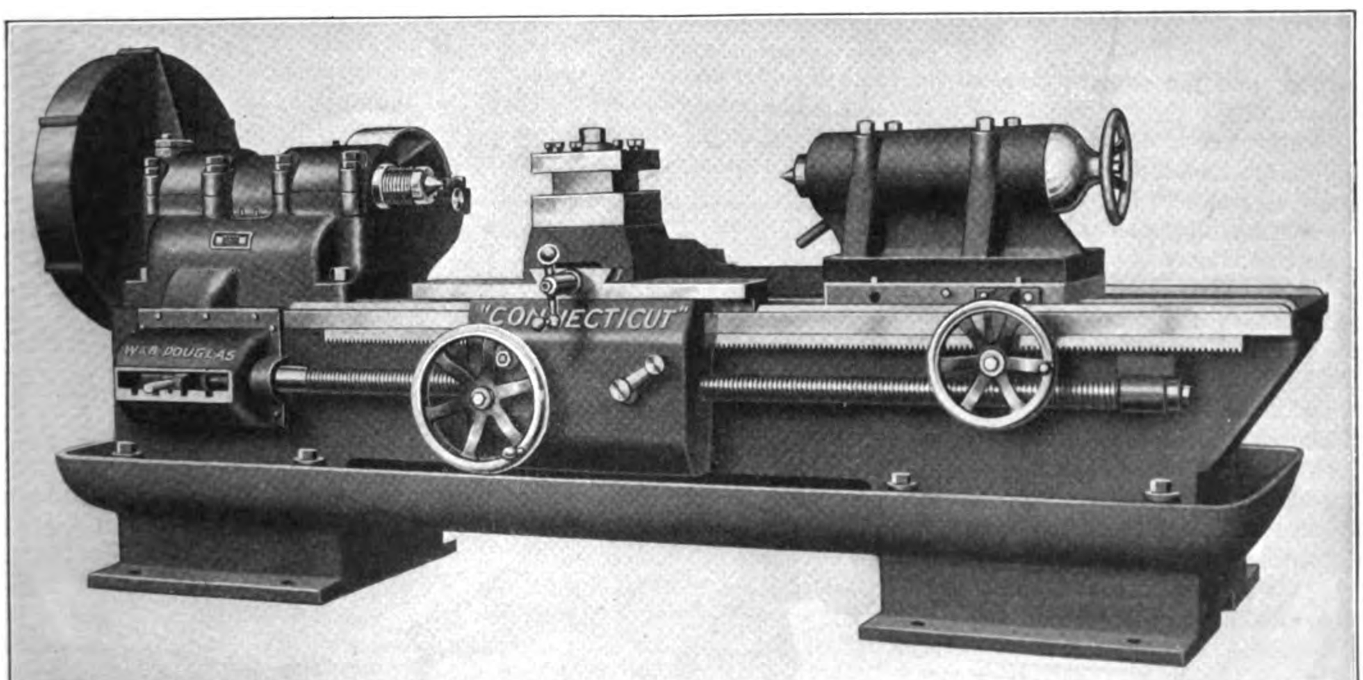
The cutter head is fed by means of an automatic feed case having two changes of feed controlled by a slip pin. For setting the bar up in valve-chamber bushings a novel device is used, enabling the operation to be quickly and accurately performed. This consists of a set of taper cone sleeves in halves, fitting in the counterbore, supporting the bar central while bolting up the blocks and crossheads, after which the cones are removed and the bar is ready for reboring. The sleeves being taper, one set can be used in bushings of various sizes.

These portable boring bars are manufactured by E. J. Rooksby & Co., Philadelphia, Penn.

Heavy Single-Purpose Lathe

It will be observed that the lathe shown is of the single-purpose type, designed primarily for turning or boring high-carbon steel forgings at maximum speeds.

As will be seen, the machine is heavily proportioned and follows more or less conventional design. All the



HEAVY-DUTY SINGLE-PURPOSE MANUFACTURING LATHE

Swing over ways, 26½ in.; swing over carriage, 15 in.; floor space, 11 ft. 6 in. by 4 ft. 8 in.; height to center, 42 in.; distance between centers, 60 in.; length of bed, 10 ft. 8 in.; cone diameters, 12 in., 15 in., 18 in.; speed of countershaft, 240 to 500 r.p.m.; diameter of countershaft pulleys, 18 in. for 6-in. belt; length of tool carriage, 36 in.; shipping weight, boxed for export, 16,000 lb.

bearings are fitted with removable bronze bushings, and the gears and pinions are made of steel, with the exception of the large spindle driving gear, which is made of semi-steel with 4-in. face.

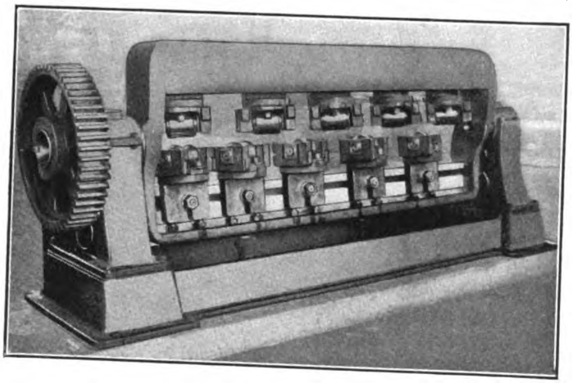
Three speeds and four feeds are provided. The turret tool post is of steel and arranged to lock in four positions. The bed is cross-ribbed with heavy box-shaped girts 15 in. apart. The central rack, which takes the end thrust of the tailstock, forms an additional rib. The feeds are all positive, transmitted through the lead screw. The main journals are provided with ring oilers, while all internal moving parts are lubricated by gravity feed.

The machine is a recent product of W. & B. Douglas, Middletown, Conn.

Roll Straightening Machine

In addition to its regular function of straightening, the machine shown puts on a high finish in one pass.

The straightener consists of a bed with upright pedestal bearings, which support a revolving frame that has hollow



ROLL STRAIGHTENING MACHINE
Capacity, 1- to 2½-in. rounds; speed, 30 to 40 ft. per min.

journals and the straightening mechanism. The latter consists of six rolls having concave surfaces. The rolls are supported by bearing blocks having a swivel and screw adjustment. The roll supports are secured to the revolving frame so as to project alternately from opposite sides, excepting at the receiving end of the frame, where two rolls are directly opposite. At each end of the straightener, tracks are provided, traversed by a gripping device that keeps the material to be straightened from revolving.

The contact of the concave rolls in the revolving frame produces varying speeds, according to the amount of concave surface put on the rolls. A certain degree of slipping that is done by the rolls will put on a fine finish. The rolls are adjusted at an angle to the shaft according to the diameter, each roll having a segmental line of contact with the shaft. This prevents gouging out or breaking of edges of flaws or cracks that might be found in the surface of the material.

The machine shown is the latest addition to the line made by the Brightman Manufacturing Co., Columbus, Ohio.

Adjustable Sizing Tap

The tap shown is an adjustable tap that may be kept accurately to size, and yet it has the advantages of a solid tap. It is made in various sizes and threads on

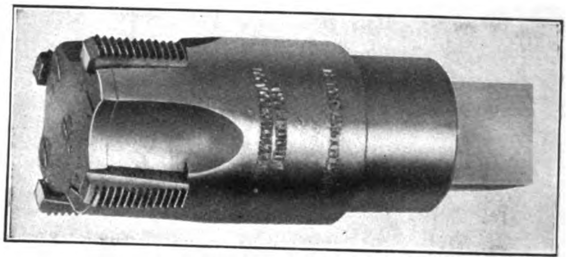


FIG. 1. ADJUSTABLE SIZING TAP
All sizes from 1¼ in. to 12 in.

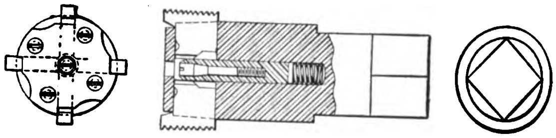

FIG. 2. CONSTRUCTION OF SIZING TAP

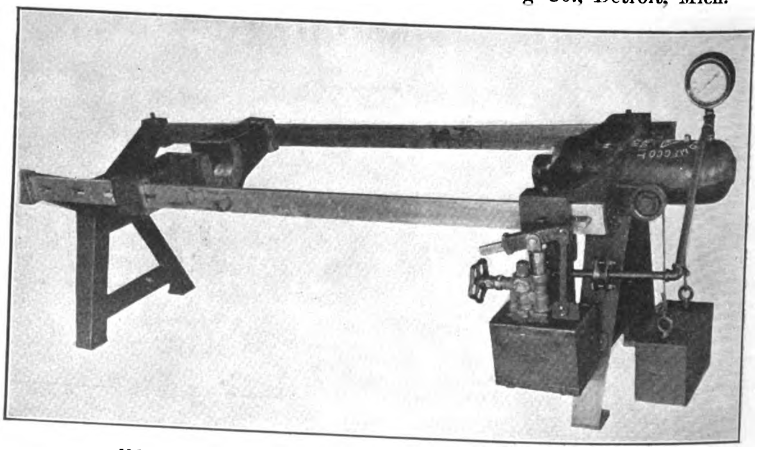
order, and additional sets of chasers may be easily obtained. Its construction is shown in detail in Fig. 2.

It is made by the Murchey Machine and Tool Co., Detroit, Mich.

Horizontal Hydraulic Press

The press shown has been designed to fill the need of a machine capable of powerful pressure, where speed and rapid production are not essential or under circumstances where power drive is not available.

The distance between the ram and the resistance head can be varied to suit the work by adjusting the head on the slotted and keyed bars. This press is a late product of the Metalwood Manufacturing Co., Detroit, Mich.

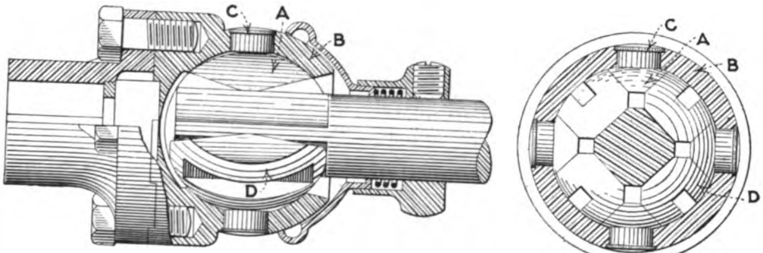


HORIZONTAL HAND-OPERATED HYDRAULIC PRESS
Twenty-ton size: Ram, 4½ in.; stroke, 12 in.; between bars, c. to c., 36 in.; length of bars, 9 ft.; ram to resistance head, extreme, 8 ft.; weight, 2,225 lb. Fifty-ton size: Ram, 4½ in.; stroke, 18 in.; between bars, c. to c., 36 in.; length of bars, 24 ft.; ram to resistance head, extreme, 22 ft.; weight, 2,930 lb.

Universal Joint

The illustration shows a new form of universal joint, which it is claimed gives a uniform motion at all parts of its revolution. It consists of four spherical driving segments *A*, held in the hollow driving case *B* by means of the pivots *C*. Between these driving segments are the floating segments *D*, which engage the squared end of the driving shaft. These floating segments fit the shaft. As they are free to move between the driving segments, they can assume any angle within the driving range, which is about 30 deg.

As will be seen, this joint has large bearing surfaces and is provided with large lubricating channels, so that it can be packed with enough grease for a year's run. The joint is compact and is provided with grease and dust covers. It is made by the Cooper Flexible Transmission Co., Inc., Brooklyn, N. Y.



FLEXIBLE SHAFT COUPLING OR UNIVERSAL JOINT

Machine Tools in France

By William D. Fitts

Recently I visited some of the important machinery houses in Paris that have connections in the United States and are the selling agents of many of the large factories there. Unusual activity was found everywhere, but the officers of the different companies found time to discuss the interesting question of the past, present and future of American machine tools in Europe. A considerable amount of information was obtained—in some instances of a disconcerting nature. One imagines that if there is a thing which Americans do really know something about it is organization and that they are wonderfully endowed with efficient methods for carrying out the details, big or little, of their business. But is seems that American business men still have two or three things to learn before Europe is quite willing to admit their supremacy in small details.

A member of one firm asked me to beg American manufacturers to put their office boys through a course of instruction in the postal rates between the United States and Europe. He said that it is not unusual for excess postage to be paid at this end by his firm, amounting in a month to 30 or 40 francs. Sometimes 20 or more invoices arrive in one cover, stamped with the minimum postage for the United States. This practice has been going on for years, notwithstanding a long and heated correspondence on the subject. Threats of fines are of no avail, and the habits of the American office boy are incorrigible, for even today the practice of putting a 2c. stamp on a letter to France prevails in many American offices.

Another firm has been writing weekly letters for the past 18 months to a New England factory, in an endeavor to persuade the manager to have the shipping cases marked with a stencil plate and in ink, rather than with a lead pencil. This kind of marking is obliterated by the time the case is on the docks at Havre, where it has to be opened and an inventory made of the goods it contains. A leather stencil and a brush were sent out to New England to be used in marking this firm's cases, and yet—alas!—the old pencil habit was too strong, and a weekly hunt has to be made upon the Havre docks for odd cases containing valuable shipments of machine tools. Delays and countless vexations are the result. Even when a stencil and ink are used, one steamer may bring three different invoices for the same firm, among which are found three No. 1's. In fact, I was begged to ask the manufacturers to take the time to perfect their markings, so that consignees will have less trouble in checking up their cases and knowing to a certainty what they contain. And too, will not the American manufacturer employ some system of checking the American Express Co. so as to be sure that cases are really shipped by it upon certain dates and upon specified steamers?

In general, the impression seems to be that the American has still many things to learn about the export business. As all the companies interviewed are anxious that the present exportation of American tools to Europe should be maintained, even after the war comes to an end, it is suggested that now is the time to study and perfect the details of the business, so as to be better prepared for the competition that is bound to come when European peace has been reëstablished.

The hazard of life has forced all foreign nations to turn to the United States for their present supply of machine tools. One estimate of the increase of American business with France in this line alone was 600 per cent.; with Russia, about the same; England, 300 per cent.; and Italy, 300 per cent. This latter country joined in the war after her allies had already made their contracts with American manufacturers, and factories were unable to make deliveries to her rapidly. Moreover, Italian methods of business are somewhat dilatory, and contracts are not so easily signed there as in France and Russia. There are always a certain hesitation and a lack of confidence on the part of the Italian buyer, which often loses him the chance of acquiring the articles he is most in need of.

Thousands of American lathes are now set up in factories all over France, turning out thousands of projectiles daily. One estimate is that France alone has bought anywhere from 5,000 to 10,000 lathes and from 1,000 to 3,000 automatic screw machines for making fuse parts. Millers and grinders have come over in great numbers and at the present moment cannot be had at any price. The French demand is in a measure beginning to fall off, although this is not so much due to the lessening in the needs of the country as to the inability of American factories to deliver or to make promises to furnish in any near future the quantity of machines required. And perhaps it is just here that, as a result, may be found the most interesting evolution which this war has brought

about in France. The great necessity for munitions of war has awakened in the French people a new conception of their own powers as an industrial nation.

Manufacturing Lathes in France

Before the war, France manufactured lathes, and those I have seen are good examples of design and workmanship. But they were turned out slowly, and it was a great event when one or more were sold. The firms who did this business were old and solid concerns, taking more pride in their well-earned prestige and the quality of the machines built than in the number sold. The war came, and it must be acknowledged that if the United States had not been there to furnish the myriads of machine tools necessary to equip the factories that sprang up all over France, the chances are that the present impregnable position of this country's army along its entire front would not have been so secure as all military authorities now admit it to be. But the country's demand for munitions of war has become insatiable, and as factories in the United States are temporarily exhausted, France itself has decided to make a superhuman effort to supply the necessary machines. Lathes are now being built in fairly large numbers. A simple type of machine has been chosen for a model; celerity in manufacture and utility for the one purpose—the making of projectiles—for which it is to be used are the only things that matter.

Future of France as an Industrial Nation

France easily acquires habits, and having made a beginning in the intensive supply of war material, it would not be surprising to find her, after peace is signed, entering upon a period of industrial expansion of great dimensions. Even now nothing is being left to chance, for finance and industry are banding together to an extent hitherto unknown. For the first time in the history of France the conception of vast schemes in business affairs is in process of formation. Until now it has never seemed possible for financiers to grasp the meaning or the value of great masses of figures, nor for the manufacturer to believe it possible that factories built and organized on any larger scale than might be necessary to supply in a measure the needs of the country itself were more than dreams of fancy. But all this has changed, and today France is talking in large figures and showing practically that no undertaking is too great for her comprehension. All this is happening while the flower and strength of the country are in the trenches. When this fighting generation of men, hardened by exposure and molded by life's forces in this giant contest now going on, returns to resume the material struggle for existence, it is safe to predict that whatever they do will bear the impress of their new-born conception of greatness.

In talking with the machine-tool companies here it was observed that all were guarded in making any prediction as to the future prospects of American manufactured articles in this market. All were convinced, however, that in order to hold the greater part of the business American firms must change many of their methods and show more willingness to conform to the habits of the different European countries.

The idea prevailing in America—that French firms are not worthy of credit—was spoken of as absurd by a member of an English firm which has done business in France for several generations. This gentleman said:

"There are no better contracts than those entered into in France. Possibly Americans who have little experience here may find the negotiations leading up to the signing of a contract somewhat tedious; but as a matter of fact, we do not mind this, and one is so completely protected by the laws of the country that losses are almost unknown. One case came up recently where the purchaser of lathes, who had already made an advance payment, finally received the machines and then upon various pretexts put off the final payment of the remainder from week to week. We waited four weeks and then made our complaint to the judge at the tribunal. Two days afterward the judge ordered the delinquent firm to pay in full, and we received our money the very same day. How long do you think the New York courts would have taken to decide a simple question of business of this kind? The fact is that, in spite of the war, French credits still remain as good as any in the world.

"The Germans beat the Americans before the war, not because their machine tools were better, or as good, but simply because they understood and were willing to cater to the prejudices of the people and arranged the matter of payments in a satisfactory manner."

Bitter Feeling Against Some American Firms

A member of another firm spoke about the very bitter feeling that has been aroused here by the manner in which American manufacturers had ignored many of their French contracts. He said:

"If it is true, and there seems to be little doubt of it, that American manufacturers, who have signed contracts for delivery in France upon certain dates, deliberately sold the promised machines to Americans or others at higher prices, I can only stigmatize this mode of business as immoral. At all events the manner in which some of the French companies have been treated has left a painful impression which cannot be easily effaced. And to add to the indignity, the Americans who have broken their contracts refuse to answer all letters, simply ignoring their undertaking.

"On the other hand, all really first-class American firms with whom we have been doing business have treated us very fairly and have kept us constantly informed of conditions at the factories and stated frankly how late they would be in making deliveries.

"Americans have become spoiled by too many orders. Before the war they were all crying out for business, and now that they have everything their own way they have become independent and arrogant. With the ending of the war, all this must change, for the French are not likely to forget the bitter lessons they have learned, and this time they will probably profit by them."

The director of one of the most important companies here had the same tale of woe to relate concerning the lasting harm that is bound to result from the smashing of many of the army contracts by American manufacturers. He said: "The army officers in charge of the factories know quite well what has been the cause of the delay in delivering machine tools contracted for. Promises had been broken time after time, and the general dissatisfaction that has been aroused will do great harm to American business prestige. France certainly will not soon forget the bitterness of this experience. America, on the other hand, does not seem to realize how serious the matter is."

Charles Churchill and Son, Charles Henry, Dead

The American machine-tool building industry will be shocked by the news of the death of Charles Churchill and his son, Charles Henry Churchill, founder and managing director respectively of Charles Churchill & Co., Limited, London, England. The death of the senior Churchill was not unexpected, inasmuch as he had been in failing health for the past few years, although it was not until last year that he relinquished active directorship of the business and his son became the managing head. Charles Churchill, the founder of the business, died on Feb. 14, following his son, Charles Henry, by only six days.

The story of the founding and growth of the giant machine-importing business built up in England by the Churchills dates back to 1861 and envelops the vision and faith of one of the first Americans to realize the future of the then infant American machinery-building industry.

Charles Churchill was born in Hamden, Conn., just outside of New Haven, on July 8, 1837. Upon completion of his early education he entered his father's business, which was that of auger manufacturer. In the early sixties his father became associated with the firm of Thompson, Langdon & Co., New York City, for which he went to London in 1861, to supervise the installation of some wire-covering machinery exported by that firm. In connection with the same work, the son Charles followed the next year, and the interest that this machinery aroused and the impressions he gained concerning the possibilities of other classes of machinery decided the young man in the choice of a career—American machinery importing. The business took hold almost immediately, and before many years it became a large one.

In 1864 Charles Henry Churchill was born in London. He received his early education in that city and joining the business when a young man, was associated with his father continuously.

With headquarters in London the firm established branches in Birmingham, Manchester, Newcastle-on-Tyne and Glasgow. The latest development was a manufacturing plant in Manchester.

Two sons survive, one of whom, Arthur, is at the head of the small-tool division of the business.

TRADE CATALOGS

D & W Fuse Co., Providence, R. I. Catalog. Deltabeston wires and insulating materials. Illustrated, 24 pp., 4x7 in.

The Hartford Special Machinery Co., Woodland St. and Homestead Ave., Hartford, Conn. Circular. Bench taper gage. Illustrated.

Union Caliper Co., Orange, Mass. Catalog. Callipers, dividers, tap wrenches, steel rules, hack saw frames, tool holders, etc. Illustrated, 56 pp., 5x7 in.

Julius King Optical Co., 10-12 Maiden Lane, New York. Booklet. "Let Us Save Your Workmen's Eyes." Safety goggles. Illustrated, 18 pp., 6x9 in.

BUSINESS ITEM

To provide additional manufacturing facilities to meet increased demands for their line of sheet-metal working machinery, the V. & O. Press Co., Glendale, L. I., has added to its plant a one-story saw-tooth building of mill construction. The addition will more than double the capacity of the plant and will be in full operation by March 1.

PERSONALS

Maurice Stanley, for sometime past in charge of the foreign department of the Russell & Erwin Co., New Britain, Conn., has become secretary of the Fafnir Bearing Co.

R. S. Coe has been appointed assistant manager of the Norton Company's publicity department. Mr. Coe was formerly advertising manager of Landers, Frary & Clark, New Britain, Conn.

Frederick A. Robinson, Jr., has been appointed assistant manager of the Becker Milling Machine Co., Hyde Park, Mass. Until recently Mr. Robinson was associated with the Pennsylvania Steel Co.

Charles E. Thomas, who some years ago was general manager and treasurer of the Cleveland Punch and Shear Works Co., has joined the sales organization of the Hilles & Jones Co., Wilmington, Del.

Walter Knapp, formerly superintendent of the Lea-Courtenay Co., Newark, N. J., has become connected with the Fore River Shipbuilding Corp., Quincy, Mass., where he will be in charge of the brass machine-shop division.

E. L. Cushman, president of the Cushman Chuck Co., Hartford, Conn., has assumed the treasurership of the company, succeeding Richard Cushman in that capacity, who has resigned to devote his time to outside interests. Charles G. H. Schomacher has become assistant treasurer.

J. E. MacArthur, who was recently superintendent of the Robinson Fire Apparatus Mfg. Co., St. Louis, Mo., and formerly connected with the Pierce-Arrow Co., and the Brown & Sharpe Co., has accepted the position of superintendent of the No. 1 plant of the Russell Motor Car Co., Toronto, Can.

OBITUARY

V. P. Buck, president, Shawmut Machinery Co., Boston, Mass., died in that city on Feb. 15.

J. S. Peacock, president of the Carbon Steel Casting Co., Lancaster, Penn., died in Miami, Fla., on Feb. 15.

John W. Hill, mechanical engineer and sales manager in charge of the Detroit Office of the Bantam Anti-Friction Co., died suddenly in that cley on Feb. 12.

Thomas J. Moore, for the past eight years sales manager of the Philadelphia branch of the Halcomb Steel Company, died at Atlantic City on Feb. 6, after a brief illness.

FORTHCOMING MEETINGS

A course of free lectures on military engineering will be given under the auspices of a committee representative of the four national engineering societies, by Captains Robins, Colner and Ardery, Corps of Engineers, U. S. A. This course will be under the direction of Major-Gen. Leonard Wood and is designed to assist those who desire to enter the engineering battalion which will be formed at Plattsburg next summer. All engineers interested in preparedness will be welcome, but attendance at these lectures does not imply obligation to subsequent camp duty. Through the cordial attitude and coöperation of the United Engineering Society, the auditorium of the Engineering Societies Building has been placed at the disposal of the army officers. These lectures will be given weekly, having begun on Feb. 14, under the following divisions:

March 6, 1916—Seacoast defenses and battlefield illuminations.

March 13, 1916—The construction, maintenance and repair of roads, bridges and ferries; the selection and preparation of fords.

March 20, 1916—The selection, laying out and preparation of camps and cantonments; the service of general construction; and the special services, including all public work of an engineering nature which may be required in a territory under military control.

March 27, 1916—The construction, operation and maintenance of railways under military control and the construction and operation of armored trains.

American Society of Mechanical Engineers. Monthly meeting first Tuesday. Calvin W. Rice, secretary, 29 West Thirty-ninth St., New York City.

American Society for Testing Materials. Annual meeting June 27 to July 1, 1916, Hotel Traymore, Atlantic City, N. J. Edgar Warburg, secretary, University of Pennsylvania, Philadelphia, Penn.

Prices--Materials and Supplies

IRON AND STEEL

Pig Iron—Quotations were current as follows at the points and dates indicated:

	Feb. 25, 1916	Jan. 28, 1916	Feb. 19, 1915
No. 2 Southern foundry, Birmingham	$15.00	$15.00	$9.50
No. 2 X Northern foundry, New York	19.75	19.75	14.25
No. 2 Northern foundry, Chicago	18.50	18.50	13.00

Basic, Eastern Pennsylvania	19.50	19.50	13.50
Gray forge, Pittsburgh	18.45	18.45	13.45

Steel Shapes—The following base prices in cents per pound are for angles 3 in. by 1/4 in. and larger and tees 3 in. and larger from jobbers' warehouse, New York:

	Feb. 25, 1916	Jan. 28, 1916	Feb. 19, 1915
Steel angles, base	2.95	2.60	1.85
Steel T's, base	3.00	2.65	1.90
Machinery steel (bessemer)	2.95	2.60	1.80

Steel Sheets—The following are the prices in cents per pound from jobbers' warehouse, New York:

	Feb. 25, 1916	Jan. 28, 1916	Feb. 19, 1915
No. 28 black	3.50	3.50	2.60
No. 26 black	3.40	3.40	2.50
Nos. 22 and 24 black	3.35	3.35	2.45
Nos. 18 and 20 black	3.30	3.30	2.40
No. 16 black	3.75	3.45	2.35
No. 14 blue annealed	3.70	3.35	2.25
No. 12 blue annealed	3.65	3.30	2.20
No. 28 galvanized	5.65	5.50	3.75
No. 26 galvanized	5.35	5.20	3.45
No. 24 galvanized	5.20	5.05	3.30

Standard Pipe—On carload lots f.o.b. Pittsburgh, the discounts follow:

	Black		Galvanized	
	Feb. 25, 1916	Feb. 25, 1915	Feb. 25, 1916	Feb. 25, 1915
3/4- to 2-in. steel butt welded	75%	81%	59 1/2%	72 1/2%
2 1/2- to 6-in. steel lap welded	74%	80%	58 1/2%	72 1/2%

At these discounts, the net prices in cents per ft. follow:

Diameter, In.				
3/4	2.88	2.20	4.66	3.15
1	4.25	3.24	6.89	4.67
1 1/4	5.75	4.38	9.32	6.30
1 1/2	6.88	5.25	11.14	7.55
2	9.25	7.05	14.99	10.15
2 1/2	15.21	11.70	24.28	16.70
3	19.89	15.25	31.75	21.80
4	28.34	21.80	45.24	31.00
5	38.48	29.60	61.42	42.20
6	49.92	38.40	79.68	54.60

Swedish Steel Sheets—To consumers requiring fair-size quantities tool steel sheets sell at 16c. base and spring steel sheets at 12c. base. These prices are f.o.b. warehouse, New York.

Swedish (Norway) Iron—This material sells at $4.50 base per 100 lb. f.o.b. New York. In coils an advance of 50c. is charged.

Swedish Drill Steel—The following prices are base in cents per pound to consumers f.o.b. warehouse, New York:

Carload lots and over	6.50
Over 10 tons, less than carload	7.00
Over 1 ton, less than 10	7.50
Over 500 lb., less than 1 ton	8.00
Less than 500 lb.	8.50
Hollow steel—	
Carload lots and over	10.50
Over 10 tons, less than carload	11.00
Over 1 ton, less than 10	12.00
Over 500 lb., less than 1 ton	13.00
Less than 500 lb.	14.00

Bar Iron—Prices are as follows in cents per pound at the places named:

	Feb. 25, 1916	Jan. 28, 1916
Pittsburgh, mill	2.20@2.30	2.10
New York	2.45	2.20@2.25
From New York	2.60	2.50@2.60

Cold Drawn Steel Shafting—From New York warehouse to consumers requiring fair-sized lots the price is 10% off list.

METALS

Miscellaneous Metals—The present New York quotations in cents per pound, with a comparison of practically a month and year ago, are as follows:

	Feb. 25, 1916	Jan. 28, 1916	Feb. 19, 1915
Copper, electrolytic (carload lots)	27.25*	25.50	14.75
Tin	44.00	41.75	36.25
Lead	6.30	6.10	3.85
Spelter	21.65	19.50	8.75
Copper sheets, base	35.00	31.00	19.75
Copper wire (carload lots)	35.00	31.00	15.50
Brass rods, base	37.00	37.00	16.50
Brass pipe, base	41.00	42.00	17.50
Brass sheets	37.00	37.00	16.75

The Algoma Steel Corporation has awarded the contract for the construction of a plant at Sault Ste. Marie, Ont. Estimated cost, $50,000.

John Pirson, Stevensville, Ont., is in the market for tight barrel machinery, drum saw, 36-in. stave joiner, etc.

The contract has been awarded for the construction of a plant at Windsor, Ont., for the Maxwell Motor Co., Detroit, Mich. Estimated cost, $45,000. Noted Feb. 24.

The Ford Motor Co. will construct 4-story, 130x200-ft. assembling plant at 8th St., W., and 11th St., Calgary, Alta. Estimated cost, $200,000.

The contract has been awarded for the construction of a plant at North Vancouver, B. C., for the Drydock and Engineering Co., Ltd. Estimated cost, $5,500,000.

GENERAL MANUFACTURING

NEW ENGLAND STATES

A dynamite plant is being constructed near the Westbrook line, South Gorham, Maine (Gorham post office), by T. M. Block.

Plans are being prepared for the construction of a 4-story, 45x150-ft. factory at Manchester, N. H., for Willar H. Griffen Shoe Co. Estimated cost, $30,000.

Fire, Feb. 14 destroyed the barrel factory of Proctor Bros. at Rochester, N. H. Loss, $45,000.

Fire, Feb. 12 damaged the plant of the American Linen Co. at Fall River, Mass. Loss, $18,000.

Plans have been prepared for the construction of a 1- and 2-story, 30x200-ft. addition to the plant of the Falulah Paper Co. at Fitchburg, Mass.

The contract has been awarded for the construction of a 4-story, 72x159-ft. addition to the plant of the Converse Rubber Co., Pearl St., Malden, Mass. Estimated cost, $100,000. Noted Feb. 17.

Bids will soon be received for the construction of a 2-story, 60x160-ft. mill on Prairie Ave., Pawtucket, R. I., for the Railroad Island Textile Co.

Plans are being prepared for the construction of an addition to the plant of the Central Worsted Co., at Central Village, Conn.

Plans are being prepared for the construction of an addition to the plant of the Morley Button Co. at New Haven, Conn. Estimated cost, $100,000.

MIDDLE ATLANTIC STATES

The Clifton Manufacturing Co., Buffalo, N. Y., manufacturer of electric tape and rubber heels, will build an addition to its plant for the manufacture of metal tubes and conduit.

Plans are being prepared for the construction of a 4-story, 24x146-ft. factory at Buffalo, N. Y., for the Mentholatum Co. Estimated cost, $15,000.

The Stephen Jerry Co., 436 Manhattan Ave., New York, N. Y. (Borough of Brooklyn), will construct a 2-story, 50x 100-ft. cooperage shop at Parker St. and Vandervoort Ave., (Borough of Brooklyn). Estimated cost, $5,000.

The Avalon Knitwear Co., Broad St., Utica, N. Y., has awarded the contract for a 4-story addition to its plant. Estimated cost, $30,000. Noted Feb. 10.

Fire, Feb. 10, damaged the chemical plant of the Midvale Chemical Co., Elizabeth, N. J. Loss, $25,000. Stephen S. Krayer is Supt.

Plans are being prepared for an addition to the plant of the Grasselli Chemical Co., Grasselli, N. J. Estimated cost, $75,000.

The Henbert Silk Co. and the Harrison Textile Co., Harrison, N. J., will construct a plant on Elm St., Kearney, N. J.

The Aryl Chemical Co., New York, N. Y., has purchased the plant of the American Chemical Co., Keyport, N. J., and will expend about $60,000 for improving same and installing new machinery.

Plans have been prepared for the construction of a 1-story brick factory on Berlin St., Newark, N. J., for Frank Euler, manufacturer of paper specialties.

The Martin Dennis Co., manufacturer of tanners supplies, will construct a plant at Newark, N. J. Estimated cost, $75,-000.

Plans have been prepared for the construction of a 50x 75-ft. factory at Newark, N. J., for Levy & Charlon, 675 South 10th St., manufacturer of woolen goods. Estimated cost, $5,000.

Maas & Waldstein, manufacturer of chemicals, Ave. R and Central R.R., Newark, N. J., is building an addition to its plant to be used as an acid concentration plant. Noted Sept. 30.

The Howe Rubber Co. will construct an addition to its plant at New Brunswick, N. J. John Tenney, Jr., is Pres. Noted Feb. 24.

The German Artistic Weaving Co., Paterson, N. J., will construct an addition to its plant at Pompton Lakes, N. J., for the manufacture of silk ribbons, labels and shoe lacings.

The Jericho Silk Co., Phillipsburg, N. J., recently organized, has acquired the property of the Mauchline-Firth Silk Co. and will enlarge the plant and install new machinery.

The William F. Taubel Hosiery Co., Trenton, N. J., will rebuild its plant which was recently destroyed by fire at Chestnut and Grand St., Trenton.

The C. H. Masland & Co., Philadelphia, Penn., manufacturer of carpets, has awarded the contract for its 4-story manufacturing building at Westmoreland and Collins St., Philadelphia. Estimated cost, $24,000.

The Philadelphia Textile Co., Philadelphia, Penn., has awarded the contract for a new factory at 6th and Tabor Rd. Day & Zimmerman, Philadelphia, is Engr.

Bids will soon be received for the construction of a 1-story, 50x50-ft. and 50x200-ft. welt factory for the Eberly Tannery Co. at Westfield, Penn. Estimated cost, $30,000. Noted Nov. 18.

The Duplan Silk Co., Wilkes-Barre, Penn., will construct a factory at Philadelphia for the manufacture of piece dyed silk and mixed goods.

The Mutual Manifold Co., Baltimore, Md., recently organized with a capital stock of $100,000, plans to construct a factory for the manufacture of sales books. Charles F. Macklin, 408 Maryland Trust Bldg., Baltimore, is Pres.

Plans being prepared by George F. Sansbury for an addition to the plant of the Parker Hosiery Mill, Frostburg, Md.

SOUTHERN STATES

H. W. Kirby, Williamson, and associates contemplates constructing a 2-story hosiery mill at Spartanburg, S. C. Estimated cost, $50,000.

L. H. Oden, Blackshear, Ga., is interested in a project to construct a cold-storage plant.

Plans are being prepared by Westinghouse-Church-Kerr Co., Arch., 30 Church St., New York, N. Y., for the construction of a refinery at Savannah, Ga., for the Savannah Refining Co. Estimated cost, $50,000.

A cottonseed oil mill will be constructed at Douglas, Ga.

The Newport Rosin and Turpentine Co., Pensacola, Fla., has awarded the contract for its new turpentine and oil distillation plant. Estimated cost, $250,000.

Asher P. Gluck, Chicago, Ill., plans to establish a canning plant at Lawtey, Fla.

The Florida Packing and Provision Co., Tampa, Fla., is having plans prepared for a plant.

A. P. Fuquay, Secy., Alexander City Commercial Club, Alexander City, Ala., is interested in a project to establish a factory at Alexander City for the manufacture of corn brooms.

J. Sanders Gordon of the North American Fire Works Display Co., St. Louis, Mo., is interested in a project to construct a plant at Birmingham, Ala., for the manufacture of fireworks.

The Linde Air Products Co., New York, N. Y., will build a plant at Birmingham, Ala., for the manufacture of oxygen gas.

The Gadsden Fertilizer Co., Gadsden, Ala., will build a cotton gin.

George Terry & Son, Biloxi, Miss., will build a cannery. Estimated cost, $10,000.

The Granada Cotton Compress Co., Falls Bldg., Memphis, Tenn., will rebuild its plant at Holly Springs, Miss., and will install new equipment.

The Independent Compress and Warehouse Co., Tupelo, Miss., has increased its capital stock and plans to rebuild its cotton compress. H. H. Womble is Pres.

R. B. Embree, Philadelphia, Penn., plans to construct a large paper-making plant at Kingsport, Tenn.

R. W. White and A. B. du Pont, New York, N. Y., plan to construct a chlorine plant at Kingsport, Tenn.

G. H. Miller, Chattanooga, Tenn., will establish a hosiery mill at Spring City, Tenn. Estimated cost, $50,000.

The Business Men's Club of Memphis, Tenn., has appointed H. W. Benner as chairman of a committee to arrange for the financing and construction of a cotton mill at Memphis. Estimated cost, $500,000.

MIDDLE WEST

The Barrett Manufacturing Co., 17 Battery Pl., New York, N. Y., manufacturer of coal tar products, will establish a 200x400-ft. plant in Ironville, Ohio (Toledo post office).

The Gerke Chemical Co. plans to construct a factory at Marietta, Ohio. Robert H. Gerke is Gen. Mgr.

The Lindley Box Co. will construct a factory at Marion, Ind.

The Mandel Bros. Manufacturing Co., manufacturer of phonographs, cameras, etc., will establish a plant at Benton Harbor, Mich.

The Dryden Rubber Co. purchased a site at Chicago, Ill., and will construct a factory in the spring.

A 1-story, 120x200-ft. building is being constructed at 57th Ave. and 65th St., Chicago, Ill., and will be leased by the Hydro-Stone Products Co.

The Appleton Wood Products Co., manufacturer of butchers' blocks, contemplates constructing a 1-story, 40x200-ft. factory at Appleton, Wis. R. Miller, 428 John St., Appleton, is Pres.

The Fox River Valley Envelope Co. contemplates the construction of a 3-story, 48x250-ft. factory at Menasha, Wis. Thomas J. Taylor is Pres.

WEST OF THE MISSISSIPPI

The Marshall Oil Co., Marshalltown, Iowa, will soon award contract for improving its plant. Estimated cost, $20,000.

The Farmers Terminal Packing Co., St. Paul, Minn., will build a packing plant at Newport, Minn. Estimated cost, $400,000.

The American Manufacturing Co., St. Louis, Mo., will build a 1-story factory at 1026 South 11th St., St. Louis, for the manufacture of bagging and cordage. Estimated cost, $11,500.

Plans being prepared for 4-story addition to the plant of the Krey Packing Co., St. Louis, Mo. Estimated cost, $150,000. Noted Feb. 10.

F. H. Mitchell, Fordyce, Ark., will build a factory at Benton, Ark., for the manufacture of handles.

The Phillips County Farmers' Exchange is interested in a plan to organize the company with a capital stock of $50,000 to construct a cotton compress at Helena, Ark.

The Texas City Compress and Concentration Co., Texas City, Tex., has been organized with a capital of $30,000 to build and operate a cotton compress. J. H. W. Steele is interested.

The Bohnefeld Cleaning Works, Tulsa, Okla., has awarded the contract for a 3-story factory at Tulsa.

WESTERN STATES

F. S. Brandon, Medford, Ore., has purchased the grist milling plant at Eagle Point, Ore., and will install new machinery.

Fire recently damaged the glove factory of Liebreich & Gold, 1321 Kelley St., Portland, Ore. Loss, $8,000.

CANADA

The Bird Woolen Co. is constructing an addition to its factory at Bracenbridge, Ont., and will be in the market for new machinery.

Edwards & Edwards, 762 Dupont St., Toronto, Ont., has leased a building at Bridgeburg, Ont., and will equip it for the manufacture of leather goods.

Fire, Feb. 13 destroyed the plant of the Northumberland Paper and Electric Co. at Campbellford, Ont.

The Gutta Percha and Rubber Co., Ltd., 47 Younge St., Toronto, Ont., will construct an addition to its plant on West Lodge Ave., Toronto.

Murphy, Stedman & Co., Ltd., 180 Gray's Inn Rd., Holborn, London, W. C., England, has an inquiry for machine tools both for British use and for export to countries outside as follows: 526 lathes, all sizes and types; 51 grinders, all sizes and types; 20 millers, all sizes and types; 4 sawing and cutting-off machines; 11 screw machines; 9 boring machines; 92 power hammers; 16 bar cutters; 19 punching and shearing machines; 10 gear-cutting machines; 66 drilling machines; 4 forging machines; 12 planing machines; 3 boring mills; 6 presses; 4 rifling machines; 24 shaping machines; 40 slotting machines; foundry equipment, machinery, etc.; eight 6½-in. by 6-ft. surfacing, sliding and crew-cutting lathes; ten 7½-in. by 8-ft. surfacing, sliding and screw-cutting lathes for chasing threads in 3'3, H. E. shells, at least 7-in. centers; 3 screw-cutting lathes; 45 lathes, No. 4 Warner & Swasey, or similar, chuck and bar feed, cutoff overhead chasing attachment, geared friction head; 13 No. 2 Warner & Swasey, or similar, chuck and bar feed, cutoff overhead chasing attachment, lathes, plain head; No. 1 Warner & Swasey, or similar, chuck and bar feed, cutoff overhead chasing attachment lathes, plain head; 20 capstan lathes, ¼- or ¾-in. capacity; 6 lathes, 1½-in. through wire feed, chasing arm and cross-slide; ten 2-spindle sensitive drilling machines to drill up to about ⅝-in., cheap simple type; ten 3-spindle sensitive drilling machines, to drill up to about ⅝-in., cheap simple type; 60 plain horizontal milling machines for power, table about 34x10 in., cheap and simple; 3 sensitive drilling machines to drill up to 20 mm., cheap, simple type; 3 multiple drilling machines, 3 spindles, to drill up to 20 mm., cheap, simple type; 64 milling machines, vertical, Brown & Sharpe No. 1, or alternative; 40 milling machines, vertical, Brown & Sharpe No. 2 Y or alternative; 1 planning machine, 2 tools, admit 3M 500x1M250; 1 slotting machine, 450 mm. stroke; 1 slotting machine, 450-mm. stroke, largest size available; 2 planning machines, single tool, circular motion, admit 2 m. 400 long by 1 m. 250 wide by 1 m. to 1 m. 500 high; 1 horizontal boring machine, 100 mm. through spindle, length of table capable of being used 3 m. 500; 1 radial drilling machine, drilling capacity 800 mm.; 1 vertical drilling machine, drilling capacity 25 mm.; 2 electric drilling machines, drilling capacity 15 mm., continuous current 110 volts; 30 gold-sawing machines capable of sawing up to 170 mm.; 2 center machines for 60 mm. shafts; 1 slotting machine, preferably with inclined top, 300 mm. stroke; 1 slotting machine, preferably with inclined top, 300 mm. stroke; 1 slotting machine, preferably with inclined top, with 200 mm. stroke; 2 shaping machines, 16-in. stroke; 2 purifying or filtering machines, for filtering oils after use with automatic lathes; 4 twist drill grinding machines, take drills 5 mm. to 500 mm.; 2 twist drill grinding machines, take drills 5 mm. to 80 mm.; 5 universal grinders, capacity 5 to 200 mm.; 1 grinding machine to sharpen saw teeth; 4 multiple-spindle drilling machines to drill up to 7 mm.; 4 multiple-spindle drilling machines, reversible, to drill up to 7 mm.; 9 drilling machines up to 15 mm.; 7 drilling machines, reversible, to drill up to 15 mm.; 7 drilling machines, reversible, to drill mm. in steel; 2 drilling machines to drill up to 30 mm. in steel; 2 drilling machines to drill up to 30 mm. in steel; 1 shaping machine, 10-in. to 20-in. stroke; 1 shaping machine, 20-in. to 24-in. stroke; 1,000 plumbago crucibles of an equivalent size to Morgan's D. 60; crucibles in following sizes: 150 lb., 440 lb. and 1,120 lb. capacity.

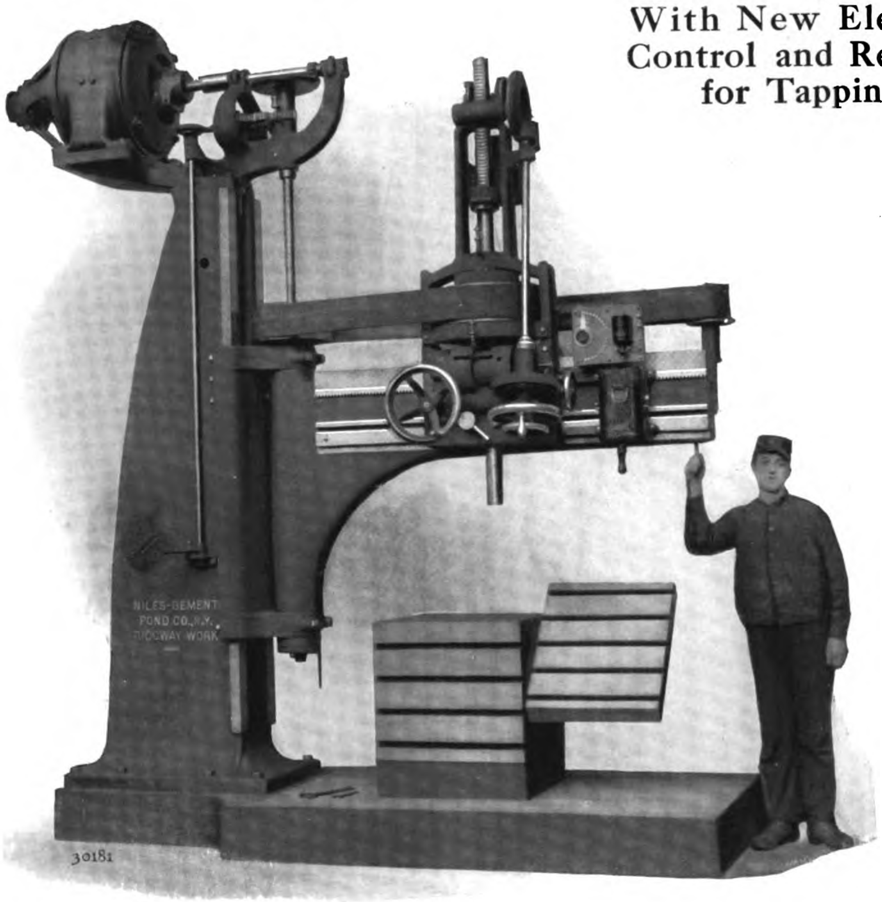
Heavy-Duty Radial Drills

With New Electric Control and Reverse for Tapping



ABOVE illustration shows one of our radials for heavy drilling. It is equipped with direct-connected reversing motor drive through 6-in. belt. Although of heavy construction throughout, it is easily and quickly handled, and the entire control is very conveniently arranged for the operator. For reversing the spindle when tapping there is provided a controller by which the motor is stopped instantly by dynamic braking and then reversed in direction. This controller, and also the rheostat for varying the speed of the motor, are attached to the drill head, where they are always within easy reach from the operator's working position.

After setting the rheostat for any given speed the controller handle can be thrown into the starting position and the motor will automatically pick up to that speed.

The arm is easily swung, as it is supported by ball bearings at both top and bottom trunnions.

This drill can be furnished in sizes ranging from 5 to 10 feet.

Write for Circular No. 30181.

"His Master's Voice"

"THE great fault with manufacturers and merchants," declared H. C. Brown, of the Victor Talking Machine Company, to a group of Camden business men on January 27, as reported in Printer's Ink, "is the fact that they are satisfied to plug along at the same rate of speed without looking to the future. If that were the policy of the Victor company we should worry ourselves to our graves."

"You here to-day," he continued, "remember the great holiday advertising of the Victor company in the newspapers and magazines. But you don't know that *we invest* $250,000 *in Christmas advertising in newspapers alone, for a product that was greatly oversold long before our advertising began.* I want to be frank, and tell you that we would not be satisfied if we did not have orders on hand sufficient to run our plant for several years without taking another order. But *we must keep this condition going,* and we succeed only by the fact that we are continuing to advertise and will continue to do so as long as newspapers and magazines are published."

Another manufacturer said:

"I would just about as soon take the fire insurance off our million-dollar plant as I would take the advertising off our million-dollar trade-mark. I am not sure which we value the most highly.

"If all my competitors would stop advertising too, if no new competitor entered the field, if nobody discovered a substitute for my product, if the trade failed to notice that I am no longer pushing the goods, and if the public would stop dying and being born and forgetting until I am ready to advertise again — everything might be lovely. But since the rest of the world is not likely to be so accommodating, there are a number of things to be taken into consideration before deciding to cut off the advertising because the factory happens to be oversold.

The effects of a discontinuance of advertising upon the trade and the sales force are the more obvious because they are more immediately apparent. But they are far from representing the most serious effects of such a policy.

The most disastrous results are not quite so apparent, perhaps, but they are all the more serious on that account. *Loss of prestige* cannot be definitely located, perhaps cannot even be detected until months, and maybe years, have elapsed, but for all that it comes pretty close to being the worst thing that can happen to a concern.

A concern which deals with the public—directly or indirectly—can as little afford to permit its trade-mark or name to be forgotten, as it can afford to let doubts be cast upon its credit."

Manufacturing 120-Millimeter Serbian Shells--I*

By Fred H. Colvin

SYNOPSIS—One of the most difficult problems for the shop manager is the economical production of pieces in comparatively small lots and in a variety of sizes. The compensation comes in the developing of ways and means to overcome the difficulties presented. These articles on the manufacture of Serbian shells show how a shop of moderate size handles shells from 70 mm. to 150 mm. in diameter and of different types, making nine different shells altogether. The methods and times are interesting as showing what can be done under adverse conditions.

The shop of the Providence Engineering Works, Providence, R. I., affords an example of the way in which a plant of moderate size can be transformed from heavy engine work to the making of shrapnel and high-explosive shells from 70 to 150 mm. in diameter. True, a portion of the shop had been accustomed to the making of the Providence shaper, while another department had made automobile parts; but even these are considerably removed from the work of turning out shells in large quantities, and the way in which regular machine equipment has been utilized has many interesting phases. The shells are all made from forgings and in four diameters—70, 75, 120 and 150 mm. They are again divided into shrapnel and high-explosive shells, while the 120- and 150-mm. sizes are also made in two lengths. All of this goes to make the manufacturing problem more difficult, but adds interest to the final solution.

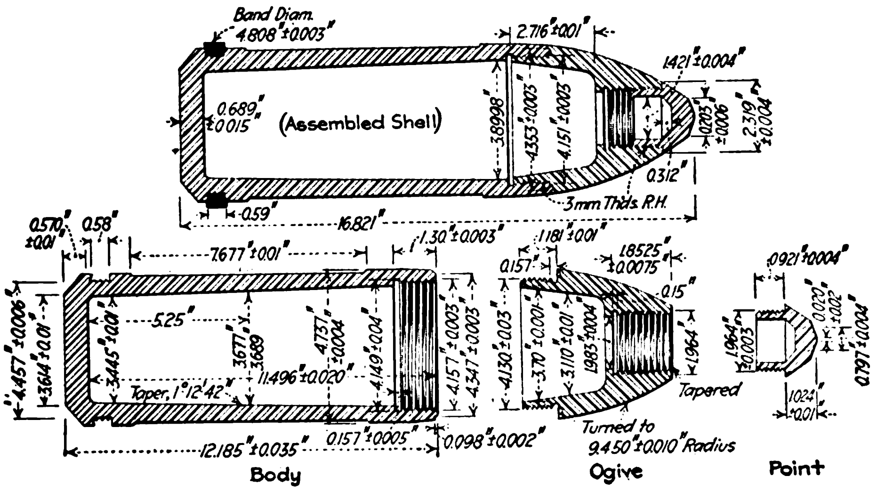

FIG. 1. SERBIAN HIGH-EXPLOSIVE 120-MM. SHORT SHELL

Taking the 120-mm. short high-explosive shell as the subject, the manufacturing operations will be followed through, and the methods used on the other sizes will be shown. Fig. 1 gives a general view of the complete shell, with the protecting point screwed in place.

The rough forgings weigh about 55 lb. and are approximately $5\frac{1}{4}$ in. in outside diameter, $3\frac{1}{4}$ in. in the bore and probably average $11\frac{1}{2}$ in. long. The first operation is cutting off the open end to length on the Espen-Lucas saw. The forgings are clamped in the holders at each side of the saw, being handled in pairs, as shown in Fig. 2. They are gaged from the bottom of the forged hole by means of simple stops, shown on the machine and also in detail in Fig. 3. There is a varying amount to be cut off, owing to the difference in the depth of the forged hole, but all operations are gaged from the bottom of the pocket. The back end of the shell is also faced off by a large milling cutter suitably spaced on the same arbor as the cutting saw, so that the face of the shell is given an approximately equal thickness in each case for all future operations.

The device for setting these shells in the cutting-off machine, as shown in Fig. 3, has several points of interest. It consists primarily of the arm *A*, which swings on a stud screwed into the bed and carries the gages *B* and *C*. These are a good sliding fit through the arm *A*, have the inner point tapered and the outer end knurled for easy handling. They also have two $\frac{3}{8}$-in. grooves, one near each end, for locking them in either the in or the out position.

This locking is done by the latch handles *D* and *E*, which are pivoted so that the weight of the hooked end will keep them in place in the notch unless they are lifted out by the other end. The latches hold them in either position, and the whole arm can be easily swung out of the way except when the blanks are being gaged for location in the machine. Next comes the centering of the back end. This operation is done in the fixture shown in Fig. 4, which is mounted on a 24-in. Snyder vertical drilling machine, that carries a centering pintle mounted on trunnions in the side of the fixture and is fitted with two sets of three centering fingers, so as to insure the hole being drilled central with the bore of the shell. This fixture is shown in two positions in Fig. 4, while Fig. 5 gives the details of its construction. The action of the centering fingers can be easily seen from the sectional view in Fig. 5, these fingers *A* and *B* being forced out by adjusting the nuts *C* and *D* on the rod *E*. The nuts carry right and left threads, and the rod *E* is easily controlled by the handwheel *F*, beneath.

In operation the shell is placed over the spindle while in the horizontal position shown. The shell is then thrown into the vertical position and locked by the index pin *G*, on the side. The handwheel *F* is turned until the locking fingers grip the bore of the shell, centering it for the drill, which comes through the bushing at the top. Details of this pintle are also shown in Fig. 5. The fingers *A* and *B* are held in a closed position.

Although it might appear that a shell of this size would be hard to handle in such a device, the trunnions are so placed that the long lever carrying the index pin makes it very easy to swing the shell from one position to the other.

Rough-Turning the Back End

The third operation brings the shell blanks to the lathe for rough-facing the back end and turning the bevel, which is considerably larger on these shells than on some others. Several old 21-in. lathes are utilized for this purpose, and also some new LeBlond lathes of the same size. The difference in production is very noticeable, varying from 2½ per hr. on the old lathe to 4 per hr. on the new. This operation removes a large amount of metal, as can be seen from the operation sheet, which, together with the time required for handling, makes up the total operations.

The shell is held on a three-jawed mandrel, or pintle *A*, these jaws being expanded by a taper draw-in plug oper-

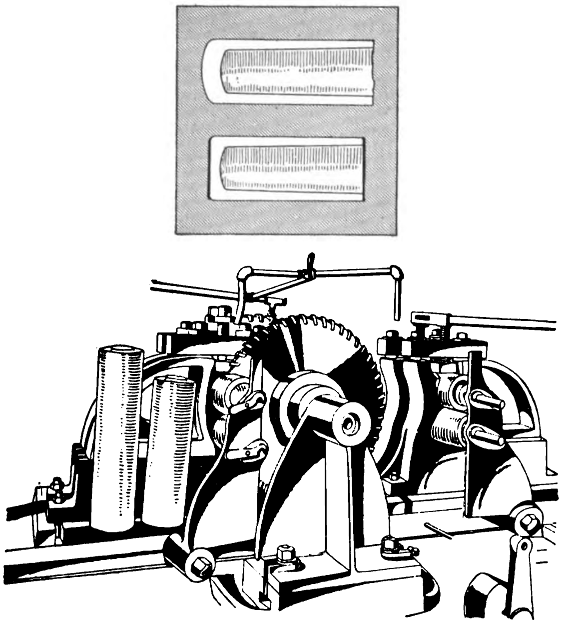

FIG. 2. OPERATION 1: CUTTING OFF END

Machine Used—Espen-Lucas.
Special Fixtures and Tools—Milling cutter face back end.
Gages—Special depth gages on machine, see Fig. 3.
Production—10 per hr.

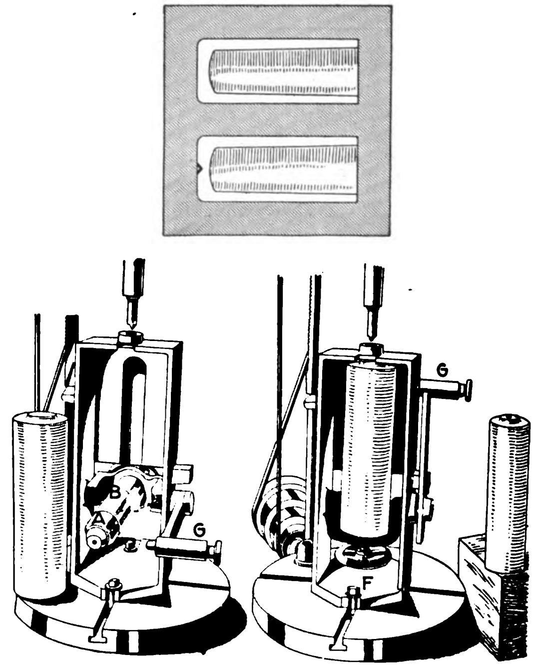

FIG. 4. OPERATION 2: CENTERING BACK END

Machine Used—Snyder 24-in. vertical drilling machine.
Special Fixtures—Swinging drill jig.
Gages—None; use stop on center drill.
Production—50 per hr.

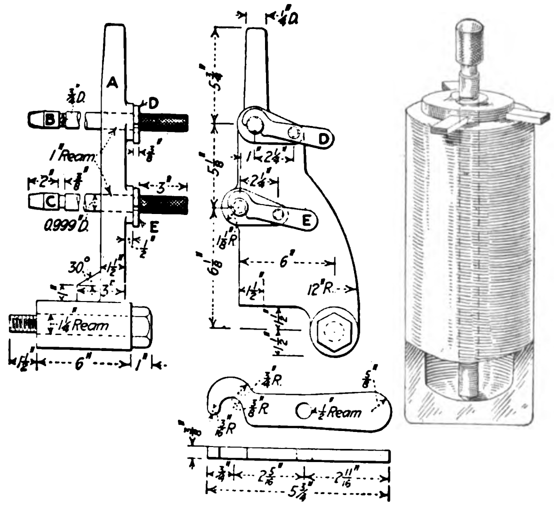

FIG. 3. DETAILS OF DEPTH STOP

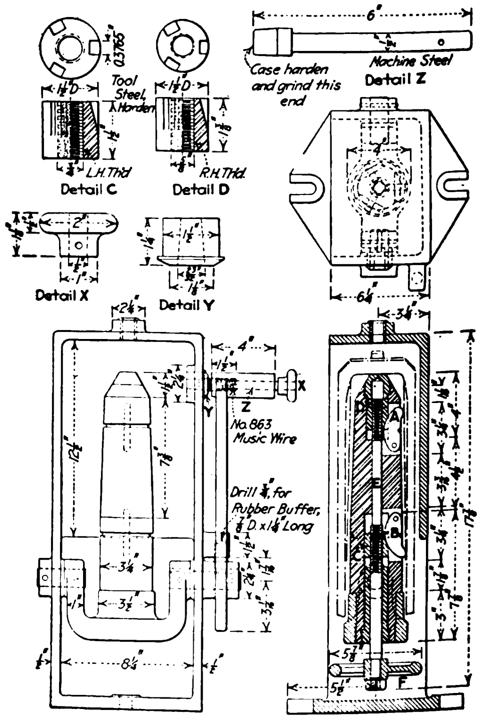

FIG. 5. DETAILS OF DRILLING JIG

ated by a handwheel on the rod that goes through the hollow spindle. The three jaws are of hardened steel and are curved on the bottom to insure even seating on the inside forged surface of the shell.

Fig. 6 gives a view of the tool layout, with the squaring tool *C* and beveling tool *D* shown in position in the turret tool post. This picture also shows how the face of the firer is set into a recess in the faceplate and is then bolted to it. Fig. 7 shows all details of the holding mechanism. It is set into the faceplate, as shown at *B*.

A similar holding device is used for the fourth operation of rough-turning the outside diameter of the shell. This work is in reality split into two suboperations, the first lathe leaving about $\frac{1}{16}$ in. to be removed by a second lathe, as this method has been found more satisfactory in maintaining the desired allowance for finishing on the last cut. No particular lathe set-up is required, except as represented in Fig. 8, the only difference between this and the layout in Fig. 6 being in the tool used. The production on the first lathe is 4 per hr.; and on the second roughing cut, a production of 8 per hr. is easily reached.

The work has now progressed to the boring of the shell, which is done in a LeBlond turret lathe equipped with a special chuck, shown in Fig. 12. The tool layout is shown in Fig. 9, while Fig. 12 gives a general view of the lathe set-up for this operation.

Details of the special chuck are shown in Fig. 10 and contain several interesting features. It consists of the cylindrical body, which is bolted to the faceplate by the flange *A* and turned on the outside at *B* to run in the steadyrest shown. The chuck carries two adjusting collars *C* and *D*. The front collar carries the split taper bushing *E*, which is forced inward by the front plate *F*, and closes on the shell by means of the saw cuts on the comparatively thin taper section. The other end of the shell is screwed up by the collar *C* forcing three equally spaced pins *F* down against the shell.

The boring tool, shown in Fig. 11 at *A*, is for rough-boring the inside of the shell and consists of a heavy steel shank carrying a ½-in. square high-speed steel cutter. This is hollow and has a brass tube that carries the lubricant direct to the cutting point. The construction of the other boring bars can be readily seen from the details and require little explanation. Another reamer is shown at *B*, carrying two long blades, that lap by each other so that each can present its cutting edge on the center line. Each also has adjusting and clamping screws.

Behind the cutter blade is the pilot bushing *A*, which is pressed forward by the helical spring *B*. This pilot enters the shell body in the space bored for the thread and assists in guiding the bar so that the whole will be reamed true to the correct taper of 1° 12′ 42″. The finishing reamers are shown at *E* and *F*, also the tool for recessing

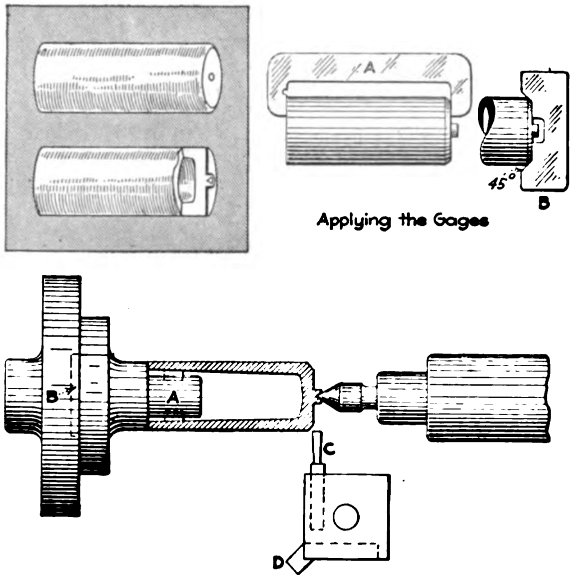

FIG. 6. OPERATION 3: FACING BACK END

Machines Used—Blaisdell and LeBlond 21-in. lathes.
Special Fixtures—Driving mandrel, multiple tool block.
Gages—Flat former A, length; B, form of bevel.
Production—2½ to 4 per hr., depending on lathe.

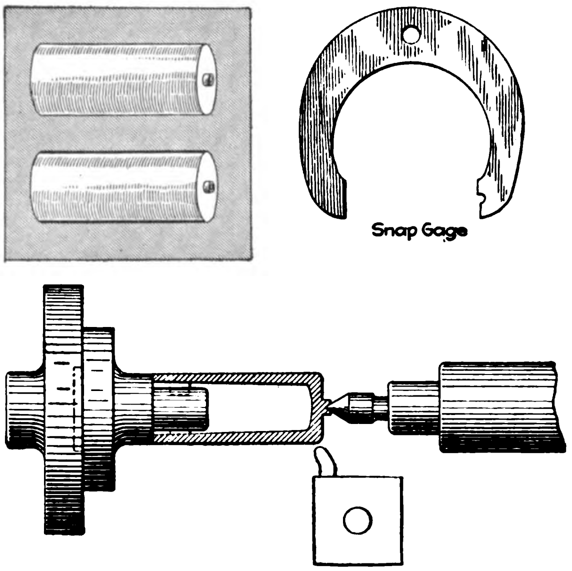

FIG. 8. OPERATION 4: ROUGH TURN

Machine Used—LeBlond 21-in. lathe.
Special Fixture—Same driving mandrel as operation 3.
Gages—A, diameter.
Production—4 per hr. first cut, 8 per hr. for second cut.

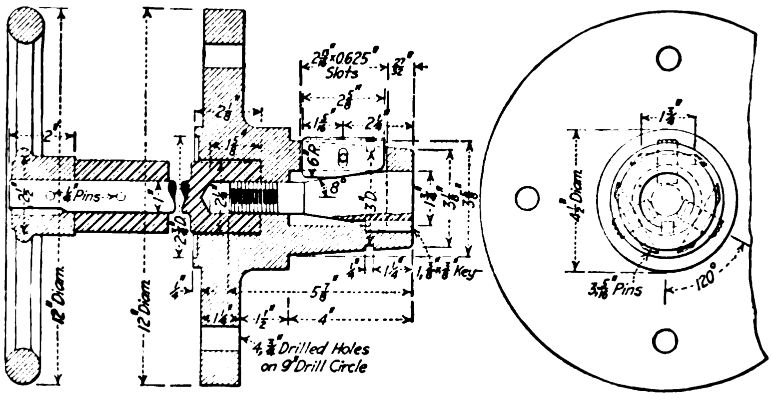

FIG. 7. DETAILS OF DRIVING MANDREL

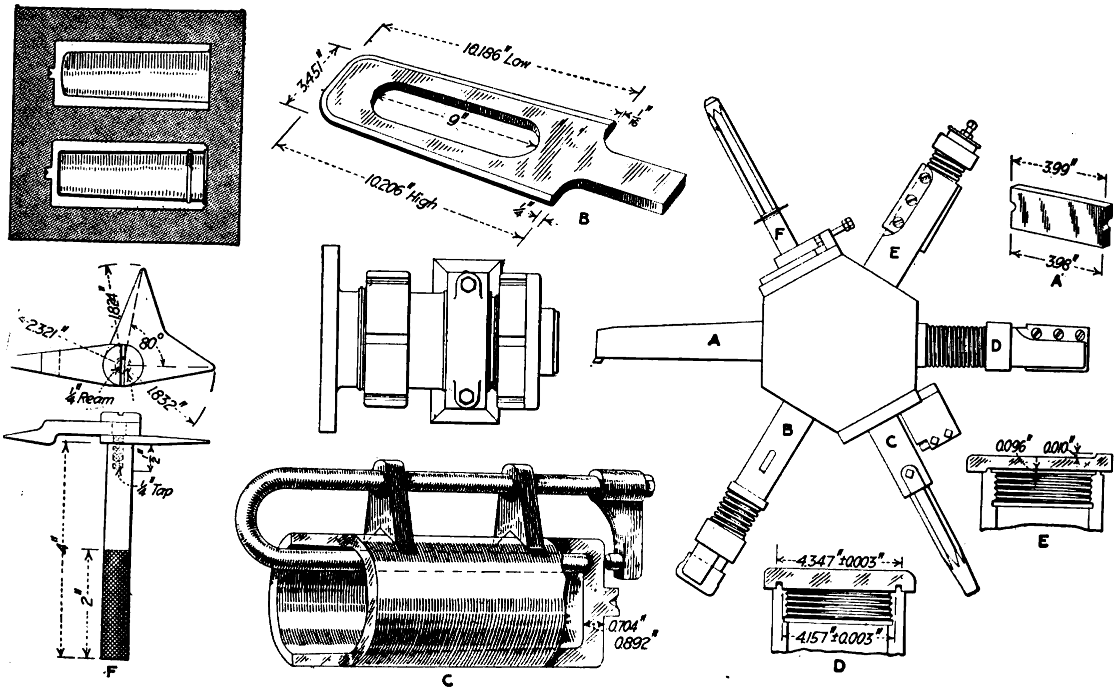

FIG. 9. OPERATION 5: BORING SHELL

Machine Used—LeBlond 21-in. turret lathe.
Special Fixtures—Stops, position index—special chuck.
Gages—A, bore for thread; B, form of bore; C, thickness of bottom; D, width of tongue; E, length of tongue; F, recess for thread.
Production—40 min. each.

at the bottom of the thread. This carries a central stud, or distance piece A, which locates the recess with reference to the bottom of the bore. The necessary side movement is obtained by means of the lever B.

Fig. 12 shows the carriage stops at C, a separate stop being provided for each turret position. A large multiplying lever A has also been added on the front of the lathe carriage to aid in quickly setting the turret central at any time. The short end of this, at the left of the capscrew B that forms the pivot, is in the form of a bell crank, having a curved surface presented to the end of the turret slide.

The upper surface of the cross-slide way is graduated so as to make it easy for the operator to bring the turret to the desired position quickly. This view also gives a good idea of the construction of some of the tools shown in Fig. 11. It shows the roughing reamers, the tool for trimming the end of the shell, and the circular recessing tool, which cuts the groove at the bottom of the thread in the shell nose.

The boring is divided into six suboperations, the first being to rough-bore by using the taper attachment at the back of the carriage, which has been fitted with a form of the proper shape. This is then released by means of a special nut, and the turret is brought to its central position by using the pointer already referred to.

The second suboperation rough-faces the bottom of the hole and rough-bores the thread diameter. The third suboperation finishes the taper at the bottom of the shell with a two-bladed reamer, shown at E in Fig. 11 and also in the turret-tool layout. The fourth suboperation finishes the taper reaming and also finishes the thread

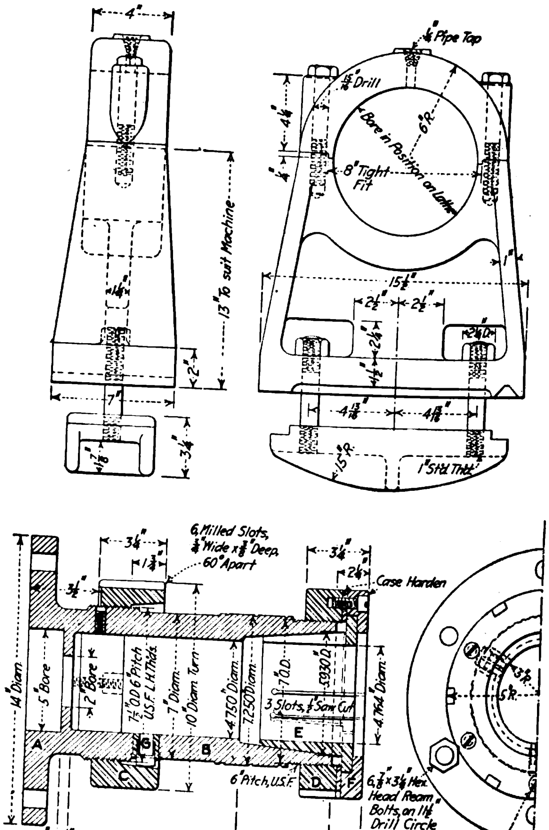

FIG. 10. DETAILS OF CHUCK AND REST

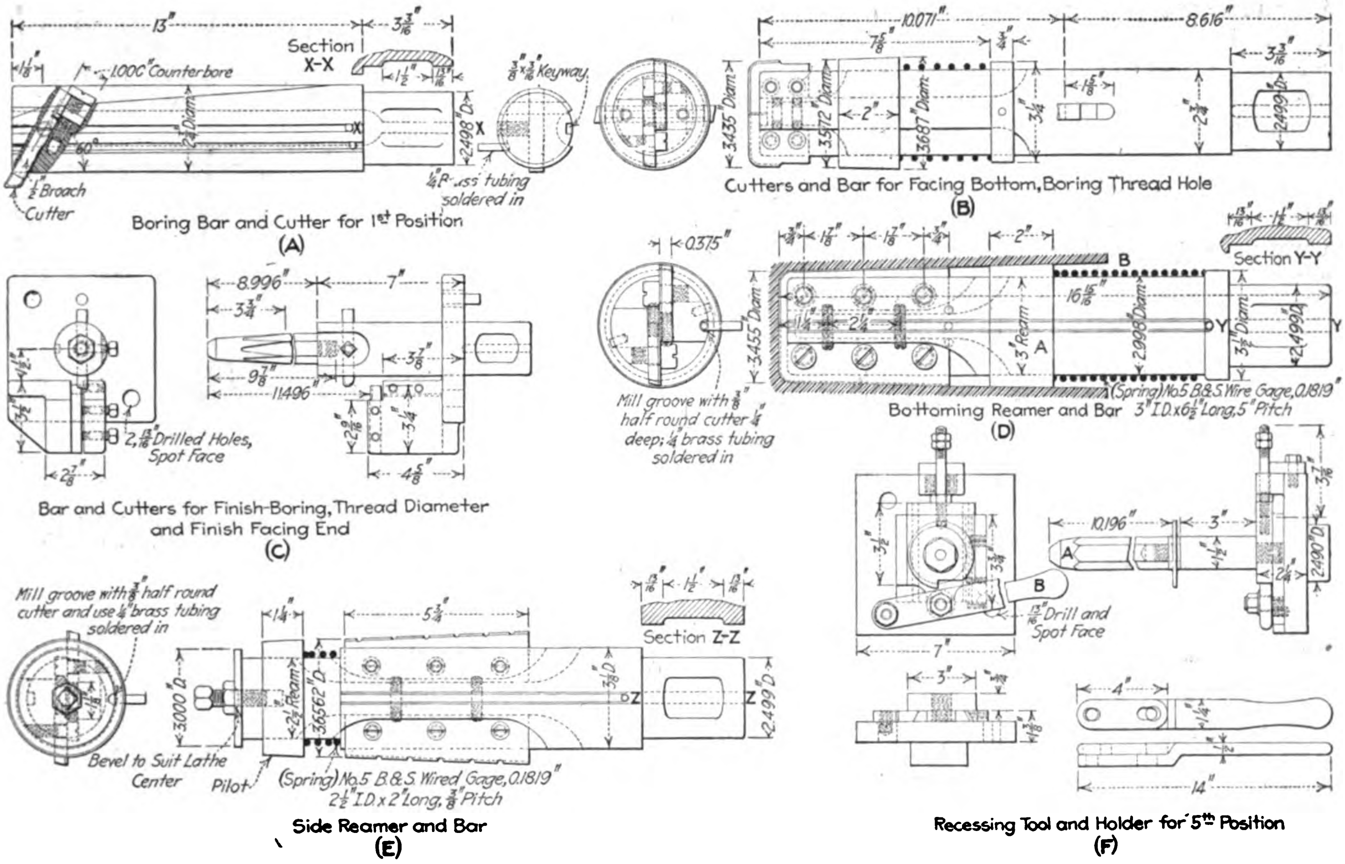

FIG. 11. DETAILS OF BORING TOOLS SHOWN IN FIG. 9

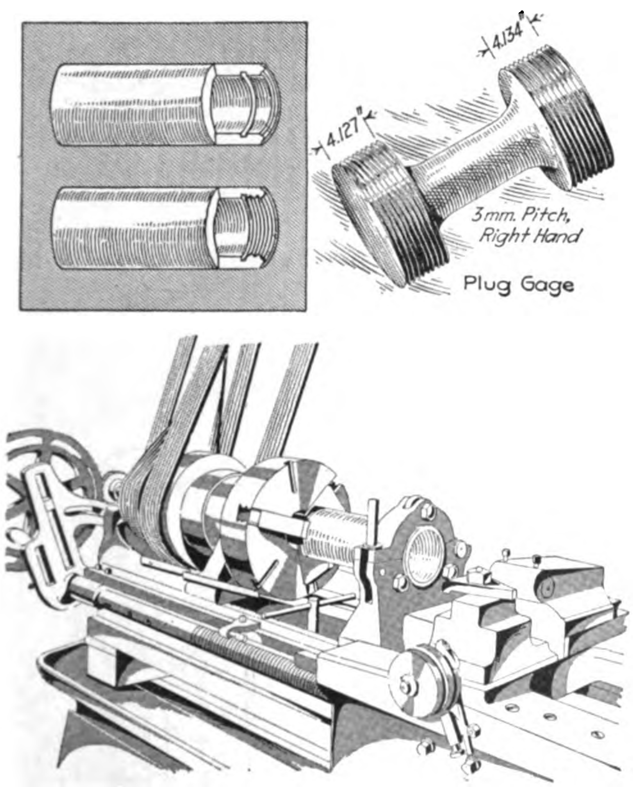

FIG. 13. OPERATION 6: THREADING NOSE OF SHELL

Machines Used—Automatic threading lathe and Lees-Bradner hobber.
Special Fixture—Roller rest; one tool only in lathe.
Gage—Threaded plug.
Production—8 per hr.

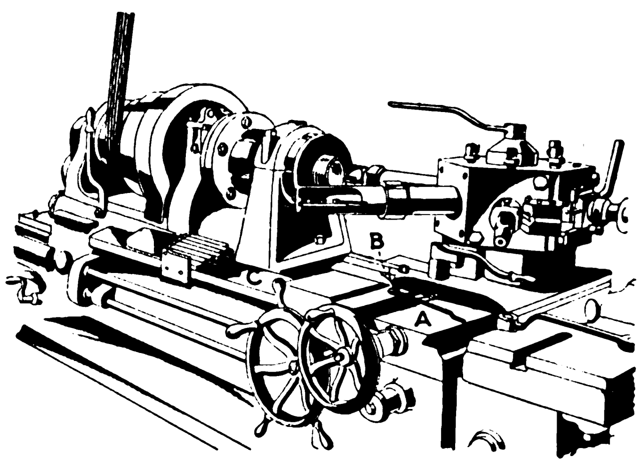

FIG. 12. THE LATHE WITH STOPS AND INDEX NEEDLE

diameter. Suboperation No. 5 takes care of the recess for the thread and chamfers the inside of the shell, while the sixth and last suboperation finishes the tongue at the outer end of the shell, completing the fifth operation in an average time of 40 min., although the operation has been done in 24 min.

After this comes a bench inspection, from which the shells go to a Lees-Bradner thread miller, to have the threads cut in the nose. Three threading lathes of the Automatic Machine Tool Co. are also used for this work, a roller rest being provided, as shown in Fig. 13. Only one threading tool is used on the work in the automatic threading lathe. The production averages 8 shells per hr.

The seventh operation is grooving and knurling, Fig. 14. The driving plug is screwed into the nose of the shell, as shown, the work being done in a 21-in. LeBlond lathe with a turret tool post. The groove is roughed out with a square-nosed tool in an Armstrong holder. The second suboperation cuts the eight small grooves, leaving seven ridges.

The third suboperation is undercutting the back side of the groove, this being done by a tool fixed at the

proper angle and fed into the bottom of the groove before cutting. By moving the carriage the desired distance to the right the undercut is easily made. This is controlled by two stops on the lathe bed, as shown, the depth of all the tools being determined by a single stop at the back of the cross-slide.

The fourth and last suboperation is the knurling, with a knurl about 2 in. in diameter and having plain, straight grooves properly spaced so that the resulting effect at the bottom of the band groove is a series of square raised points all around the groove. The use of the large knurl, mounted on a substantial ½-in. pin, makes this a comparatively easy operation.

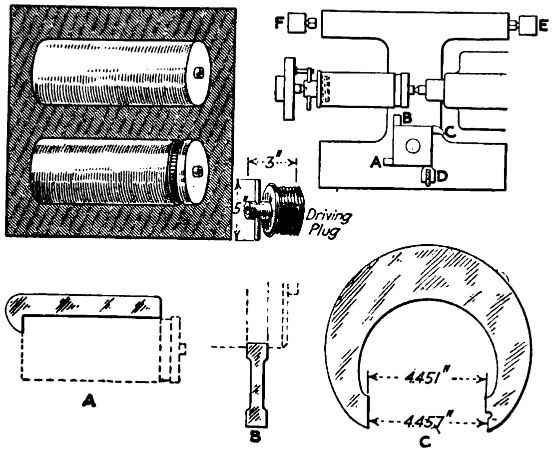

FIG. 14. OPERATION 7: GROOVING AND KNURLING

Machine Used—LeBlond 21-in. lathe.
Special Fixtures—Stops for carriage in undercutting driving plug.
Gages—A, location of groove; B, width of groove; C, diameter of groove.
Production—5 to 6 per hr.

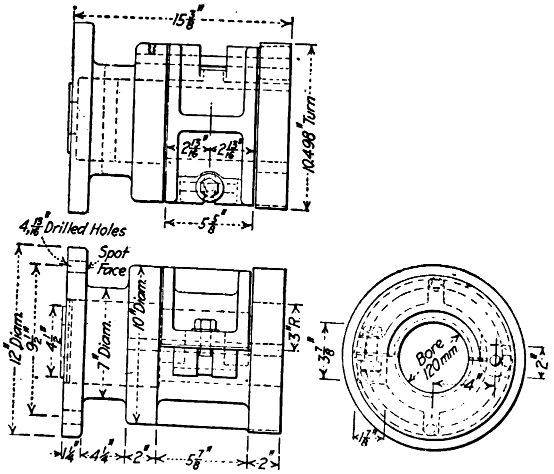

FIG. 17. DETAILS OF FLAP CHUCK

With the driving plug still in the end of the shell, it goes to the eighth operation—finish-turning in a Prentice geared head lathe. Three tools are used in a special tool post, as shown in Fig. 15. One tool turns the relief ahead of the groove, the second roughs the back end for the cartridge case, and the third finishes. This operation averages 14 min. each.

Then follows a bench inspection, after which the driving plug is unscrewed and the shells go to a lathe equipped with a flap chuck, as shown in Fig. 16, to have the back end faced off and the finish bevel put on the corner. This requires 11 min. Details of the chuck are given in Fig. 17.

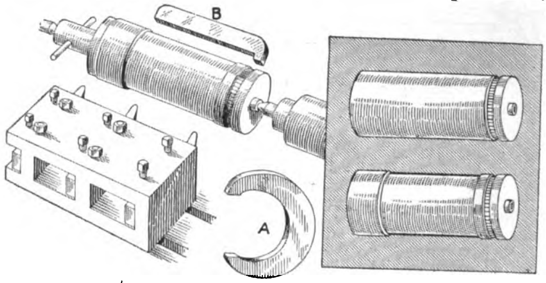

FIG. 15. OPERATION 8: FINISH TURNING

Machine Used—Prentice geared head lathe.
Special Fixtures—Driving plug and multiple tool block.
Gages—A, diameter, one for size, one for relief; B, length of relief from groove.
Production—14 min. each.

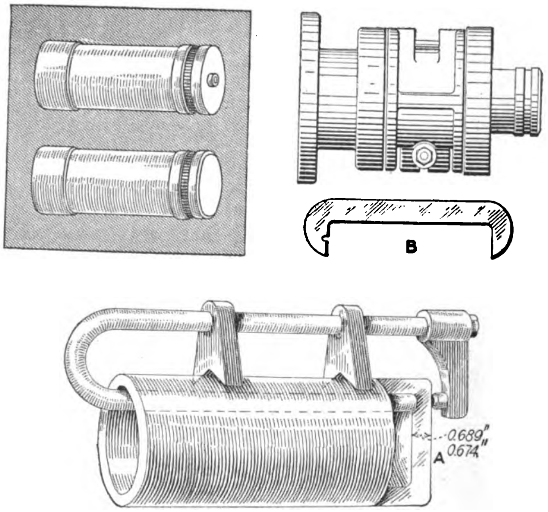

FIG. 16. OPERATION 9: FINISH BACK END

Machine Used—Le Blond 21-in. lathe.
Special Fixture—Flap jaw chuck.
Gages—A, thickness of bottom; B, length.
Production—11 min. each.

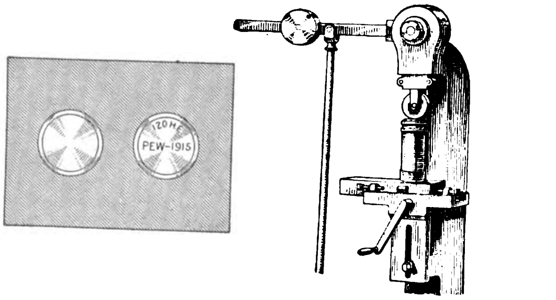

FIG. 18. OPERATION 10: MARKING BACK END

Machine Used—Noble & Westbrook.
Special Fixture—Roll stamp.
Gage—None.
Production—50 per hr.

The back end is then marked on a machine of the Dwight-Slate pattern, Fig. 18, at the rate of about 50

per hr. Then comes the Government inspection. After the stamping, the shells are cleaned in a soda tank to cut out all the grease and oil, after which they go to the inspection bench to be looked over by the Serbian

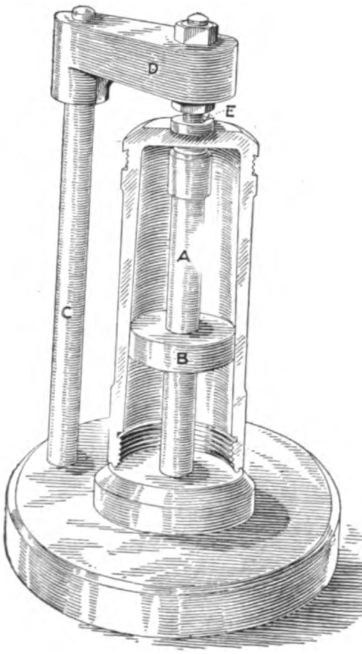

FIG. 19. BENCH INSPECTION GAGE FOR THICKNESS OF BOTTOM

Government inspectors. If satisfactory, the shells are stamped and passed for further operations.

They are now ready to have the ogives screwed in, so that these can be finished in place on the shell body. Before carrying this work through, it will probably be best to take up the manufacture of the ogives themselves.

The inspection benches are well equipped with gages and are built of the most convenient height for the

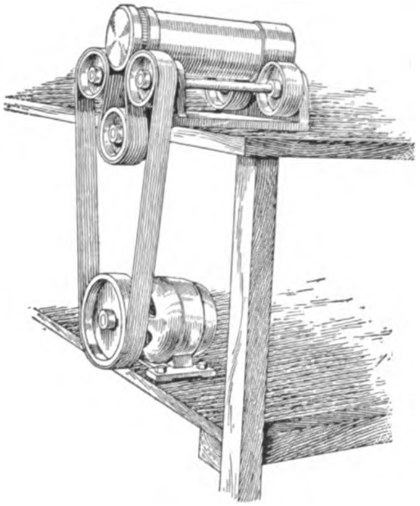

FIG. 20. RUNNING BELT FOR THREAD INSPECTION

work to be done. A gage used for testing the thickness of the back end is shown in Fig. 19. The shell is placed over the center spindle *A*, being guided by the enlarged portion *B*. The measuring upright *C* carries the head *D*, which is located by a shoulder on *C* and carries the adjustable measuring point *E*. This can be handled very rapidly and gives good results.

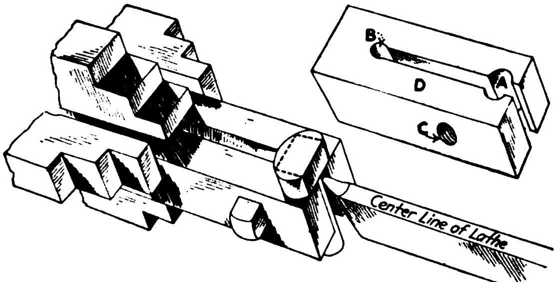
For testing the threads in the ends of shells a belt arrangement is used, as shown in Fig. 20, which saves both time and fatigue on the part of the inspector. This belt runs continuously. By laying a shell on the belt-covered pulleys it is revolved so that the plug gage need only be held still in the hand. For running the gage out, the inspector uses the gage as a handle and turns the shell end for end on the belt. In this way the rotation is reversed and the plug gage is unscrewed.

How To Square the Heads of Bolts in a Lathe

By John Hayes

A large number of extra-long $\frac{7}{16}$-in. square-head screws were to be made, and neither miller nor shaper was included in the equipment. The heads of the screws were squared in the lathe, using the little kink shown, which may of use to others up against the same proposition.

A 6-in. piece of $\frac{3}{4}$x$\frac{7}{8}$-in. cold-rolled steel was drilled $\frac{7}{16}$ in at *A* and $\frac{3}{16}$ in. at *B*. It was then slotted with the



SHOWING POSITION OF CHUCK JAWS AND POSITION OF TOOL

hacksaw, as shown; drilled for a $\frac{3}{8}$-in. screw at *C*; relieved on one side of the slot and threaded on the other, making a clamp, as shown.

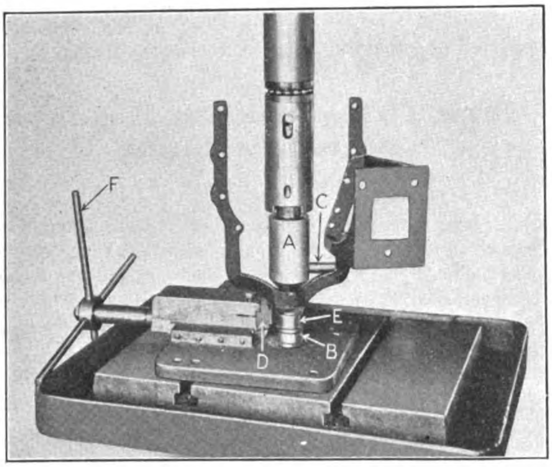
The piece was held in a four-jawed chuck, with the face *D* set at about the center. A piece of flat steel and a C-clamp on the bed of the lathe acted as a stop for the carriage. After one side was faced, the screw was turned one-quarter way around and the operation repeated. The job was done much quicker and better than it could have been done by filing or grinding.

Iron-Ore Production—In 1880 the production of iron ore was 7,000,000 long tons, as compared with 60,000,000 tons in 1913. The production of pig iron increased in the same period from less than 4,000,000 tons to more than 30,000,000 tons, the value of which in 1913 exceeded $458,000,000. The United State produces annually about 40 per cent. of the world's supply of iron, and is abundantly supplied with iron ore, yet there are excellent arguments in favor of encouraging imports of ore from Cuba and South America. Iron ore forms the basis of the largest manufacturing industry in the United States. The profits to both labor and capital are made from the manufacture and sale of iron and steel products rather than from iron-ore mining. Therefore so long as the United States can utilize the cheap ores from Latin America and export to those countries as well as to Europe the fabricated iron and steel goods there is reason to favor the continuance of these conditions.

Turning an Awkward Piece in a Drilling Machine

By E. A. Thanton

A method of doing a very awkward job is here shown. To turn the end of the casting in a lathe would have meant the making of some sort of holding fixture, more or less complicated and difficult to handle. By using a drilling machine the difficulties were greatly lessened, and a good job was the result. The work is done in the shop of the Disco Electric Starter Co., Detroit, Mich., and may suggest similar applications to other classes of products.



TURNING AN AWKWARD JOB IN A DRILLING MACHINE INSTEAD OF THE LATHE

The casting is put into a drilling jig, the holes in the "arms" drilled and also a hole drilled lengthwise of the bearing to be turned. The driver *A* has on the end a pilot that goes down through the hole in the bearing and into a bushed hole in the center of the boss *B*. A pin *C* rests against one of the arms and serves to rotate the casting as the drill spindle revolves. The cutting tool *D* is fed to the bearing *E* by turning the capstan wheel *F*. It will be noticed that the cutting tool is a formed one and set into the end of the tool slide at an angle, so that, as it dulls, the end may be ground and the tool set up again without changing any adjustments and with little trouble.

A Rapid Method of Milling Flutes in a Reamer

By C. Smith

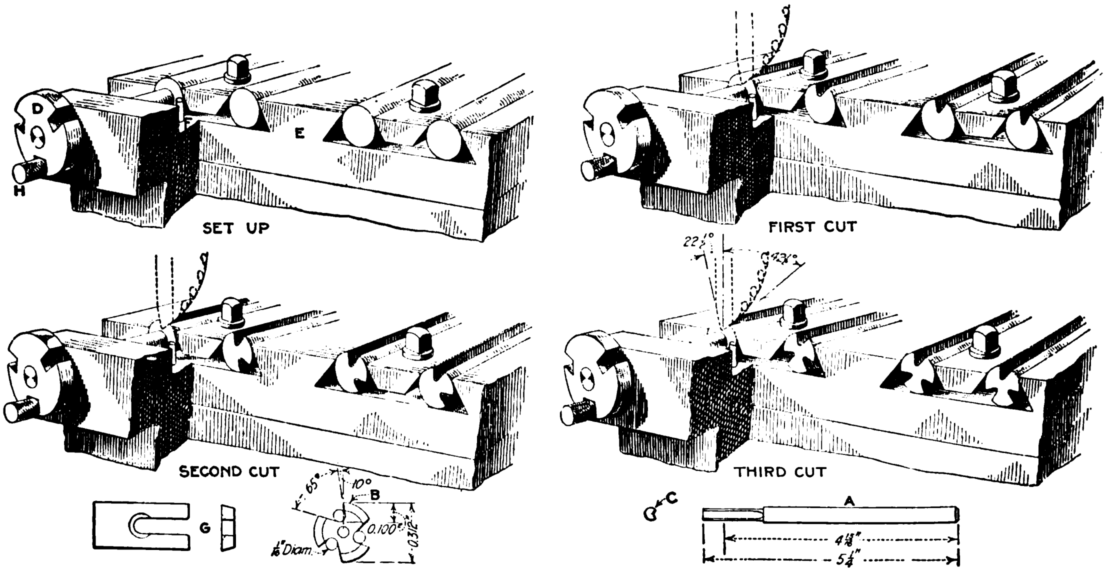
The illustration shows how flutes were milled in a barrel roughing reamer. The fixture is shown with *A* representing the reamer blank to be milled and *B* an enlarged view showing the style of flutes wanted.

The first milling operation is to take hold of the body of the reamer in a hand-miller chuck to mill the $\frac{3}{32}$-in. radius oil groove in the shank, as in the section shown at *C*. This groove acts as a locating point. The point of the screw in the index collar *D* lines up the oil groove with the first flute cut. The index collars were put on the shanks of four reamers and put into the fixture *E*, against stop pins *F*, with the index pins in the fixture, as indicated at *H*, clamped down with four screws and four straps *G* into 20-deg. angle jaws in the fixture.

The 20-deg. angles did not work well, so 5-deg. angle jaws and straps were put in and found to be a decided improvement.

Four reamers are milled at a time. After the first cut is taken, the four clamp screws are loosened and the four index pins, shown at *H*, pulled out. The index collars are rotated to the next slot in the collar, the pins put in and the second cut milled. The third cut is made in the same manner.

This method holds the reamers rigid, and they can be milled with a good stiff feed and a great deal faster than it would be possible to mill them on centers where there is very little support to avoid excessive vibration.



DETAILS OF A RAPID METHOD OF MILLING FLUTES IN REAMER

The Small-Shop Grinder

By John H. Van Deventer

SYNOPSIS—Machine grinding is not by any means restricted to large shops. It is true that the average small shop cannot afford to install a specialized machine with a small range of work for this purpose, but it should investigate the use of grinders of the universal type having a broad range. In this article the problem is attacked from the small-shop angle, and the causes and remedies of common grinding troubles are given.

The small-shop man does not ordinarily make his acquaintance with the art of grinding on what is called a "grinder." His introduction to this method of removing metal comes by way of a casting snagger, such as was described in "The Small-Shop Grinding Wheel," on page 11 of this volume. This acquaintanceship broadens out through experience with various improvised grinding devices, which are applied at various times to each machine in the shop, from the engine lathe to the planer, usually with more or less unsatisfactory results. Finally comes the ultimate achievement—the purchase of a "tool grinder"—which usually accompanies the advent of the first miller. In the majority of small shops the owner "guesses" that this is as far as it is safe to go in the installation of grinding equipment. Whether this is a good or a bad guess depends greatly on the kind of work that is being done, but I venture to say that it is a bad guess in a great many cases.

One of the wrong notions of grinding is that its object is only to obtain a fine, smooth, accurate job. In 75 per cent. of the large shops that finish work by this means the compelling object is not the fine finish so much as the reduction in cost that can be obtained over the old method of finishing by fussing with fine cuts and a file. Lathe hands will not start to file on a shaft that is left full of grooves from a roughing cut—it is too much like work. The grinder has no such notions about the matter, however, and will tackle the roughest job with the same degree of self-confidence that it displays on going over a glasslike surface. One good way to look at the grinder is as a filing and polishing machine, a device that will do the finishing much more quickly and with less need of skill than is required to manipulate the file and emery cloth.

"I don't need a grinder in my shop," says Bill Jones; "my lots are too small. I seldom have more than six like pieces going through the shop at the same time." By the same token, as the Irishman would say, Bill doesn't need a lathe or any other tool in his shop; for having such small lots, he should hog out the work with vise and cold chisel. You will find someone able to advance the most plausible objections against the use of any improvement that ever was invented, and the old

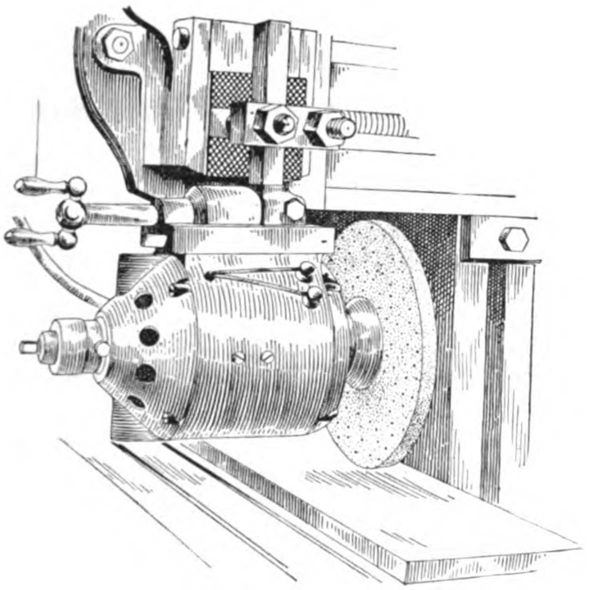


FIG. 1. SURFACE-GRINDING ATTACHMENT APPLIED TO THE PLANER

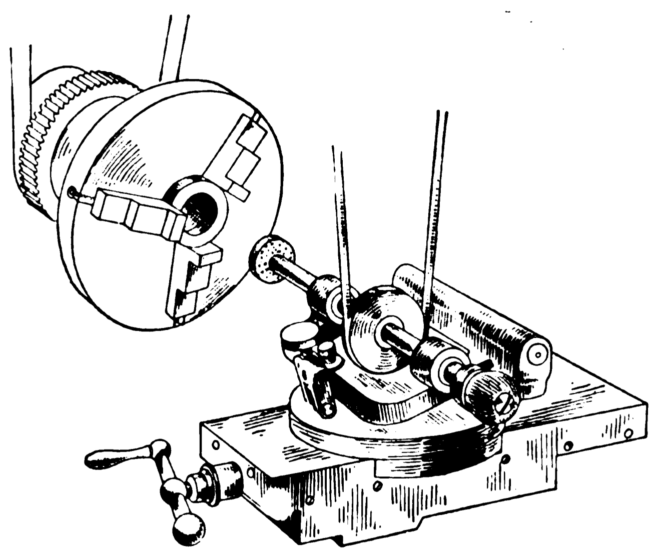

FIG. 2. TRAVERSE SPINDLE GRINDER ATTACHED TO THE ENGINE LATHE

excuse of "small lots" is a standby in the shop where progressiveness has taken a back seat in favor of precedence and habit.

It is easier to set up a grinder for an average job than to get a lathe ready for business, and the time saved even on one piece will often overbalance the setting-up time of the additional machine. Work that is similar, such as grinding shafts of various lengths, can be handled with the same set-up simply by moving the tailstock and obtaining a suitable work speed. Where there's a will there's a way; and where a way is found, nine times in ten there is profit also discovered.

The small shop that wishes to cut its eye teeth on the subject of grinding, at a minimum of expense, may do so by means of a tool-post grinder similar to that shown in Fig. 1. The advent of a small and durable electric motor makes this arrangement practical, as it dispenses with long overhead pulleys and traveling belts. An outfit of this kind will convert almost any machine tool into a grinder of sorts. In the illustration, Fig. 1, it is shown applied to a job of surface grinding, in

which a planer table is used to traverse the work and the planer head to crossfeed the wheel. Such a device cannot be expected to do the work of a machine especially designed for grinding. For one reason, the bearings are less rigid and will in time get loose; but if they are kept in first-class condition and too heavy cutting is not attempted, this tool-post grinder will answer the double purpose of grinding the lathe tools and cutting down the time otherwise wasted in walking to and from the regular tool-grinding wheel.

For a more accurate class of work the traverse-spindle grinder, shown in Fig. 2, is applied to lathes or millers with satisfactory results. The accuracy of the grinding, assuming that the fixture is in good condition, depends

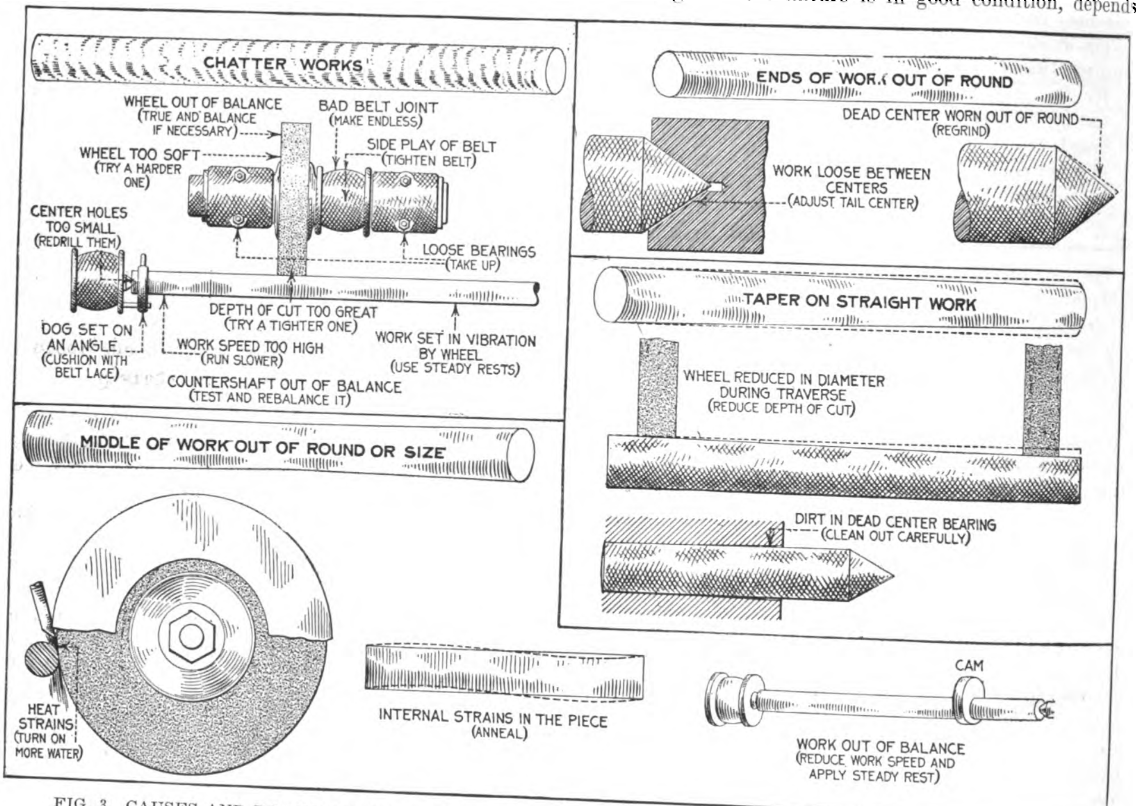

FIG. 3. CAUSES AND REMEDIES FOR MANY OF THE COMMON GRINDING TROUBLES MET IN BOTH SMALL AND LARGE SHOPS

purpose on the occasional job that cannot be handled by any other means. A grinder of this same type does excellent work in the lathe, if the precautions necessary to be followed in doing the same kind of work on a regular grinder are observed.

In many shops it is considered sufficient to stick the motor-driven grinding wheel in the tool post, put long slender work between centers and start to cut. In such cases it is usual to run the work speed well beyond the limit required for turning the same diameter, and also to use a hard close-grained wheel. When the job is finished, the boss wants to know who has been hammering at the shaft and has put in all the flat spots that are plentifully distributed over the surface of the work. A much softer wheel, a work speed one-third that required for a high-speed tool cutting on similar material and the use of back rests supporting the work from the back and from beneath on shock-absorbing wooden blocks will give quite different results.

A portable grinder of this kind can be used all around the shop. On the miller it will grind a fresh edge on cutters without removing them from the spindle; and when no other pressing use can be found, it can be bolted to the vacant end of the lathe bed and made available for solely on the truth of the headstock or miller spindle by which the piece to be ground is rotated. An outfit of the kind shown is inexpensive and will handle the most accurate work. It is driven from overhead, usually by means of a round or twisted belt, and necessitates the use of a drum pulley for this purpose, unless a small motor equipped with a driving pulley is mounted on the same slide.

One of the peculiar things about a traverse-spindle grinder that its operator must learn by experience is that the bearings are not in proper condition unless they run hot. If they do not, it is a sign that they are too loose for an accurate grinding job to be obtained. When you can rest your finger with comfort on the bearings of a contrivance of this kind, there is something the matter with it!

A grinding device of this simple and inexpensive type is suitable, not only for internal work, but also for angular and external work, since it can be swiveled about to any angle. In spite of its apparent lightness and the small dimensions of its spindle and bearings it will handle a very respectable cut in hardened steel.

The universal grinder presents itself as the next step in advance for the small-shop man who has outgrown

the use of the foregoing expedients. It is true that a machine of this kind costs considerably more than a simple tool grinder that may fill the bill for some time after its purchase. On the other hand, the range of work of a universal machine is so great that this must be taken into consideration and weighed as a part of the value received per dollar expended. A machine that costs $800 and that is capable of earning $8,000 during its life of usefulness is a much better investment than one that costs but $200 and can earn $1,000. In the case of the universal grinder you have as an asset its capability of handling commercial grinding, not as rapidly, of course, as it could be done on a plain machine of the same capacity, but fast enough to bring in a good profit. Such a machine should always be equipped for wet grinding.

This type of tool will handle not only all the grinding requirements of the small-shop tools and cutters, but also its commercial precision grinding—internal, external and angular—and a good range of commercial cylindrical and taper grinding in addition. In the average small shop it will be a long while before the demands for commercial work on a machine of this sort exceed its capacity in spare time. When such a time does arrive, it will be sufficiently soon to investigate the plain grinder as a means of handling this work.

Wet or Dry Grinding

The question of "wet or dry" is an absorbing one to the citizens of many of our states, where the matter is eventually settled by ballot. When it comes to grinding, opinion is more unanimous and is quite in favor of "wet." The use of a lubricant, or rather "coolant," on the grinder helps to make quick time and to give a smooth job, but its main purpose is to prevent the distortion that would otherwise occur, due to heating. When you consider that the chips torn from the work in grinding are raised to a temperature corresponding to the welding point of steel, the subject of temperature and the need of a cooling fluid take on a new importance. Oftentimes the water attachment is dispensed with as being a mussy contraption, a green hand finding that he needs a bathing suit more than a micrometer to help him navigate a grinder. This is all wrong and unnecessary; for if the stream is properly directed against the work, there will be absolutely no splash.

Among the things to keep in mind in operating a grinder are to use work surface speeds ranging from 25 to 35 ft. per min. whne roughing, and 25 per cent. faster for finishing. As soft a wheel as possible should be used for the job, and the traverse per revolution should be between five-eighths and seven-eighths of the wheel face, in order to prevent wearing away its edges.

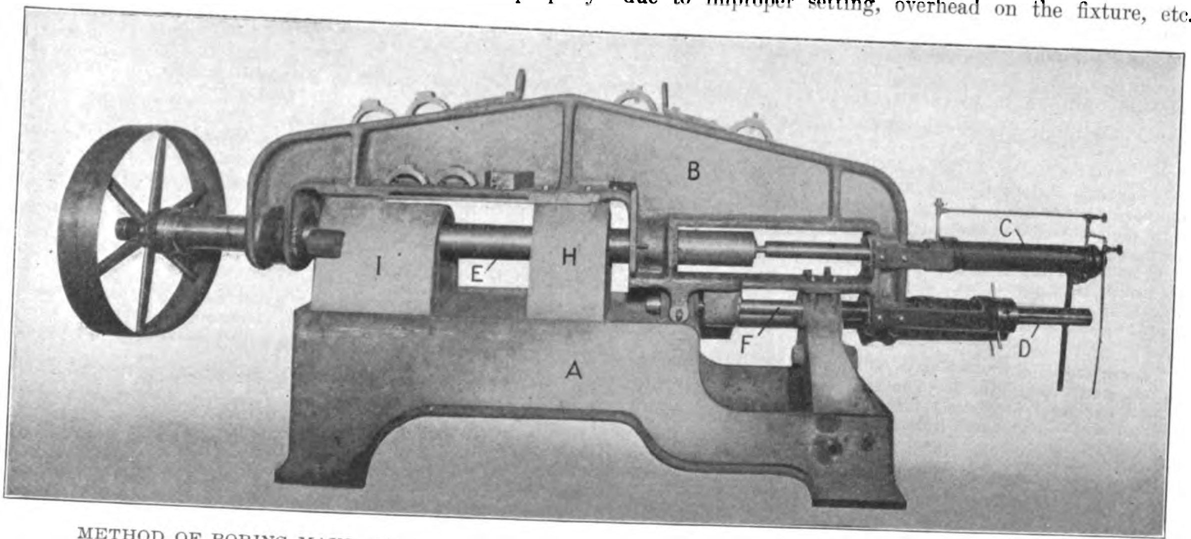
Some of the most common grinder troubles are represented in Fig. 3, which gives their causes and also the remedies to be applied in getting rid of them. They are included in this article, not to dishearten one who is contemplating the use of the grinder, but as a help for those who already have such machines. The former must remember that even in a foundry there are forty-seven ways of making a bad casting and that the comparatively few causes of trouble on grinders are really a recommendation for this type of machine.

Boring Lathe-Frame Bearings with Portable Fixture

The illustration shows a portable fixture designed and used by the Lombard Governor Co., of Ashland, Mass., for boring the spindle and turret bearings in the frame of the Warren automatic hydraulic lathe.

The frame *B* of this fixture is arranged to bolt to the frame of the lathe *A*, becoming practically a part of it. The boring bars are driven by pulleys and are fed longitudinally, as shown at *C* and *D*. The upper bar, which bores out the bearings *I* and *H*, is fed by hydraulic pressure; and the lower bar is fed by hand by means of a capstan screw. In this way the spindle and turret bearings are brought into close alignment more easily than could be accomplished on a horizontal boring machine.

This is an excellent example of the use of a large fixture, the body of the fixture being fully as long as the lathe bed. The utilization of fixtures of this size is not common, but there can be no question as to the economy of the method when the product is of sufficient volume to warrant the outlay. This is one of the problems that must be figured from many points—labor, spoiled work due to improper setting, overhead on the fixture, etc.



METHOD OF BORING MAIN AND TURRET BEARINGS OF WARREN AUTOMATIC HYDRAULIC LATHES

Machining Bearings and Bracket for a Printing Press

By Robert Mawson

SYNOPSIS—The drill jigs used in machining some of the bearings and brackets used on a printing press are here described. Owing to the fact that these elements are of a simple character, the tools designed and used are also simple. The parts produced, however, are as desired and are interchangeable and produced at a low cost in time, both as regards machining and assembling in the jig.

The two-sheet rotary printing press manufactured by the United Printing Machinery Co., Woonsocket, R. I., was described on page 58. Some of the tools, jigs and fixtures used in machining various elements used on the press were shown on pages 138, 232 and 318. Other well-designed jigs used in machining three bearings and two brackets on the press are described in this article.

When drilling the transfer and delivery cylinder the casting is placed on a turned plug, which fits into a reamed hole and is locatel by a key which sets into a cored notch of the part.

The jig used in drilling the driving shaft bearing has a novel method of locating. The bored casting is placed on the jig base fitting over a turned plug and is located by a swinging strap. Not only does this method hold the work to close limits, but it is unusually rapid.

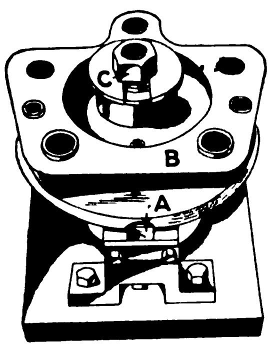


FIG 2

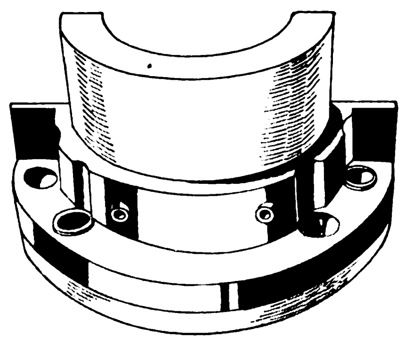

FIG 4

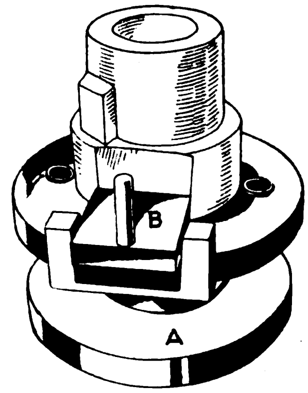

FIG 6

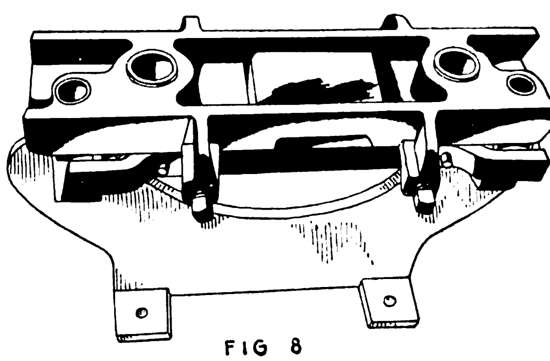

FIG 8

JIGS USED IN MACHINING PRACTICE ON TWO-SHEET ROTARY PRINTING-PRESS BEARINGS AND BRACKETS, WITH WORK SHOWN IN POSITION

FIGS. 2 AND 2-A

Operations—Drilling and reaming holes in transfer and delivery cylinder bearing, Fig. 1. The casting is placed on a 3-in. plug fitting into the machined hole and is located by the spring-operated key A. The cover B is then placed over the part and held down with the open washer and nut C.

Holes Machined—Two $\frac{3}{32}$-in. drilled, two $\frac{31}{64}$-in. drilled, two $\frac{5}{8}$-in. spot drilled and reamed, and one $\frac{1}{4}$-in. drilled.

FIGS. 4 AND 4-A

Operation—Drilling holes in upper and lower plate cylinder boxes, gear side, Fig. 3. The jig is slid over the casting, which has been previously bored, faced and turned. A pin-headed screw draws and holds the jig in position. The jig is designed so that both the upper and the lower parts may be drilled.

Holes Machined—Two $\frac{3}{32}$-in. drilled and one $\frac{1}{4}$-in. drilled.

FIGS. 6 AND 6-A

Operation—Drilling holes in driving-shaft bearing, Fig. 5. The casting, which has been previo[illegible]ored, turned and faced, is slid over the base A, made with a machined spindle to fit the bored hole in the piece. The jig is then dropped over the machined outside diameter of the piece and located with the swinging plate B.

Holes Machined—Three $\frac{13}{16}$-in. drilled. These holes are afterward tapped with $\frac{7}{8}$-in. U.S.S. threads.

FIGS. 8 AND 8-A

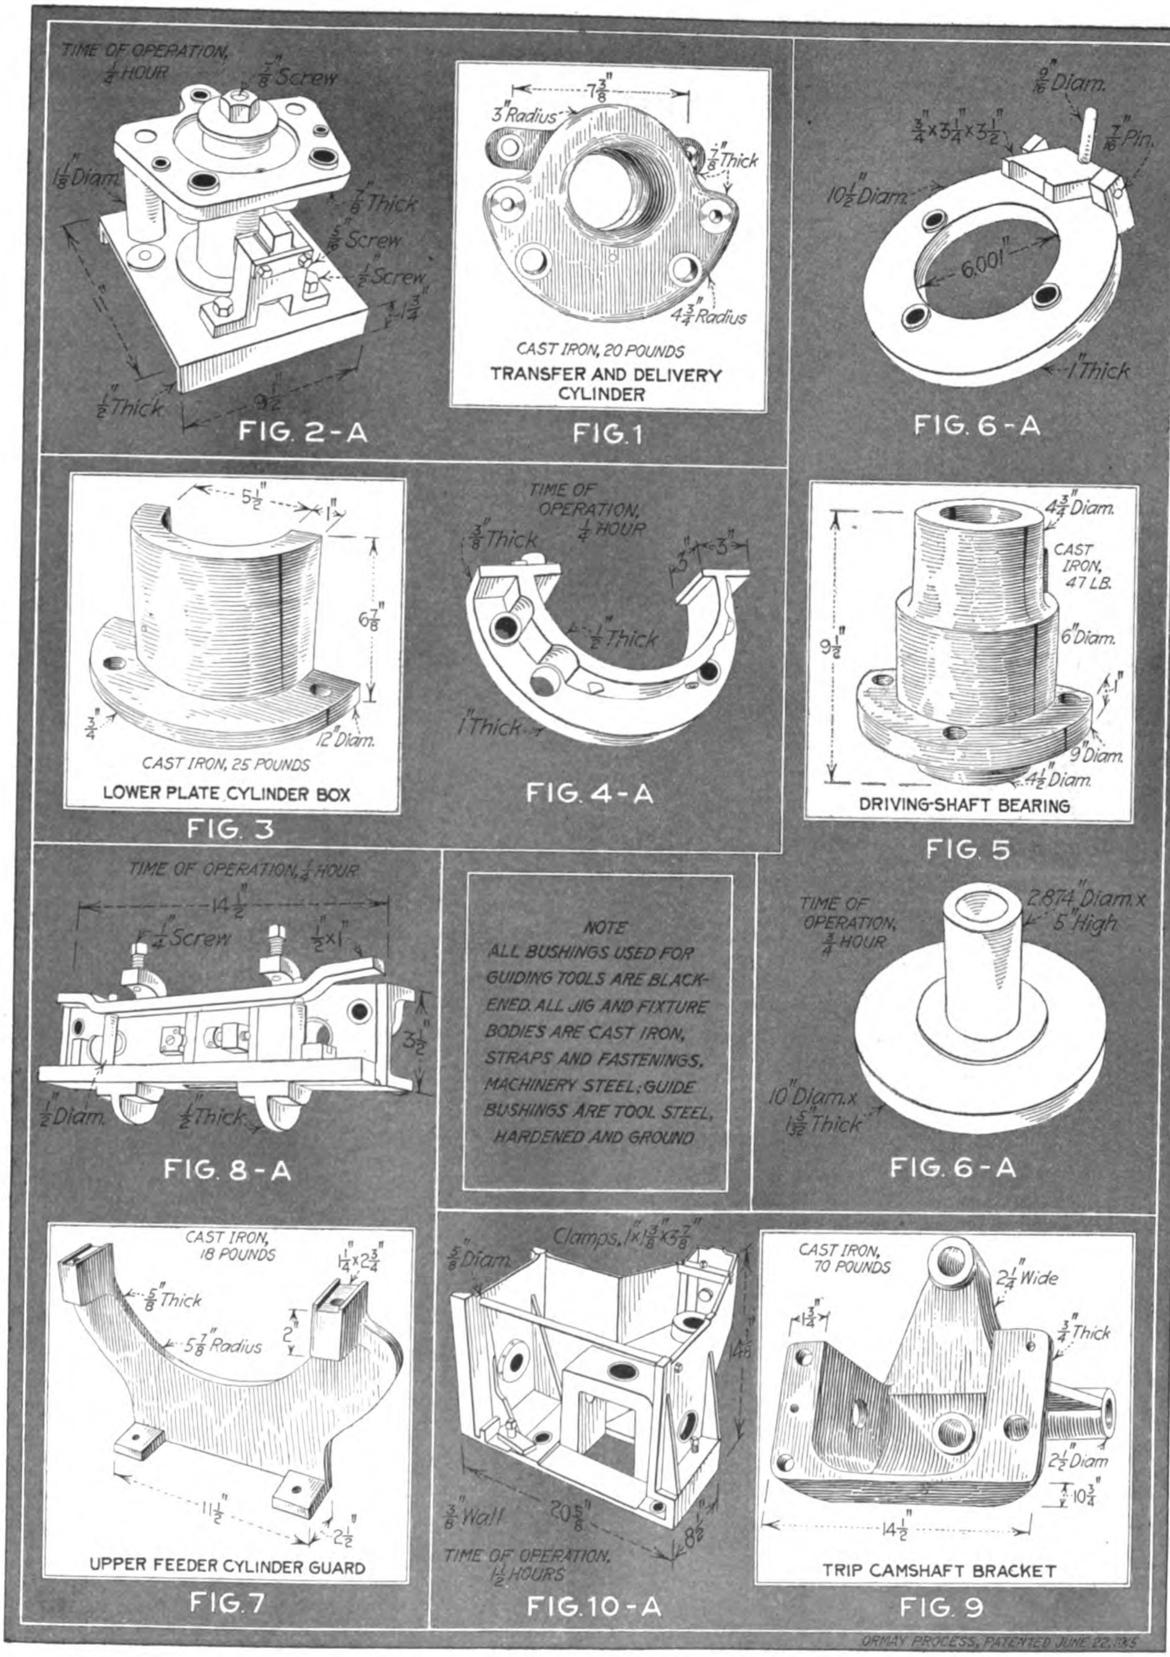
Operation—Drilling holes in upper surface of upper feeder cylinder guard, Fig. 7. The jig is dropped over the rough casting and forced against a stop with a pair of square-headed setscrews.

Holes Machined—Two $\frac{41}{64}$-in. drilled.

FIGS. 10 AND 10-A

Operation—Drilling and reaming trip camshaft bracket, Fig. 9. The milled casting is located against adjustable screws and held down with setscrews and straps.

Holes Machined—Two $1\frac{7}{8}$-in. spot drilled and reamed, one $1\frac{1}{2}$-in. spot drilled and reamed, one $1\frac{5}{32}$-in. drilled, two $\frac{5}{32}$-in. drilled, two $\frac{31}{64}$-in. drilled and one $\frac{1}{4}$-in. drilled.



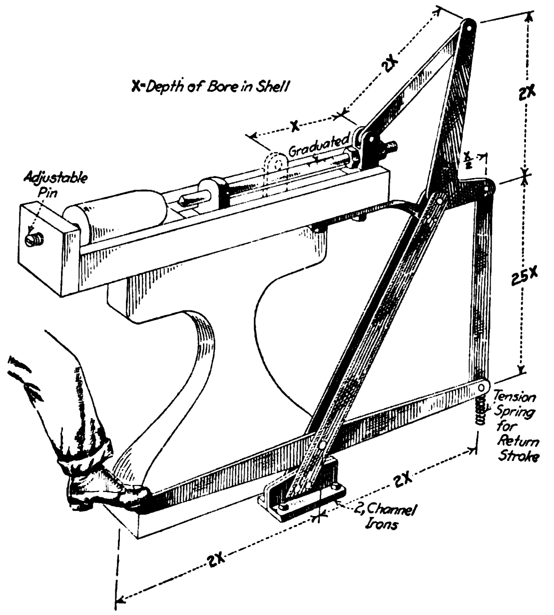
DETAILS OF JIGS USED IN MACHINING PRINTING-PRESS BEARINGS AND BRACKETS

Gage for Measuring Shrapnel

By L. E. Olsen

The gage shown in the illustration has many advantages over the common saw-frame style or the vertical standard with pin-dropping device.

It leaves both hands of the operator free and consequently increases his capacity for work. It does away



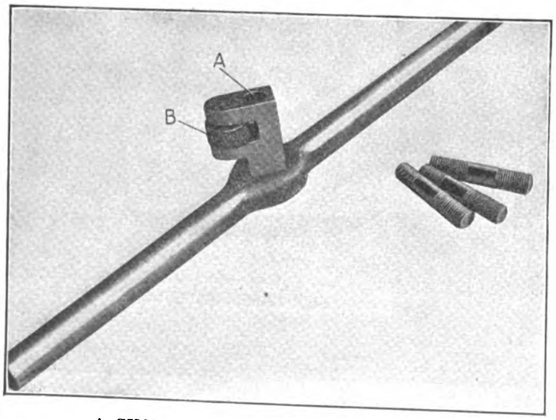
GAGE FOR MEASURING SHRAPNEL

with lifting the shells, as they can be rolled along the table into a V-groove for measurement. This gage is cheap to make, and it can be used for various sizes by making a new gage pin.

A Stud Driver

By E. V. Allen

I saw a fine stud driver in use in the Henderson Motorcycle Co. shop in Detroit not long ago. It is shown in the accompanying illustration. Various sizes were in use, the one shown for driving studs into crank cases.



A SIMPLE AND RAPID STUD DRIVER

The wrench was placed over the stud, which went into the hole A. The knurled piece B, which is eccentric, was turned so as to lock the stud, which was then easily run down as far as the threads would allow. A stud can be removed just as easily with the same tool, by simply turning the eccentric knurled driver around in the opposite direction.

The name stamped on the tool was Edmund Sprung, Detroit.

Adjustable Hollow Mill

By Edward L. Robenolt

The illustration shows an adjustable hollow mill that has proved useful in service. It is made in a manner similar to an adjustable milling cutter.

In changing from one size to another, slacken the cap A slightly and press the blades back against the

All Dimensions in Inches

DESIGN DATA FOR ADJUSTABLE HOLLOW MILL

adjusting nut B; screw up the nut until the tools cut the proper size, and then tighten the cap.

When this mill is used on a drilling machine, the shank should be made like style 1; and when used in a lathe, like style 2.

The accompanying table contains data that will aid in designing mills for the various sizes shown.

Attractive Calendars

Among the numerous 1916 calendars received those distributed by the following machinery-building firms are especially attractive: The National-Acme Manufacturing Co., Cleveland, Ohio; The Cleveland Twist Drill Co., Cleveland, Ohio; The American Tool Works Co., Cincinnati, Ohio; Pacific Tool and Supply Co., San Francisco, Calif.; Diamond Saw and Stamping Works, Buffalo, N. Y.; J. N. Lapointe Co., New London, Conn.; White & Bagley Co., Worcester, Mass.; Portage Lake Foundry and Machinery Co., Hancock, Mich.; Noble & Westbrook Manufacturing Co., Hartford, Conn.; The Ashton Valve Co., Boston, Mass.; De La Vergne Machine Co., New York City; Goldschmidt-Thermit Co., New York City; The Standard Tool Co., Cleveland, Ohio.

It is assumed that any available supply of these calendars can be drawn upon by our readers.

Manufacturing Adapters for 18-Lb. High-Explosive Shells

By J. H. Moore

SYNOPSIS—In this article are shown the methods, tools and gages used in manufacturing No. 4 adapters for 18-lb. high-explosive shells. The adapter is made from bar stock and the turning, threading, recessing and final cutting off are performed on turret lathes. Two jigs are then used for the subsequent drilling and tapping operations, and after a thread-sizing operation the adapters are nickel plated on two faces as the final operation.

It is now no matter of surprise in the munition-manufacturing line of business to hear of sudden changes from regular lines of work to that of war material. This article describes the methods employed in a factory whose regular product is cream separators. Although still manufacturing these machines, with extra equipment the factory turns out some of the required munitions. The part handled is the No. 4 adapter, and it might be profitable to describe this part of a high-explosive shell, so that

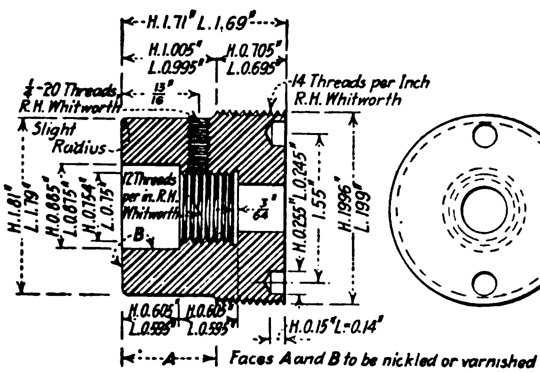

FIG. 1. DETAILS OF NO. 4 ADAPTER

readers will be well acquainted with the piece and its position in the shell.

In Fig. 1 is shown a detail of the adapter. The high-explosive shell is of the same shape at the nose as the English shrapnel, but differs in that in place of the brass socket of the shrapnel there is a steel socket. It is into this socket that the adapter screws. The material used is mild steel, with a minimum breaking test of 25 tons and an elongation of at least 12 per cent. in a 2-in. test piece. The internal thread takes what is known as the gaine, which is an altogether separate piece. The stock for this work is rolled specially, being rolled to the nearest diameter to the required size, so that the least amount of stock is left to turn off.

The lathe work is completed in one operation or setting, the stock being cut off in bars of suitable length to accommodate the machines. As can be readily understood, it is not necessary in this case to have any special chucks, the collets being satisfactory for this work. In Fig. 2 is shown the plan layout of turret positions.

In the first turret position a three-step drill is used, which has a 1¼-in. straight shank, this being a very convenient size to grasp in the holder. The drill has ample allowance for grinding and is made of high-speed steel. Allowance of $^1/_{64}$ in. per diameter is made for reaming.

On the second position this reaming is done with a three-step reamer, a detail of which is shown in Fig. 3.

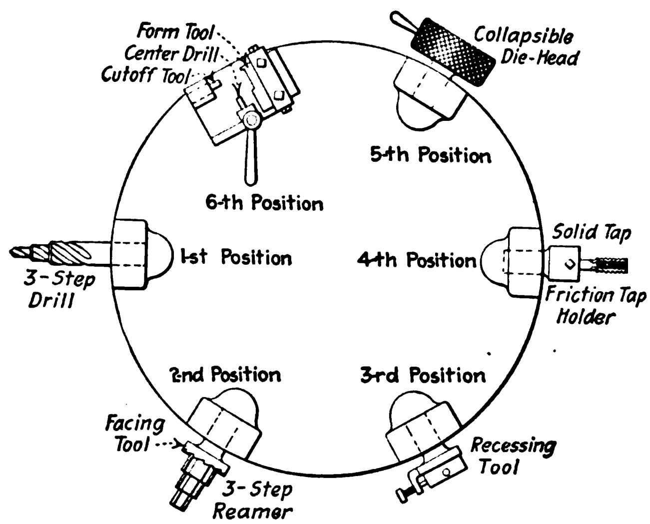

FIG. 2. LAYOUT OF TURRET POSITIONS ON J. & L. LATHES FOR NO. 4 ADAPTERS

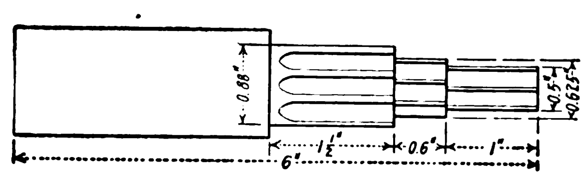

FIG. 3. DRILL AND REAMER FOR NO. 4 ADAPTERS

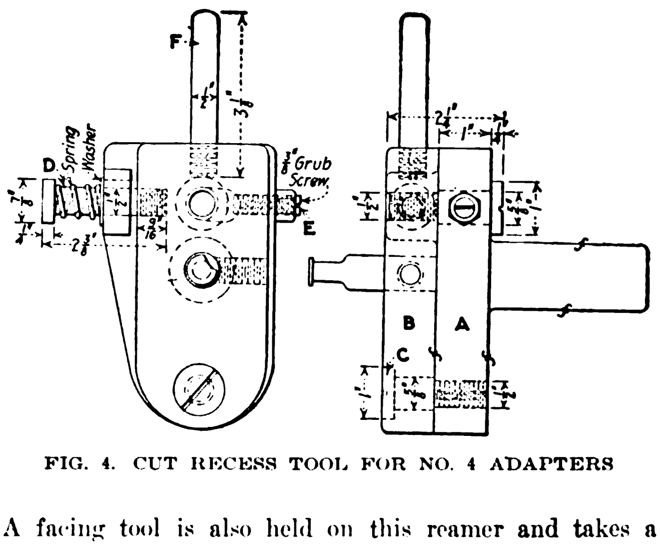

FIG. 4. CUT RECESS TOOL FOR NO. 4 ADAPTERS

A facing tool is also held on this reamer and takes a slight skim off the adapter.

The third position is a rather difficult and awkward one. First, the recess tool must be of such size as to enter a ⅝-in. diameter hole. Another trouble is the width of the recess, $^3/_{64}$ in. To overcome these two features, the tool, Fig. 4, was made.

Referring to the illustration, *A* is the part held in the turret. *B* is the swivel or moving part. A radial slot to accommodate the slide bolt is made in part *A*, the radius being of course the distance from the swivel bolt *C* to the center of the slot. The spring *D* is placed to pull the tool always back to the dead center, as this point is most important; otherwise the tool would get jammed and broken. The recessing tool is plainly seen and needs no description. Briefly the action of the tool is as follows: Adjust the stop screw *B* to the required recess, pull the handle *F* over toward the operator until the stop is reached. When the operator releases the handle, the tool goes to the head center and the carriage can be pulled back immediately. This spring feature makes the tool foolproof.

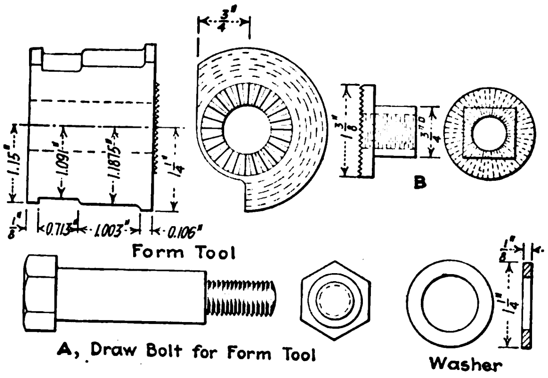

FIG. 5. DETAILS OF FORM TOOL FOR NO. 4 ADAPTERS

The fourth turret position is that of a collapsible die head for external threading. As this work is of common occurrence, no further mention is made.

The fifth turret position is the internal tapping, and here is used a friction tap holder with a solid tap.

The sixth and last position holds three tools—a center drill, which is used first to center the work, the form tool and the cutoff tool. The cutoff tool and the center drill need no comment, but the method of fastening the circular forming tool is rather out of the ordinary. In order to utilize the usual type of stand or holders for the cutoff tool as supplied by the turret-lathe manufacturers, the forming tool was made as shown in Fig. 5. The form tool proper was placed in the regular stand, a hole being drilled in the stand to allow the draw bolt *A* to pass through. A square hole was filed in the opposite side of the stand to accommodate the piece *B*. The draw bolt, pulling on the part *B*, draws it tight against the forming tool, holding it quite securely.

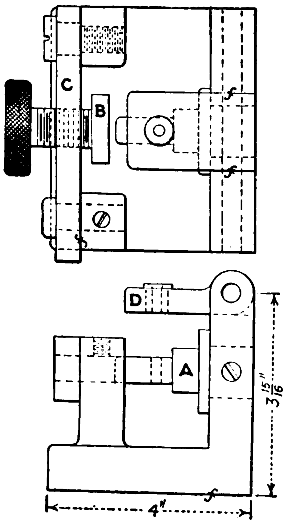

FIG. 6. FIRST DRILL JIG

After leaving the lathe the adapters are taken to a two-spindle drill press and drilled and tapped for the fixing screw in the side. A jig, as shown in Fig. 6, is used. The piece is placed on the pin *A*. The screw *B* in the swing clamp *C* is screwed up against the work. After drilling, the bushing plate *D* is swung out of the way, and the work is tapped on the second spindle.

The second drilling and facing operation is completed on similar drill presses, the work being that of drilling the two holes for the spanner. In the lathe operation, 0.015 in. more than the required length was left on, and in this operation the surplus is taken off by the facing tool shown. The pilot is made concave at the point. The reason for this is to allow no chips to gather between the stop rod of the drill and the face of the jig. The jig used for this operation is shown in Fig. 8. A rather easy and novel method of keeping the jigs in line with the centers of the spindles is used on these presses and is shown in Fig. 9. The jigs slide in the groove *A*, are always on the center and cannot turn around. Therefore they help the operator considerably.

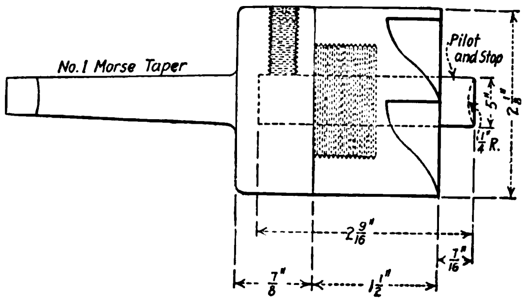

FIG. 7. FACING TOOL USED ON SECOND DRILL AND FACE OPERATIONS FOR ADAPTERS

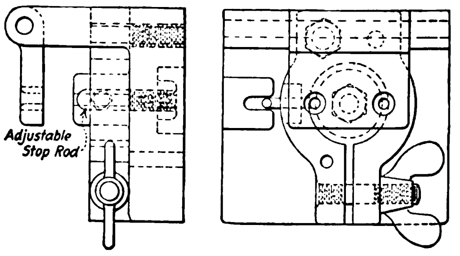

FIG. 8. DRILL JIG FOR TWO HOLES IN TOP OF ADAPTER. THIS JIG IS ALSO USED ON FACING TOP

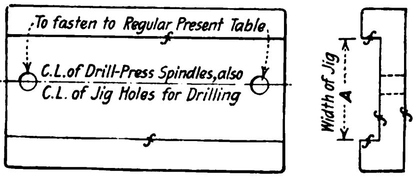

FIG. 9. GUIDE FIXTURE FOR DRILL ADAPTER WORK

The final shop operation is that of sizing the threads with an adjustable solid type of die to assure accuracy, as inspectors are most insistent on this point. A little 14-in. lathe is used for this purpose, and as the work is simple, no comment is necessary.

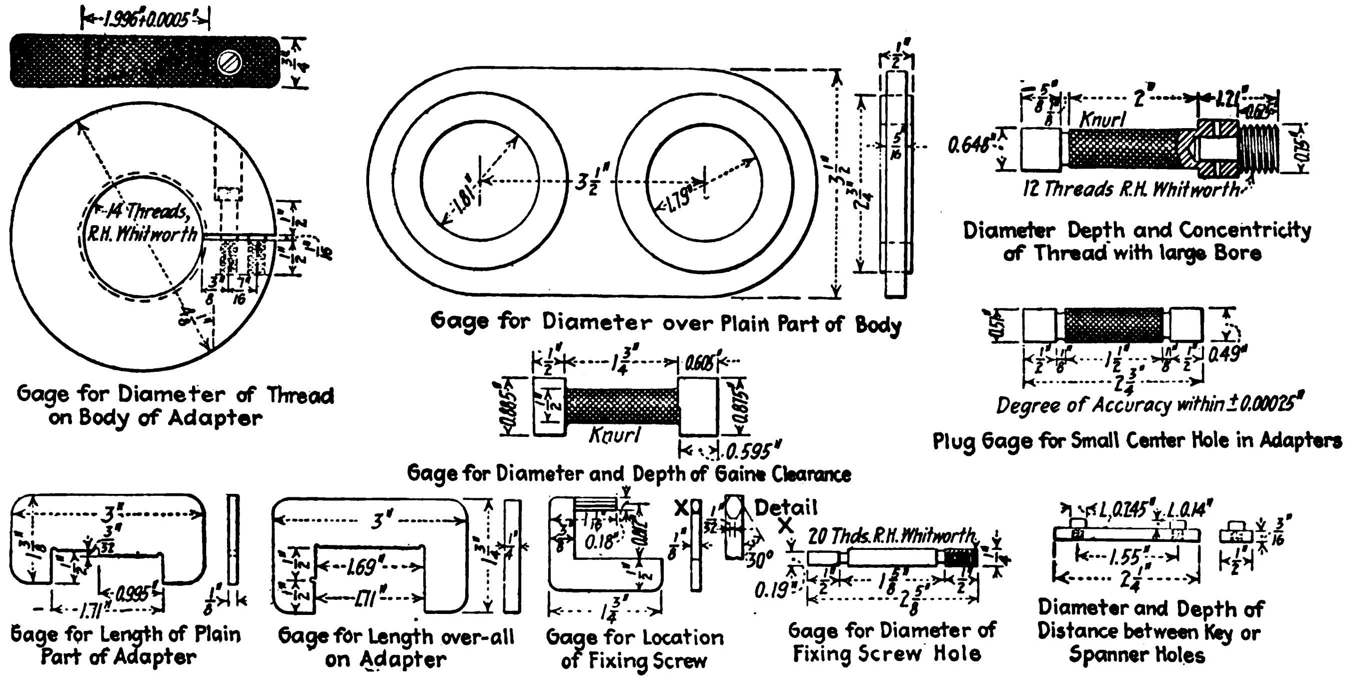

FIG. 10. GAGES USED IN MANUFACTURING HIGH-EXPLOSIVE SHELL ADAPTERS

This completes the adapter with the exception of nickel plating on the faces *A* and *B*. After being plated, the adapters are inspected by the Government inspector and must conform to the various gages shown in Fig. 10.

Souvenirs from the Trenches

By Hi Sibley*

When the irrepressible French soldier is not actually fighting for his country, he is busy making souvenirs—allowing some time for sleep and eating. He utilizes everything available that is significant of the war and turns out some remarkably ingenious specimens.

Probably the most popular bit of his handicraft is the *bague des tranchées,* or trench ring, which he fashions from the aluminum of a certain type of German shell nose picked up in the vicinity. So great is the demand for aluminum for this purpose that one of these fuse tips is rated worth a dozen of the solid brass ones, from a souvenir standpoint. The rings are made up in numberless designs, and some of the workmanship is decidedly artistic, particularly those in which a figure made from the copper compression band of a shell is inlaid in the face of the ring. Some are embellished with the lion cut from a Belgian copper two-centime piece; others have a miniature shell in relief, or a human figure or a coat of arms, and nearly all are engraved with the name and date of some battle, as the Marne or Ypres.

In making these rings the aluminum is fused in a ladle and then poured into a rough mold hewn in a brick. At Nieuport one of the soldiers was using a piece of a plaster statue from a shattered church for this purpose. The ring in the rough is then carved and scraped into shape with the crudest of tools, usually a worn-out file and a pocket knife. During my service with the American ambulance squad in Flanders last summer, I had opportunity to collect a great many of these rings. My stock was as high as twenty at one time; but the French *marins* were so liberal in giving us any ring we admired that I became prodigal with mine, too, with the result that when our squad was unexpectedly removed to a ringless district, I had only five left. They are shown at *A, B, C, D* and *E*.

The one I prize most highly was made to my measure by a soldier-jeweler at Crombeke, Belgium, and bears the symbol of ambulance service, the red cross, in copper, as shown at *A*. The workmanship is exceptionally fine. The others were made near Nieuport, which is right on the firing line. One of our men was fortunate enough to secure a bronze ring made from a Nieuport church bell, but these rings were very rare on account of the difficulty of working the tough metal with hand tools.

Combination pen-and-pencil holders made by soldering the ends of cartridges together were very common at the front. The Frenchman is a true utilitarian, for to get the solder for these souvenirs he melted up meat tins. One in my collection, *F*, was given me by an unfortunate culprit on the eve of his court-martial. I was passing his prison yard when he begged for a cigarette; and as I thrust a handful through the fence bars, he gave me this holder. Another one, *G*, is made up of British and German cartridge shells and a German and a Belgian ball. I got it from artillery Captain Bartholet, formerly wireless operator on *La Savoie,* who was convalescing in a hospital at Zuydcoote, Belgium, with shattered ear drums. Captain Bartholet was exceedingly reticent on the subject of how he became injured, but I learned from other sources that he lost his hearing when his battery had been struck by a German shell. Several of his comrades were killed. The ammunition had not been destroyed, however, and Bartholet returned and made several trips under fire to carry the ammunition to a place of safety. Naturally, I think a great deal of this particular souvenir.

Nearly every soldier we encountered carried a handmade *briquet,* or cigarette lighter, and we were constantly besieged by them for a little *essence,* or gasoline, with which to fill these *briquets.* There was no standard design or pattern, but the majority of them were very neat and

*Chauffeur in American ambulance squad in Flanders, June to September, 1915.

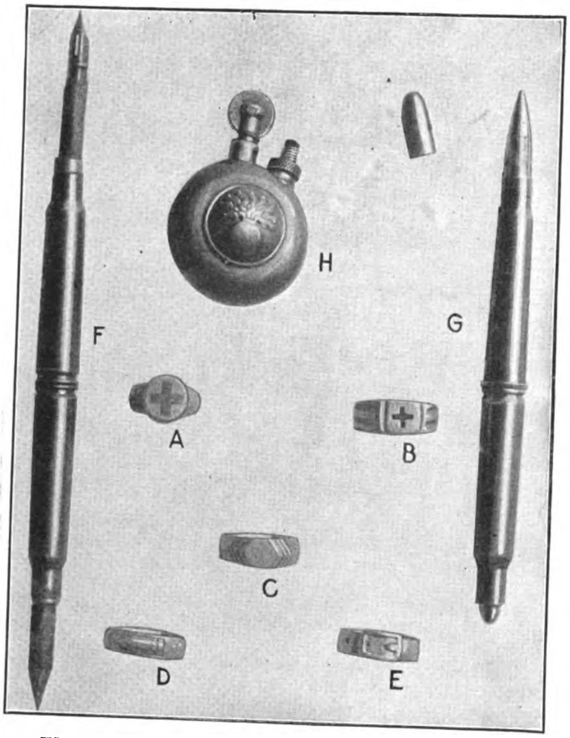

FIG. 1. SOUVENIRS MADE IN TRENCHES NEAR NIEUPORT BY FRENCH SOLDIERS

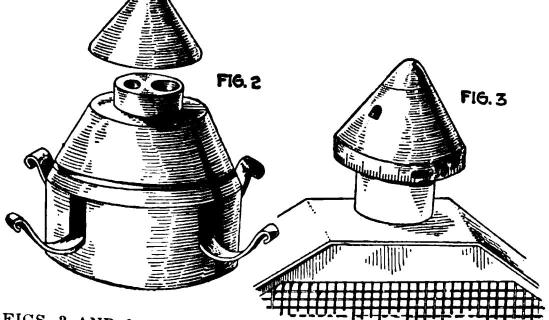
attractive; a few were really handsome. This particular specimen, *H*, has a body of brass from a shell nose, decorated with French infantry buttons on each side. The flint wheel is procured at any of the numerous tobacco shops that have sprung up all along the front. Kept properly filled with gasoline, they are very reliable. One appreciates them at the front, too, where matches are none too plentiful.

Other forms of trench-made souvenirs were legion—cigarette cases, cocktail shakers, paper weights and some very handsome paper cutters made from the brass *soixante-quinze* shells. I have a unique inkstand and pen-rack made from parts of a shell, as in Fig. 2; and several of the men on our squad used graduated time noses from German shells for radiator caps, Fig. 3.

One asks when the soldier finds time for all these things; but bear in mind that he is not fighting every minute, and besides you can leave it to a Frenchman to find time to exercise his ingenuity. Furthermore, men must have something to take their minds off the horrors which surround them. When nerves are shaken by hours of crashing shell fire and the sight of wounded comrades, work of this kind takes them into new fields of thought and is more of a relief than might be imagined.

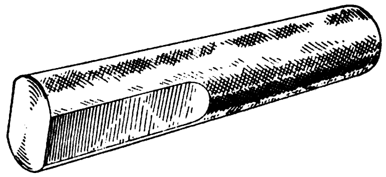


FIGS. 2 AND 3. INKSTAND WITH COVER AND PEN RACK MADE FROM NOSE OF SHELL AND BRASS CHAMBER

A Flat-Sided Brass Lap

By James McIntyre

The illustration shows a makeshift that I ran across recently. Having to lap a 0.750-in. ring gage 3 in. long, I made a brass lap as shown, milling a flat on two sides.



A FLAT-SIDED BRASS LAP

When the lap becomes small, a little peening on the flats with a hammer will make it cut again.

The tendency to bell mouth the hole is not nearly so great with this type of lap.

Alignment Charts for Design of Flat Plates--II*

By Axel K. Pedersen

The first two charts in this section finish the general cases commonly met with in the design of flat plates. The last two charts deal with stayed surfaces. Of these, Chart 8 covers the ideal case and Chart 9 applies to boiler plates and is worked out from the standards laid down in the Boiler Code of the American Society of Mechanical Engineers.

The following conditions must be considered in selecting points on the M_2 scale, Chart 9:

1. When doubling plates are fitted of the same thickness of the plates they cover, and not less in width than two-thirds the pitch of the stays.
2. If the diameter of riveted washers be at least two-thirds the pitch of the stays, and the thickness not less than the plates they cover.
3. When the plates are not exposed to the impact of heat or flame, and the stays are fitted with nuts and washers, the latter being at least three times the diameter of the stay and two-thirds the thickness of the plate they cover.
4. When the plates are not exposed to the impact of heat or flame, and the stays are fitted with nuts only.
5. When the plates are not exposed to the impact of heat or flame, and the stays are screwed into the plates, having the ends riveted over to form substantial heads.
6. When the plates are exposed to the impact of heat or flame, the steam is in contact with the plates, and the stays are fitted with nuts and washers, the latter being at least three times the diameter of the stay and two-thirds the thickness of the plates they cover.
7. When the plates are exposed to the impact of heat or flame, steam is in contact with the plates, and the stays are fitted with nuts only.

*The previous installment of this series appeared on page 373.

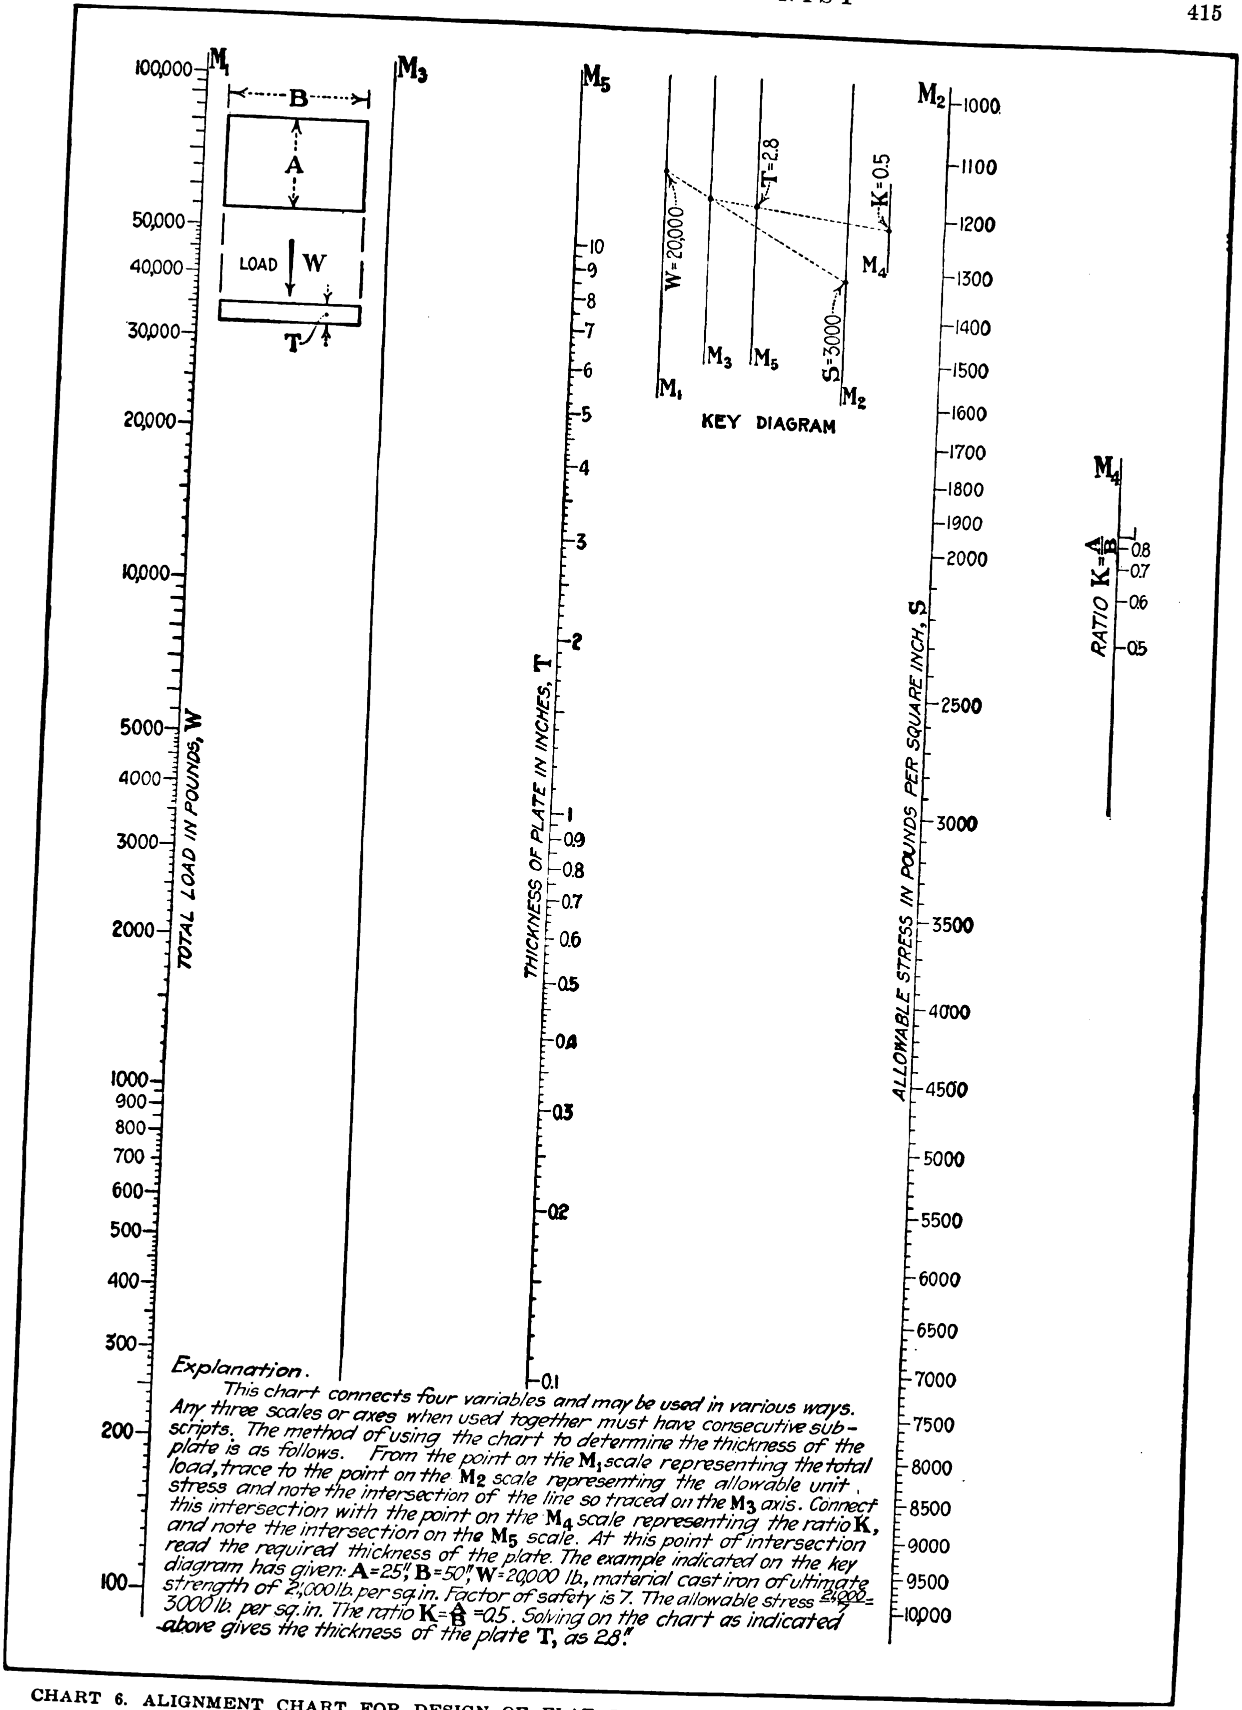


CHART 6. ALIGNMENT CHART FOR DESIGN OF FLAT, RECTANGULAR PLATES SUPPORTED AT EDGES WITH CONCENTRATED LOAD AT CENTER—BY AXEL K. PEDERSEN

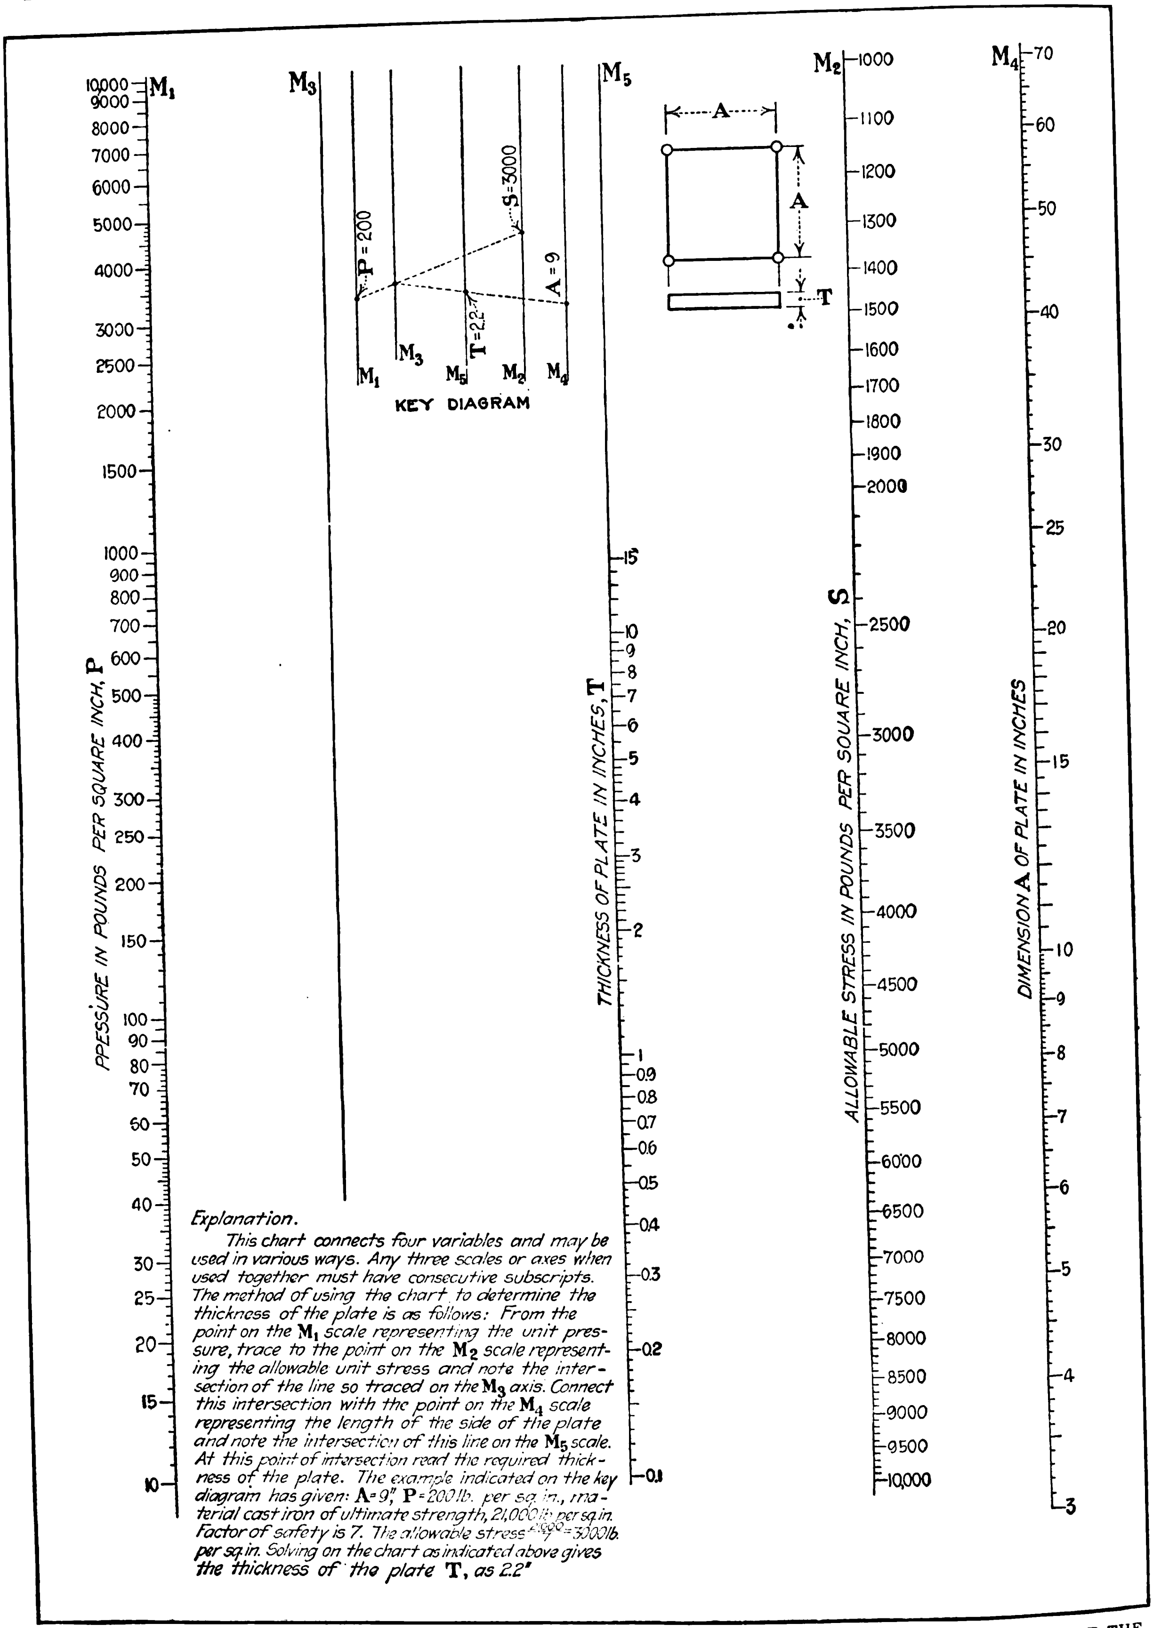
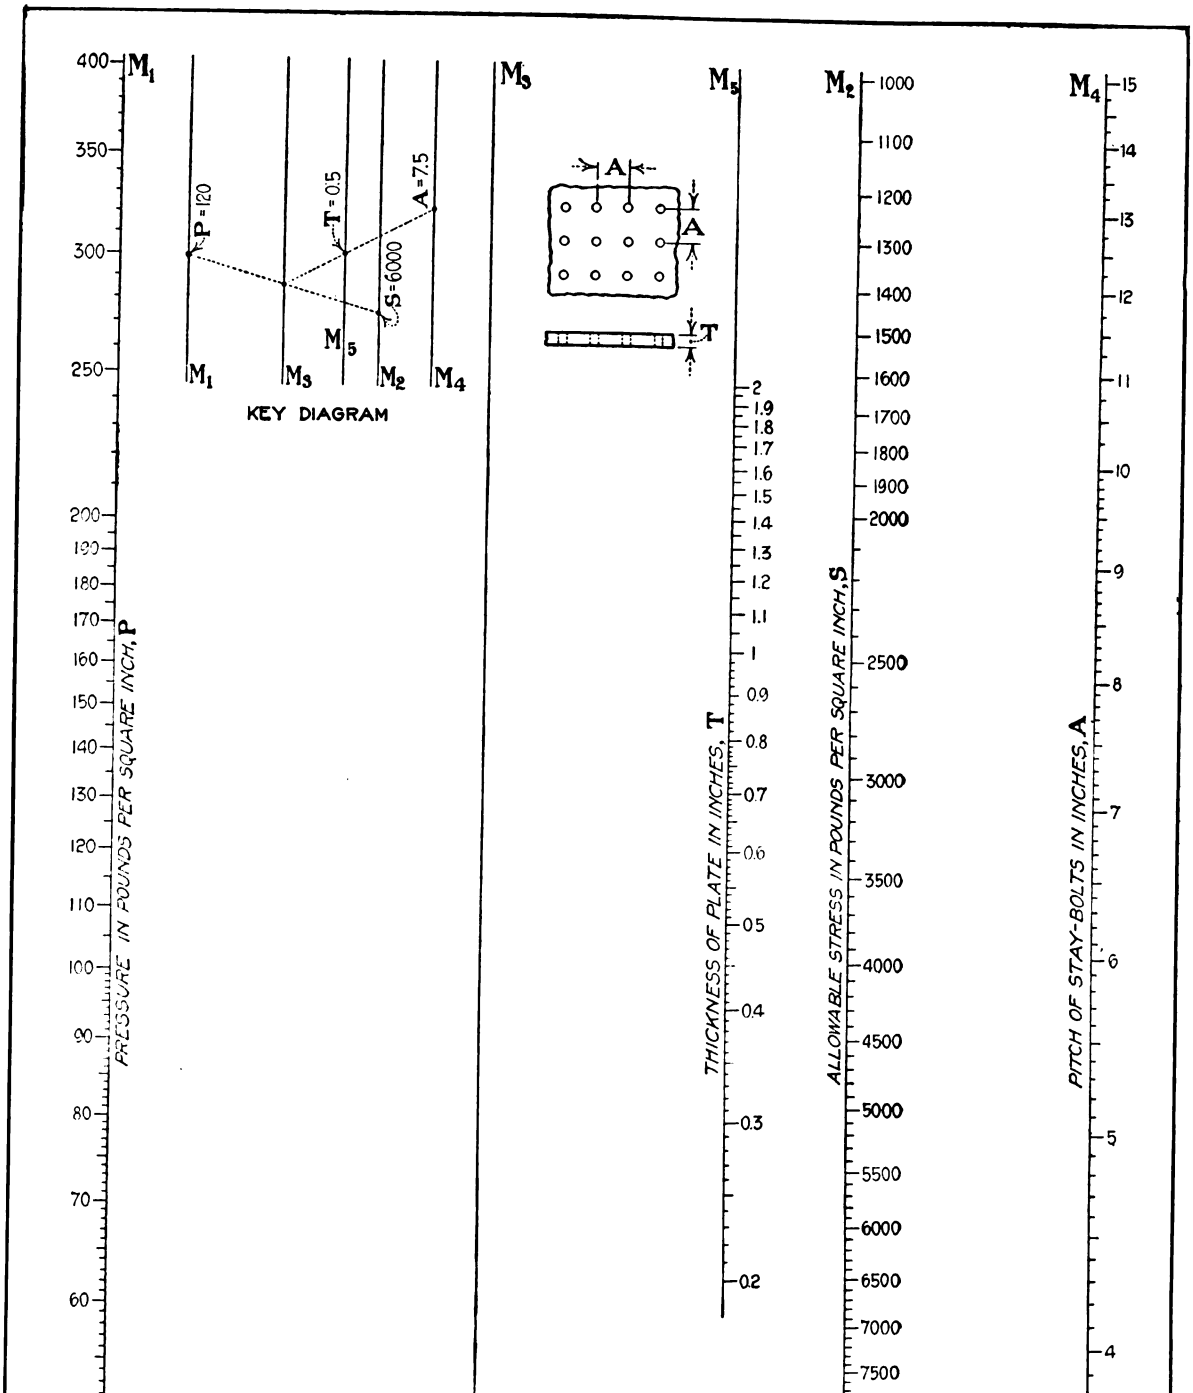


Explanation.

This chart connects four variables and may be used in various ways. Any three scales or axes when used together must have consecutive subscripts. The method of using the chart to determine the thickness of the plate is as follows: From the point on the M_1 *scale representing the unit pressure, trace to the point on the* M_2 *scale representing the allowable unit stress and note the intersection of the line so traced on the* M_3 *axis. Connect this intersection with the point on the* M_4 *scale representing the length of the side of the plate and note the intersection of this line on the* M_5 *scale. At this point of intersection read the required thickness of the plate. The example indicated on the key diagram has given:* **A** *= 9",* **P** *= 200 lb. per sq. in., material cast iron of ultimate strength, 21,000 lb. per sq. in. Factor of safety is 7. The allowable stress* $\frac{21000}{7}$ *= 3000 lb. per sq. in. Solving on the chart as indicated above gives the thickness of the plate* **T***, as 2.2"*

CHART 7. ALIGNMENT CHART FOR DESIGN OF SQUARE PLATES UNIFORMLY LOADED AND SUPPORTED AT THE FOUR CORNERS—BY AXEL K. PEDERSEN



This chart connects four variables and may be used in various ways Any three scales used together must have consecutive subscripts The method of using the chart to determine the thickness of the plate is as follows:

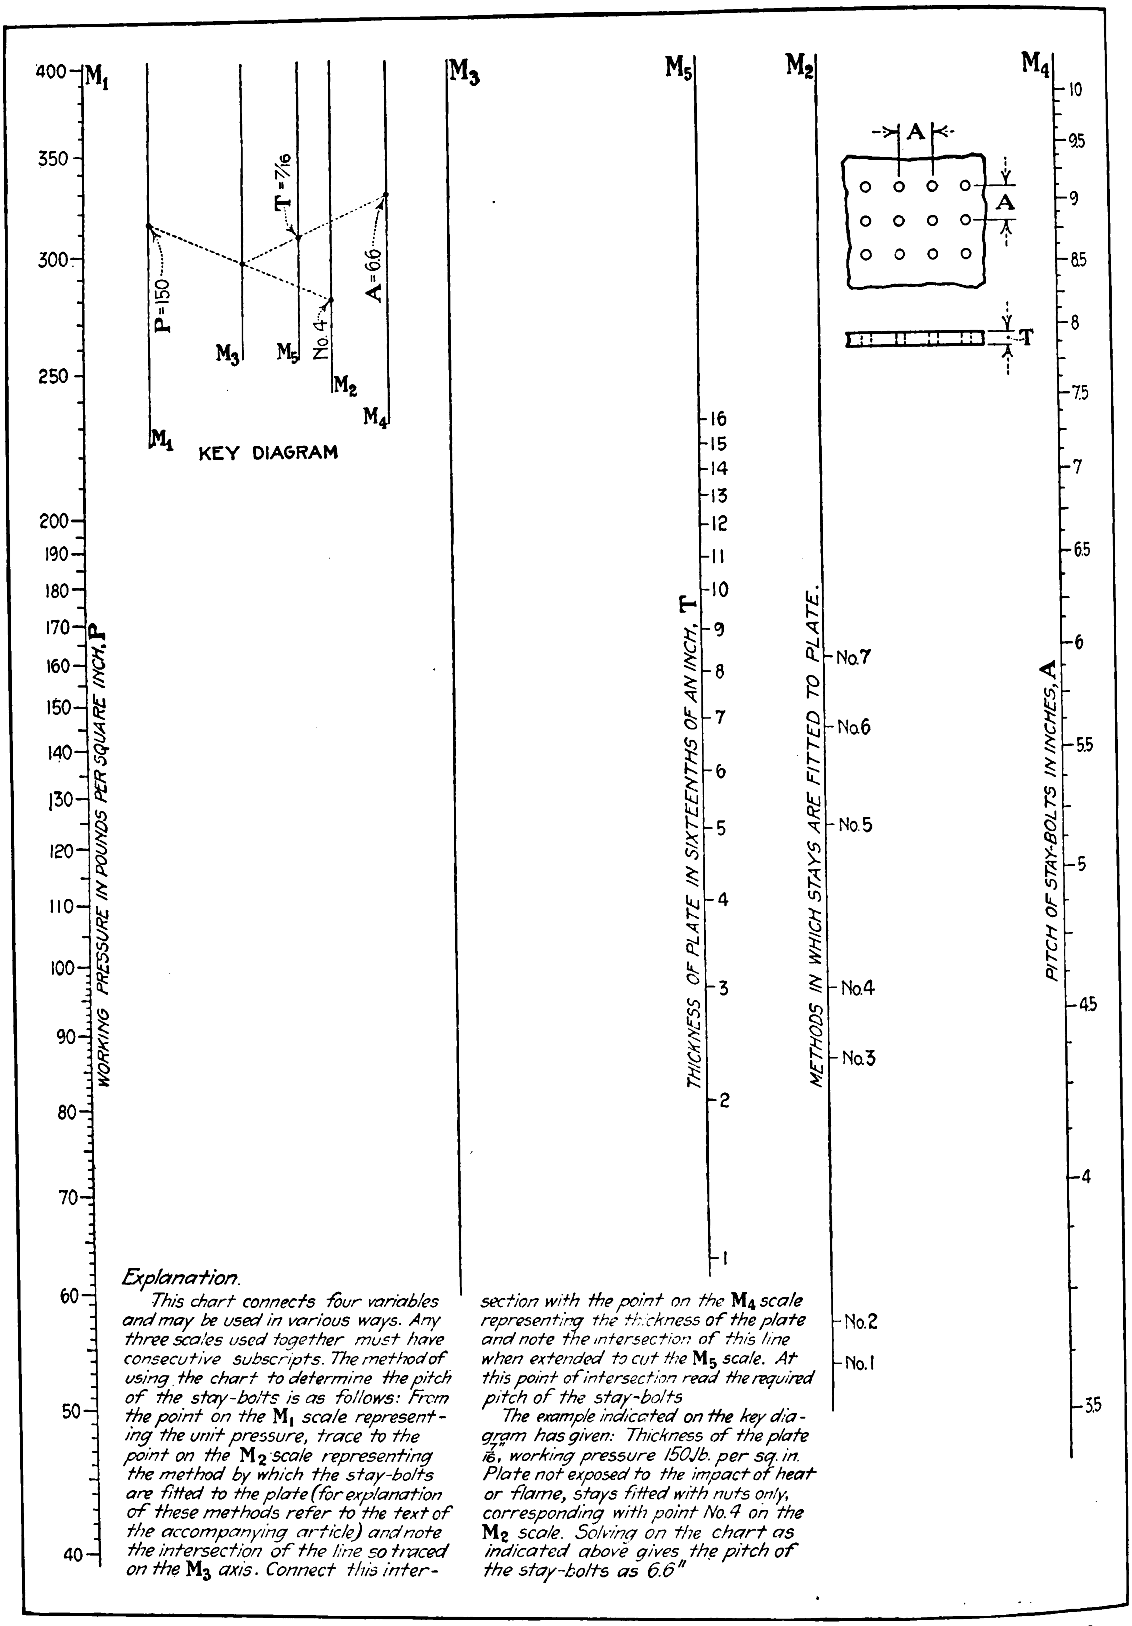
From the point on the M_1 scale representing the unit pressure, trace to the point on the M_2 scale representing the allowable unit stress and note the intersection of the line so traced on the M_3 axis. Connect this intersection with the point on the M_4 scale representing the pitch of the stay-bolts and note the intersection of this line with the M_5 scale At this point of intersection read the required thickness of the plate

The example indicated on the key diagram has given:

Working pressure, 120 lb per sq. in.
Allowable stress, 6000 lb per sq. in.
Pitch of stay-bolts, 7.5"

Solving on the chart as previously indicated gives the thickness of the plate **T** as 0.5"

CHART 8. ALIGNMENT CHART FOR IDEAL CASE IN DESIGN OF UNIFORMLY LOADED FLAT STAYED PLATES—BY AXEL K. PEDERSEN



Explanation.

This chart connects four variables and may be used in various ways. Any three scales used together must have consecutive subscripts. The method of using the chart to determine the pitch of the stay-bolts is as follows: From the point on the M_1 scale representing the unit pressure, trace to the point on the M_2 scale representing the method by which the stay-bolts are fitted to the plate (for explanation of these methods refer to the text of the accompanying article) and note the intersection of the line so traced on the M_3 axis. Connect this intersection with the point on the M_4 scale representing the thickness of the plate and note the intersection of this line when extended to cut the M_5 scale. At this point of intersection read the required pitch of the stay-bolts

The example indicated on the key diagram has given: Thickness of the plate $\frac{7}{16}$", working pressure 150 lb. per sq. in. Plate not exposed to the impact of heat or flame, stays fitted with nuts only, corresponding with point No. 4 on the M_2 scale. Solving on the chart as indicated above gives the pitch of the stay-bolts as 6.6"

CHART 9. ALIGNMENT CHART FOR FLAT STAYED PLATES UNIFORMLY LOADED, PLOTTED ACCORDING TO RECOMMENDATION OF A. S. M. E. BOILER CODE—BY AXEL K. PEDERSEN

Some Recent Developments in Tool-Steel Testing--I

By Edward G. Herbert*

SYNOPSIS—An important series of original tests and the deductions from the results of other experiments on the durability of high-speed steels are given in these articles. They are of particular interest in view of the comparative lack of data on finishing cuts, to which they chiefly appertain.

Since the tool-steel testing machine was first described in the *American Machinist* in Vol. 32, Part I, page 822, it has been the means of carrying out many investigations into the qualities of tool steel. Through the experience thus gained some modifications have been introduced in the design of the machine and the method of testing, though the principle remains unaltered.

A brief description of the machine as now made is essential for a clear understanding of the improved method of testing. The machine, Fig. 1, is essentially a vertical drilling machine, driven through variable-speed friction gearing. The spindle is weighted and carries in place of a drill a standard steel test tube *B* of ¾-in. diameter and ⅝-in. bore, guided at its lower end by a hardened-steel bushing. The sample of steel to be tested

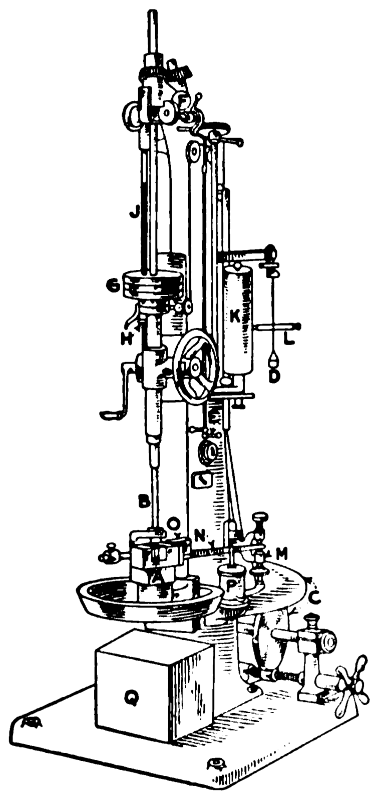


FIG. 1. THE TESTING MACHINE USED

is made into a tool, ground to standard shape and so fixed as to act on the end of the tube and turn it away. The durability of the tool is measured by the length of tube it will turn away before becoming blunted a standard amount. The feed is constant and in all standard tests is 0.0012 in. per revolution.

*Director, Edward G. Herbert, Ltd., Manchester, England.

In the original machine the feed was regulated and kept constant by adjusting the pressure of the tool against the test tube. For this purpose the tool holder or vise was mounted on knife-edges and provided with a steel guard and sliding poise. As the tool became blunt, more pressure was required to keep the feed constant, and it was applied by shifting the poise.

This adjustable feed arrangement has now been replaced by a feed screw *J* carrying a nut *H*, on which the

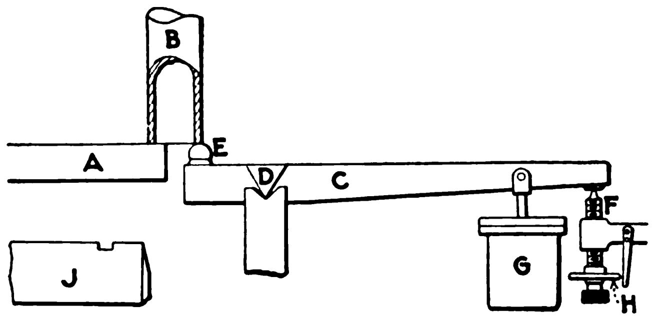

FIG. 2. EFFECT OF TEST ON TOOL

weighted spindle sleeve rests. The spindle and tube therefore receive a constant "permissive" feed. The tool *A* is fixed in a vise, which is no longer mounted on knife-edges, but rigidly attached to the machine.

The increased rigidity of the vise has a considerable effect on the test results. The tools stand up longer at all speeds and stand up at much higher speeds. There was, in fact, with the original machine an artificial limit to the speed at which any tool would keep its edge, this limit being imposed by the vibration that took place at high speeds, say above 120 ft. per min. With the tool rigidly held in a heavy vise this limit no longer exists. Consequently, the tests now show a greater contrast between carbon and high-speed steel, with respect to the maximum speeds at which they can be worked.

With the rigid vise and screw feed the former method of measuring the wear of the tool during the test is no longer applicable. The mechanism now employed for this purpose will be understood from Fig. 2, in which *A* is the tool and *B* the test tube. The beam *C* is mounted on knife-edges *D* and carries at one end a hardened-steel ball *E*, loosely resting in a conical socket so that it is free to revolve about its own center. A micrometer screw *F* is mounted in a bracket on the machine column and bears on the end of the beam opposite the ball; an oil dashpot *G* serves to hold the beam steady. The micrometer is insulated and forms part of an electric-bell circuit, so that the bell rings when the micrometer touches the beam. In making a test the procedure is as follows:

The cut is started, and the beam is allowed to take up its position with the ball pressing lightly upward against the end of the tube, its own weight and that of the dashpot plunger holding the beam in this position. The micrometer is then screwed upward until it just makes contact with the under side of the beam, this adjustment being made very accurately with the aid of the electric bell.

The dial *H* of the micrometer is set to zero and locked in that position. The micrometer screw is now turned so as to lift the end of the beam 0.005 in., which causes the beam to tilt on the knife-edges and lowers the ball from the tube end. The actual movement of the ball is one-fifth that of the micrometer, since the distance from the knife-edge to the ball is one-fifth the distance from the knife-edge to the micrometer. There is therefore a space of 0.001 in. between the tube end and the ball. At the instant when this adjustment is made, the recording mechanism is put into action and the pencil begins to register the length of the tube turned away.

As the test proceeds, the tool gradually becomes blunted. This effect, of course, takes place at the part of the edge that is actually cutting the tube, and the effect is that illustrated at *J*, Fig. 2, a slight notch being worn in the edge. The actual cutting edge is now the bottom of this notch; and the end of the tube, which is necessarily on a level with the cutting edge, is now lower than at the commencement of the test by the depth of the notch. As soon as the notch is 0.001 in. deep, the tube will come in contact with the ball and by pressing on it will tilt the beam slightly, so as to break the electric contact between the beam and the micrometer. When this occurs, the bell ceases ringing and the test is immediately stopped.

The autographic record shows the length of tube which the tool has turned away before being blunted 0.001 in., which is a measure of the durability of the tool at the particular speed under investigation. Tests are made at cutting speeds of 20, 30 and 40 ft. per min. and so on up to the highest speed the tool will stand, and the durabilities are plotted to form the "speed curve" of the steel.

Advantages of Tests Made Without Lubrication

In all the former tests the tool and tube were kept flooded with water; but this practice has been abandoned, and all standard tests are now made dry. Several advantages are gained by this alteration.

The average length of test is less than it would be with water, and this fact counteracts the lengthening of the tests that would otherwise result from the increased rigidity of the tool. The temperature of the cutting edge is of course much higher without water, and the tests can therefore be completed at lower speeds.

The coloration of the chips that takes place when cutting dry is an indication of the cutting temperature and serves to connect particular points on the speed curve with corresponding conditions of workshop practice. For instance, at a speed of 60 ft. per min. the chips produced by the testing machine are blue; at lower speeds they are yellow or white. It may be inferred that the cutting temperature at 60 ft. is similar to that of a lathe tool when cutting under conditions (speed, depth of cut and traverse) just sufficiently severe to produce blue chips. A tool steel that gives a good test result at 60 ft. on the testing machine is one that will stand up well under blue-chip conditions on the lathe. Another steel may not do well under test at 60 ft., but may prove durable at 40 ft.—the highest testing-machine speed that produces no coloration in the chips—or at 130 ft., which gives red-hot chips. In either case the steel may be expected to do well in the workshop under corresponding conditions—that is to say, under conditions which heat the cutting edge to the same temperature. These corresponding conditions include not only the speed but the shape of the tool, the hardness of the work, the dimensions of the work, the depth of cut and the traverse. The cutting speed may be either higher or lower than the corresponding testing-machine speed.

Curves Showing Chip Conditions at Various Speeds

Fig. 3 is a typical speed curve from high-speed steel, showing the condition of the chips produced at various speeds. It will be seen to include the whole range of the cutting temperatures that are found in ordinary workshop practice; indeed, the testing-machine conditions go beyond the conditions of the workshop in both directions. At 150 ft. the tool, the chip and the work are all red hot. Such a state of things is not found in normal workshop practice, though speeds much higher than 150 ft. per min. are commonly used, with much heavier cuts.

There are several reasons for the generation of such a high cutting temperature with a small cut at a moderate speed. The test tube is light in section and cannot conduct away the heat rapidly like a solid bar or heavy mass of metal; the tube is made of very tough steel

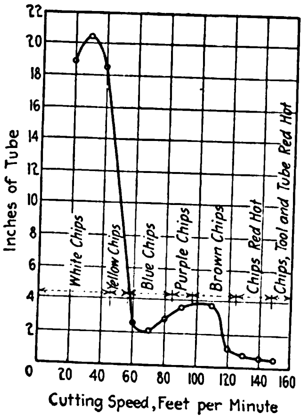

FIG. 3. CHIP COLORS ON THE TESTING MACHINE

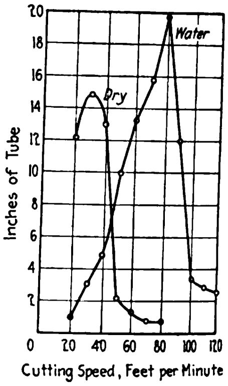

FIG. 4. CUTTING DRY AND WITH WATER

in a semihard condition, and the tool is ground to an angle that is inefficient for cutting, being equivalent to a lathe tool set opposite the work center, with no top or side rake. Such a tool necessarily generates a large amount of heat. This inefficient form of tool was adopted partly because of the ease with which it can be reproduced and partly because its inefficiency is an advantage for the purpose of the test. With a keen cutting tool a much longer range of observation extending to high cutting speed would be required to exhaust the cutting possibilities of the steel. The tests would be longer and more expensive, but would give no more information. The function of the testing machine is to measure durability through the widest possible range of cutting temperatures with a minimum expenditure of time and material, and this end is attained by using a tool shape that generates a high temperature without using excessive speeds.

At the other end of the scale—the low temperature—we have a tool taking a chip 0.0012 in. deep and $\frac{1}{16}$ in. wide at 20 ft. per min. The temperature under such conditions is lower than would be found in ordinary workshop operations, and it can of course be brought still

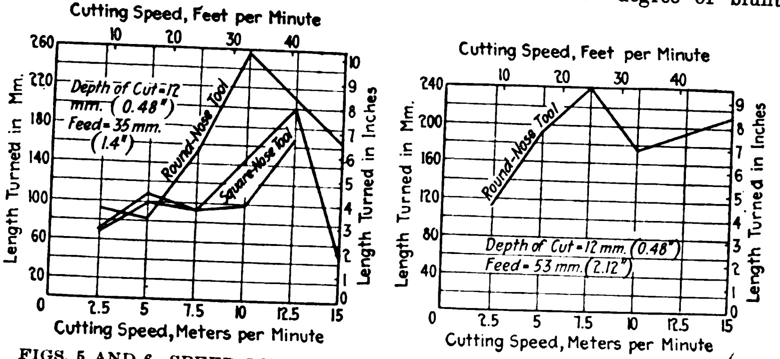
lower by turning on the water. The effect of water cooling at such a low speed as 20 ft. is always to lower the durability of the tool. Thus a comparison of the curves in Fig. 4, made from the same steel cutting with and without water respectively, shows that at speeds from 20 to 45 ft. the dry cutting tool was the more durable.

Another notable fact is that in each case the durability is less at 20 ft. than at somewhat higher speeds. These two effects, which are contrary to the general experience of the workshop, are not exceptional, but are characteristics invariably found in the speed curves produced by the testing machine. They have been shown in a previous article to be manifestations of some physical fact; namely, that a rise in temperature (between certain limits) increases the hardness and toughness of tool steel and therefore increases its durability.

The manner in which the rise in temperature is brought about is immaterial. Whether by application of artificial heat, by increasing the cutting speed or by turning off the water and cutting dry, the result is the same—the tool lasts longer.

A Peculiar Phenomenon and Occurrence

This peculiar phenomenon, first established by the tool-steel testing machine, takes place only between certain temperatures, which are not the same for all steels, but generally lie between atmospheric temperature and 200 deg. C. In the majority of workshop operations the temperature of the cutting edge is considerably higher than 200 deg. C., even when a coolant is used, and the phenomenon does not occur.



FIGS. 5 AND 6. SPEED-DURABILITY CURVES DEVELOPED FROM LATHE TESTS MADE BY PROFESSOR POLIAKOFF

Such a low cutting temperature can only occur when a very light cut is taken at a low speed. Many isolated cases have been noticed, when this somewhat unusual combination of conditions was present and the phenomenon duly made its appearance; but its occurrence has not apparently attracted much attention, and it has entirely escaped the notice of the best-known investigators of cutting phenomena, who have somewhat unaccountably confined their attention to what may be classed as roughing cuts.

The durability of tools in finishing cuts is in some respects more important, because such cuts are usually made with a fine feed and therefore take a long time and because it is essential in finishing work that the tool should retain its sharp edge, so as to leave a smooth surface. One can only surmise that experimenters have been deterred from entering this field of investigation by certain difficulties connected with the carrying out of the tests. Finishing tools are not generally run to the breakdown point, but only to the point at which they become too blunt to leave a fine finish. Therefore, it is only possible to obtain a measure of their durability by adopting some means for estimating their bluntness, and this must be done without stopping the cut.

The Experiments of Professor Poliakoff

Finishing-operation cuts have been made the subject of recent experiments by two skilled investigators. Professor Poliakoff, of the University of Moscow, whose work in connection with the testing of twist drills is well known, has carried out an important series of lathe tests with finishing cuts. His purpose was to find how the durability of the finishing tool and the character of the finished surface are affected by variations in the depth of cut and in the cutting speed. His work has been published in the Russian language only. Perhaps he may be persuaded to make it available to readers of English, but in the meantime he has kindly placed at my disposal a number of highly interesting microphotographs of turned surfaces and some speed-durability curves made with lathe finishing tools.

The tests were made by turning a steel bar in the lathe and measuring the area of turned surface that could be produced before the tool arrived at a standard degree of bluntness. In measuring the bluntness of the tool advantage was taken of the well-known fact that a tool "loses its cut" as it becomes blunt. If a tool is set to turn parallel when sharp, the effect of blunting is to make the work taper, the increase in diameter of the bar at any point being double the amount that has been worn off the tool nose. An indicator was fixed to the slide rest immediately behind the tool and was caused to bear on the turned surface. So long as the tool remained sharp, the indicator needle was stationary; but any blunting of the tool was shown by a movement of the needle. In this way the bluntness of the tool could be measured continuously, and the test was stopped as soon as the standard bluntness had been produced.

Figs. 5 and 6 are speed-durability curves produced by this method. It will be noticed that in every case the durability of the tool increased as the speed was increased, and after having attained a maximum at a certain speed, the durability declined. The curves are in conformity with those produced on the testing machine, and they establish the fact that the curious phenomenon referred to is not in any way peculiar to the testing machine, but must be taken into account in all machining operations that involve the one essential condition—a very low cutting temperature.

(To be continued)

Great Economic Waste resulting more or less directly from unscientific employment methods was made the subject of an address presented by Dr. Ernest F. Nichols, president of Dartmouth College, before the fourth annual meeting of the Chamber of Commerce of the United States. Dr. Nichols suggested the appointment of a committee by the national chamber to deal with the subject of employment managers.

The Only Shop in Argentina Making Its Own Steel

SPECIAL CORRESPONDENCE

The illustrations are from the works of La Cantabrica, Buenos Aires, Argentina, which has the distinction of being the only plant in South America that produces its own steel for making nuts, bolts and other similar products. Reverberatory furnaces are used, and Fig. 1 shows a section of the rolling mill, with some of the heated rods passing through the rolls.

Fig. 2 gives a general idea of the shop construction, showing the monitor roof with ample skylights, the steel-channel construction of the columns, crossbeams and braces and the way in which countershafts are supported. The long braces of channel section add materially to the strength of the structure and the stiffness of the roof. The monitors give an even distribution of light and assist ventilation.

A section of the bolt department is shown in Fig. 3, some of the vertical headers being shown in the background at the right. The lathe at the left, with its gap bed, proclaims its English origin, and the two columns show very clearly how the roof is supported.

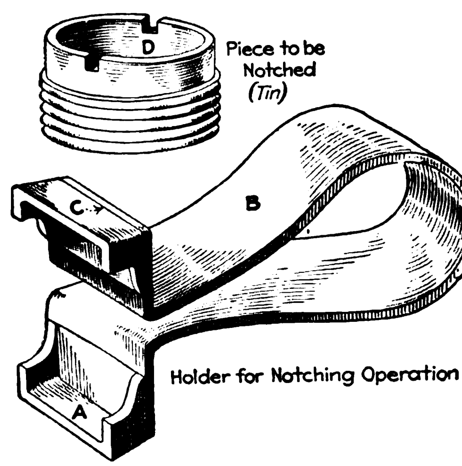
Fig. 4 shows the part of the shop where general work is performed, the usual arrangement of lathes, benches and vises being followed here. These views were taken by the *American Machinist* representative, Duncan N. Hood, through the courtesy of the manager, José De Soto.

Safety Holder for Press Work

BY J. H. MOORE

The spring safety holder shown has saved not only time, but doubtless numerous fingers, which are much more valuable. Its simplicity is apparent.

The space *A* is made of a size to suit the work, the particular piece in this case being shown at *D*. The



SAFETY HOLDER FOR PRESS WORK

spring *B* shows all the action that is required to hold the piece in position to be notched. The pieces *A* are soldered at the joint *C*. As these notching punches come in from the side, it was an extremely dangerous operation before this holder was designed and put in general use.

Standardizing Shop Drawings of Machine Details

By A. C. Spencer*

SYNOPSIS—This plan is intended to relieve the drafting room of the large amount of duplication which is often considered necessary in the details of manufactured articles. It substitutes a form, printed on bond paper for easy blueprinting, and enables stock orders and instruction cards to be made by filling in a few blanks or crossing out unnecessary directions. A careful study of some of these forms should be helpful to many drafting-room heads.

The illustrations present a number of interesting examples of a plan for reducing labor in the drawing room by making it unnecessary to draw many of the details used in standard machines, and for making possible the issuing of blueprint instruction sheets at a very low cost. A little study of these sheets will show their almost universal application, as well as the surprising amount of detailed instructions which can be given with all the necessary variations for different pieces. These variations are easily secured by crossing out unnecessary operations and putting in special figures wherever necessary, such as the length of time to be kept hot and the drawing temperature for pack hardening.

The actual size of the sheets shown is 6x8 in., although a larger size, 8x12 in., has also been used for some purposes. The sheets are printed on a bond paper in a printing press, and blueprints are easily made.

It will be noticed that the necessary stock is shown at the top of each sheet, as well as the list number of the sheet in the upper right-hand corner. An outline of the piece, not drawn to scale, gives all necessary dimensions, and below this are instructions covering the type of machines on which the work is to be done, all necessary directions as to spindle speeds and the necessary gearing, as well as the standard time per piece.

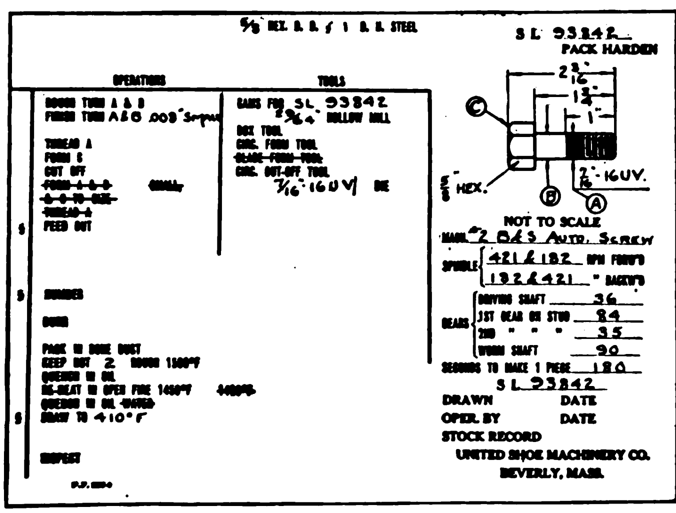

FIG. 1. SHEET FOR ⅝-IN. CAPSCREW

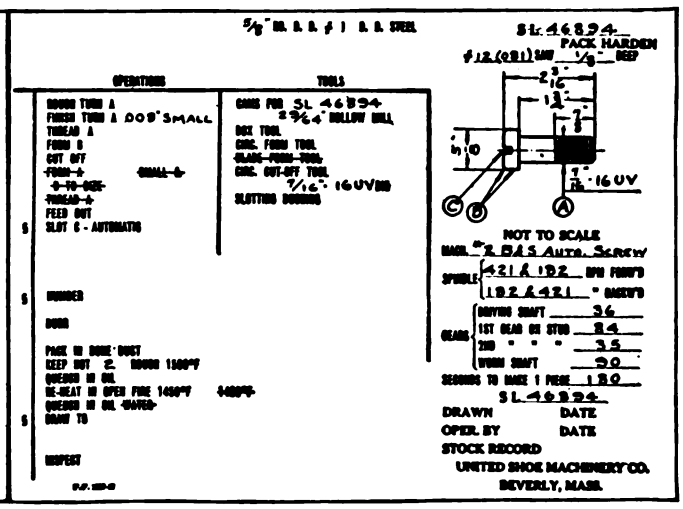

FIG. 2. SHEET FOR ⅝-IN. SCREW

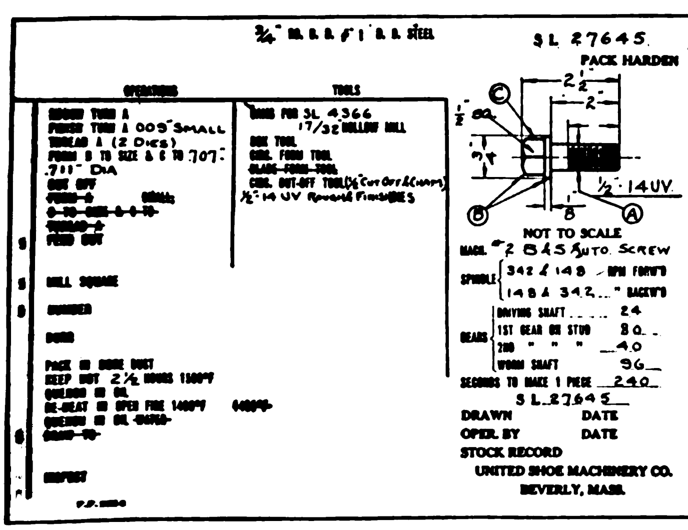

FIG. 3. SHEET FOR COLLARED CAPSCREW

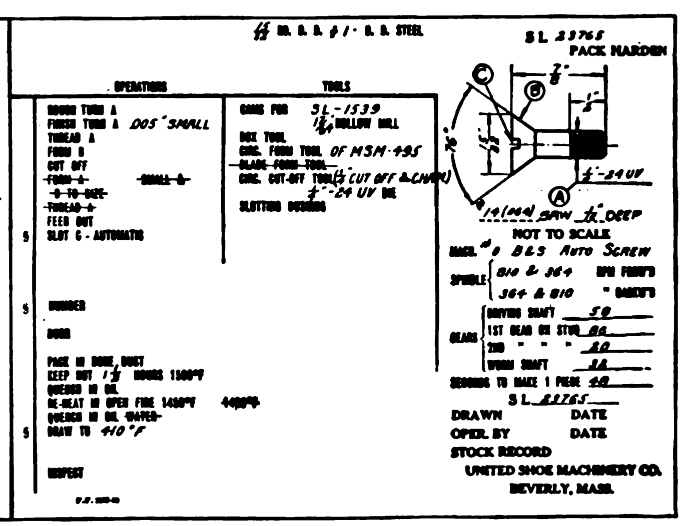

FIG. 4. SHEET FOR CONE-HEAD SCREW

*Chief draftsman, United Shoe Machinery Co.

The left-hand column contains all the necessary operations and any special directions. Unnecessary operations are crossed out, and below this there are directions for the proper pack hardening in each case. The central column shows the necessary tools to be used.

Although only 16 examples are shown these printed sheets now cover about 30 subjects and will be added to from time to time. They include, in addition to the parts shown, cam rolls, shouldered cap screws, special screws and work of this nature. It can easily be varied or enlarged to suit the individual of different shops.

This method, as will be seen, gives a very uniform set of drawings. As the draftsman is only required to add a few dimensions and perhaps cross out a few unnecessary

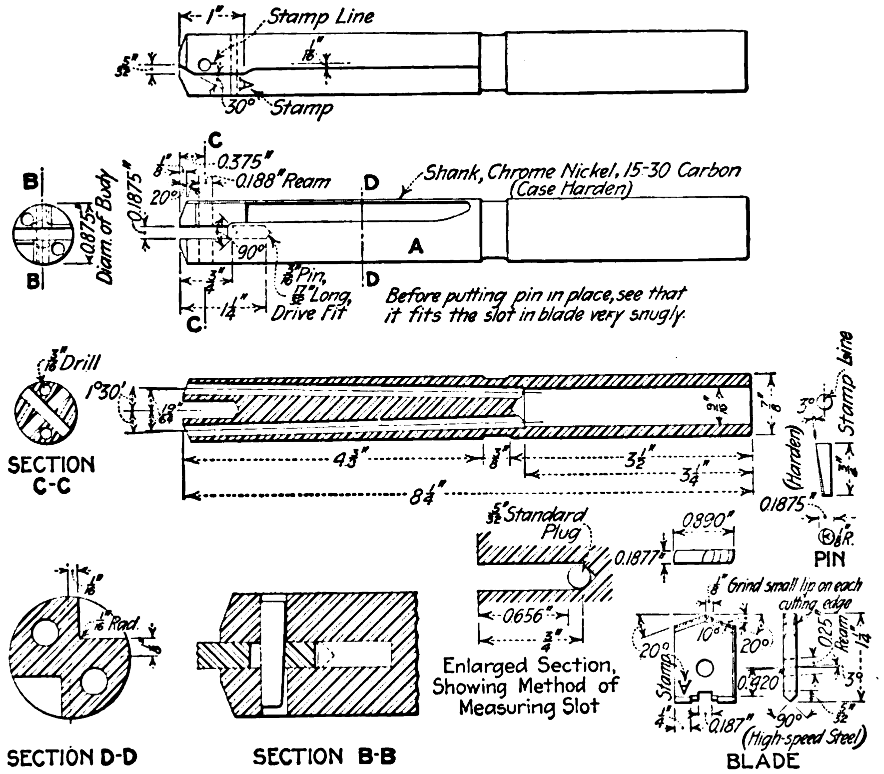
instructions, it effects a large saving of time. It also gives uniform printed lettering in each case, which avoids all difficulty as to instructions not always being perfectly legible. The instructions which are added can be done on the typewriter if preferred, as the sheets are small enough to be handled easily in that way.

This system was designed by the writer some time ago and has been put into practice in the drafting rooms of the United Shoe Machinery Co., Beverly, Mass., where it is proving highly successful in every way. This system can be modified to suit almost any shop conditions where the work is of sufficient volume to warrant printing the blanks.

An Inexpensive Inserted-Blade Oil-Feed Drill

By B. W. Raymond

With the price of high-speed steel soaring to nearly $3 per lb., it becomes necessary to take special precautions to save the high-speed steel one has on hand. The drill shown herewith was designed with this purpose in view. The body *A* is of cheap chrome-nickel 15-30 carbon steel; the blade is of high-speed steel. As it is very small, it is not expensive. The rest is self-explanatory.

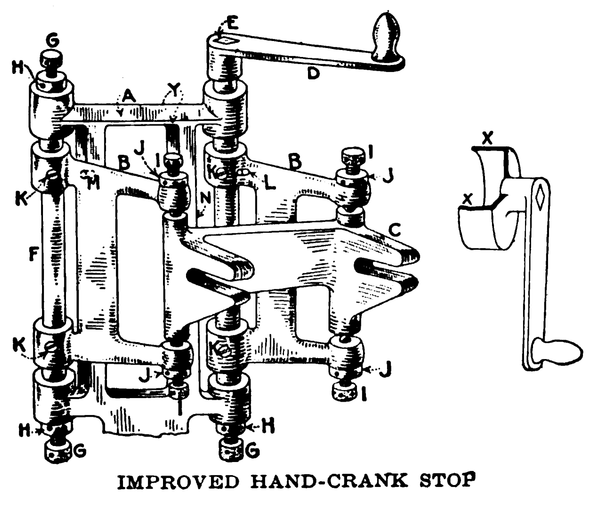


AN INEXPENSIVE INSERTED-BLADE OIL-FEED DRILL

Improved Hand-Crank Stop for a Small Machine

By George G. Little

The illustration shows the upper half of a small machine used for cutting very thin sections of specimens for microscopic work. Rigidity and free action are essential.



IMPROVED HAND-CRANK STOP

A knife, not shown, is held in the jaws of the casting *C* by two screws, also not shown. The casting *C* is moved from right to left by the swing arms *B* and works on the pivot screws *I*, which are locked by the collars *J*. The arms *B* are controlled by the shaft *E*, the upper end of which is squared to receive a hand crank *D*. By pulling the hand crank from right to left the arms *B* will be swung around until the stop pin *L* comes in contact with the corner of the frame *A* at *N*. The left-to-right movement brings the pin *M* in contact with the other side of the frame *A*, thus making two limit stops.

The headless screws *K* secure the arms *B* to their shafts *E* and *F*. These screws are large enough to stand all the strain of the work of moving the knife back and forth, but the mechanical principle of applying the limit stops is all wrong. The pull on the hand crank causes the shaft *E* to move a part of one revolution, causing the arm *B* to swing around until stopped by the pin *L* striking against the frame *A*, thus throwing all the strain on the points of the screws *K* and working them loose.

The limit stop should be applied in such a manner that any other pressure on the hand crank will not cause any part of the machine to become distorted or loosened. The small detail showing the hand crank remodeled gives a better method of stopping the arms—by the edges *X* coming in contact with the frame at *Y*. This principle is one that is easily applied, as well as one that is frequently overlooked in designing machines.

Spontaneous Explosions

Every little while an explosion occurs in a subway, sewer or trench or in an electric-wire tunnel or some other subterranean conduit or passageway under circumstances such that it is exceedingly difficult to determine the cause of the accident satisfactorily. Such explosions have often been attributed to sewer gas, which contains a considerable proportion of methane and hydrogen. These gases are exceedingly combustible and quite capable of exploding with extreme violence when mixed with air in the right proportion and fired with a spark or a flame. This much is quite generally admitted; but in many cases the difficulty is to account for the ignition of the mixture, when it appears to be impossible to ascribe it to the action of any recognizable external agent, such as electricity or flame.

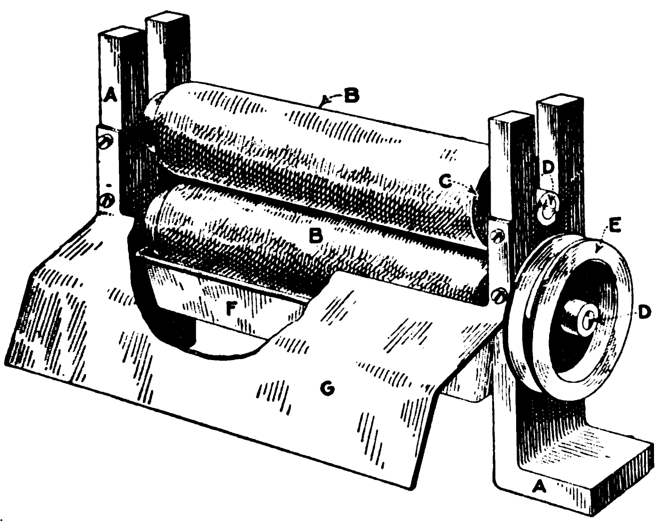
It is well known that, during the decomposition of the organic matter in sewage, microscopic plants of a certain kind grow in the mass and act upon it in such a way as to cause about two-thirds of it to liquefy, while the remaining third remains in the solid state. When the conditions are favorable, phosphine gas is occasionally generated in the course of the bacterial action; and this gas, when impure, has the peculiar and unusual property of taking fire spontaneously upon coming in contact with the air.—"The Travelers Standard."

Letters from Practical Men

Device for Oiling Stock in a Punch-Press Room

This device can be made to requirements. For oiling stock, it is both quicker and cleaner than a brush.

Two pieces of flat cold-rolled steel *A* are bent to the desired height. The rollers *B* are made of wood and covered with felt *C*. The shafts *D* are of iron pipe, one being longer than the other so as to carry the driving



DEVICE FOR OILING STOCK IN A PUNCH PRESS

pulley *E*. The oil pan *F* is carried on two side supports and two adjusting screws, at a height so that the bottom roller is in oil for about one-fourth of its diameter. The sheet-iron support *G* is to take the strain off the rollers and allow the stock to be fed in and carried off on the other side by the friction of the two rollers.

The device is driven by a belt off the main or countershafting, and when not in use can be thrown off.

New York, N. Y. A. Elting.

Chuck for Packing Rings

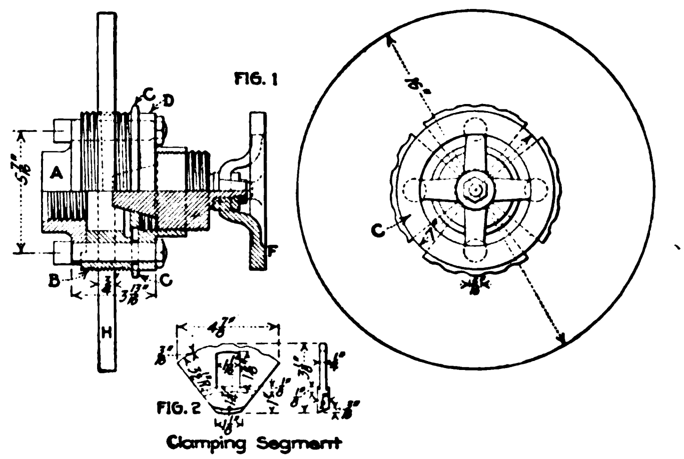
There is a variety of opinions as to how cylinder packing rings should be finished for various kinds of duty. Some men hold that grinding on a magnetic chuck is the only proper way to insure a true face; others say that facing one side at a time in a split bushing gives the best results. From close observation of both methods I have found that the chucking of the casting from which the rings are cut necessarily distorts it. After the rings are cut off with a fraction of an inch of stock for finishing, the chucking strain is relieved; and the result is a warped ring. Now if this warped ring is drawn down on a magnetic chuck and faced, the same warp will appear when the magnetic influence is withdrawn.

The principle is exactly the same when the ring is crowded into a split bushing and faced. When the holding force of the bushing is relieved, the ring will be more or less warped and will rock on a surface plate.

The illustrations show a device that overcomes these obstacles by facing both sides of the ring at the same time, and any irregularities in the ring are faced off without chucking strains. Fig. 1 shows a sectional view of the assembled chuck. The plate *A* fits the spindle of the lathe, and to it are bolted by means of the fitted bolts the parts *B*, *C* and *D*. The segments *C* are free to move on steel ferrules.

The operations necessary to chuck a ring are as follows: Revolve the faceplate *H* on the disk *B* so as to square up a packing ring that is placed over the four segments *C*. Tighten the ring by turning the wheel *F* clockwise. When the ring is sufficiently tight, start the lathe and back the faceplate *H* toward the headstock. This action will allow both the inside and the outside faces of the ring to be cut at the same time by means of a forked tool.

The segments *C* are constructed as seen in Fig. 2, with the width $\frac{1}{16}$ in. less than the finished width of the ring. The faceplate *H* can be made large enough to



CHUCK FOR PACKING RINGS

include the largest size of ring, so that it is only necessary to have one set of segments for each inch of increase in the diameters of the packing rings.

On this chuck from 200 to 250 rings can be faced in 10 hr., and every one will gage properly in any position.

Meadville, Penn. Floyd R. Stewart.

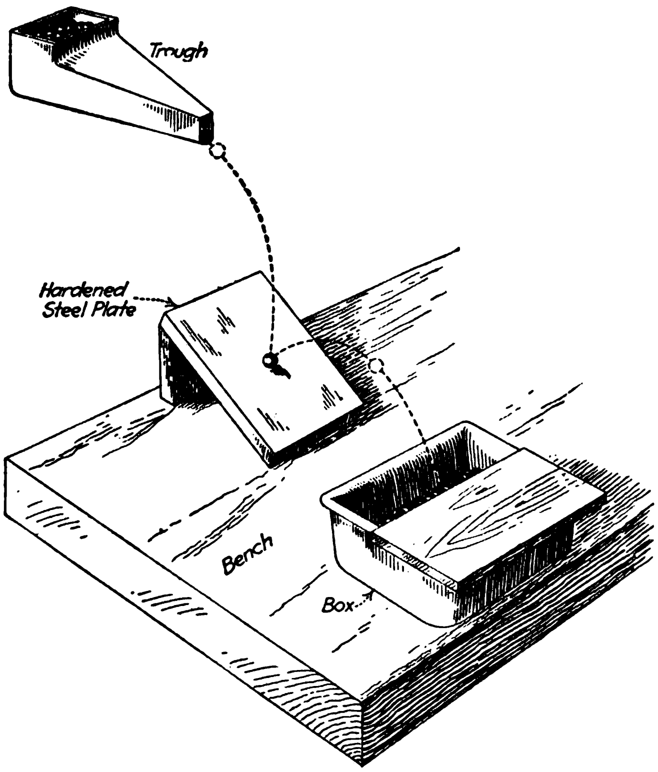
Balls for Ball Bearings

The diameters of balls that can be commercially obtained are marvelously accurate when the very low price is considered. Of equal importance is a uniform hardness in each ball, especially when the load is near the maximum. To measure the diameter of the ball is not difficult, and the spherical form seems to be generally perfect. A very clever way to select the balls so that their hardness will be practically the same is as follows:

A hardened steel plate, either firmly fastened to a bench or of sufficient weight in itself not to be easily moved, is set at an angle. The steel balls are put in a trough so made as to allow one ball at a time to roll out and drop, say a foot, onto the steel plate, from which the ball will bound and fly off at an angle. A selected ball is dropped onto the plate, and a steel box is moved

along the bench until the sample ball in bounding will just get over the edge and fall into the box.

A second steel plate is laid on the top of the box just far enough from its edge to allow the steel ball to enter it. If now a second ball is dropped from the trough onto the plate and it is of the same hardness as the first, or sample, ball, it will also bound and pass through the



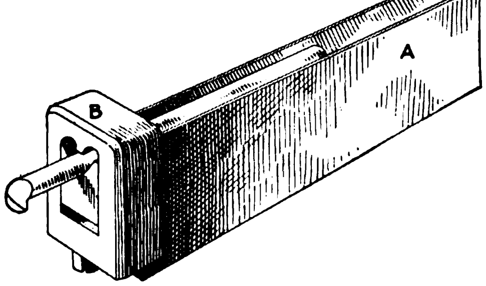
TESTING HARDNESS OF BALLS

opening into the box. It is evident that, if the balls are equally hardened, this system will separate them accordingly. Of course if the balls vary considerably in weight, this method would not work out very well; but in practice it will be found to be quite serviceable under average conditions. A. R. NEMOUR.

New London, Conn.

Holder for Small Boring Tools

The illustration shows a holder for small boring tools. I made it some time ago for sinking small circular forms in cold striking dies. It answers the purpose much better than any holder I have used of the ordinary type, as it



HOLDER FOR SMALL BORING TOOLS

projects only a short distance above the V-block of the holder and the cutting edge of the tool.

The tool is held by the screw beneath drawing the clamp down on the tool and holding it firmly in the groove. The screw does not project below the bottom and so does not interfere with the free movement of the tool holder on the shoe of the tool post.

The holder *A* is of machine steel, carbonized, hardened and ground on the bottom. The clamp *B* is of tool steel, spring tempered. This has made a very convenient tool on small boring work of various kinds.

Bridgeport, Conn. C. W. OVIATT.

Drill Jig for Pins

In the illustration Fig. 1 is shown a simple drill jig for the pin shown in Fig. 2. The clamping member consists of a wedge *A* actuated by an eccentric cam *B*.

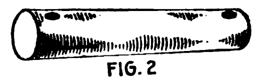


FIG. 2

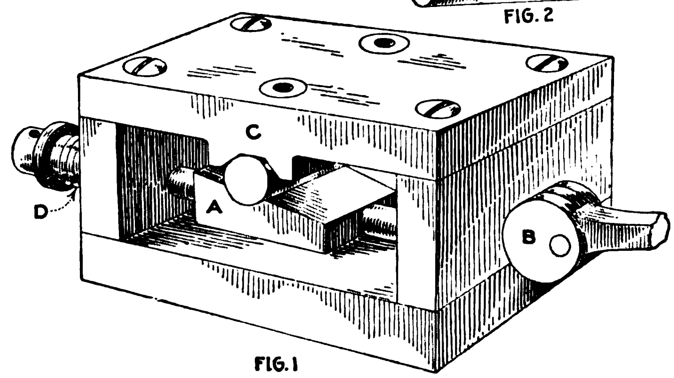

FIG. 1

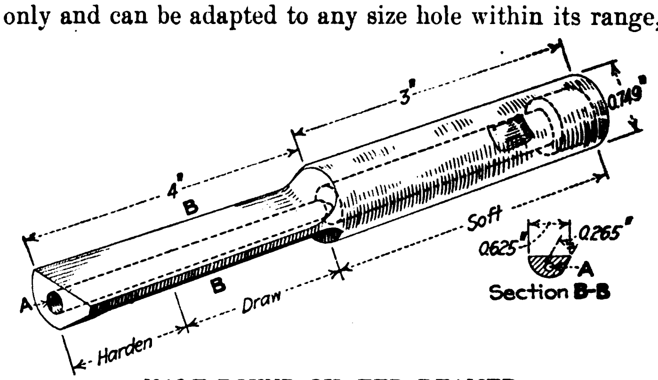
DRILL JIG FOR PINS

As the cam is rotated, the wedge bar is drawn endwise, thus clamping the pin in the V-block *C*. The function of the spring *D* is to return the wedge bar when the cam is released. The work is located by a stop pin *E* at one end of the V-block. The angle of the wedge-bar is made with the angle at least 5 deg. less than the angle of the V-block. Also, the rise of the cam should be about 10 deg., so that it will not slip. W. BURR BENNETT.

Bridgeport, Conn.

Half-Round Oil-Fed Reamer

A good design of half-round oil-fed reamer is shown in the illustration. The tool cuts on one side of the hole only and can be adapted to any size hole within its range,



HALF-ROUND OIL-FED REAMER

which in this case is 0.687 to 1½ in. The reamers were designed for extremely long holes, where other reamers got filled with chips and would not ream the hole to size.

An oil hole *A* runs through to the large hole in the shank, and the oil is pumped into the large hole at a pressure of about 10 lb. RAYMOND W. BECKMAN.

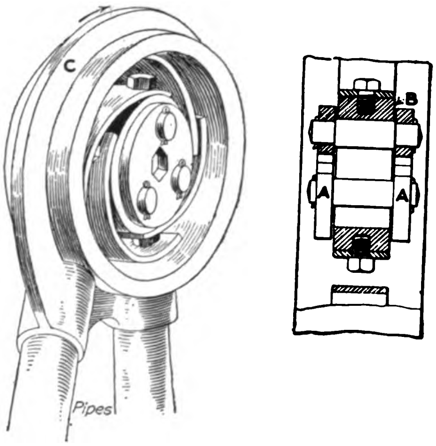
Dayton, Ohio.

Discussion of Previous Question

Preventing Rod Vibration on Automatic Screw Machines

On page 74, Raymond Grant complains about the difficulty of preventing severe vibration of the bar stock on automatic screw machines. This seems to be a common fault with screw machines and a detail to which little attention is given by designers. Of course, care should be taken to straighten the rods carefully, but even then the usual stock holder seems to be not efficient.

The accompanying illustrations show one way of helping the matter. In this device the bar stock is supported and guided by two plates *A*, which are broached to the proper section of the bar, leaving the correct clearance.



DEVICE FOR PREVENTING ROD VIBRATION ON AUTOMATIC SCREW MACHINES

These plates act as a carrier for hardened-steel rollers that track on the hardened-steel ring *B*. Thus as the bar revolves, it carries the plates and rollers with it and at the same time is free to feed endwise. Fastened to the outside of the steel ring *B* are four steel springs, shaped as shown and properly secured to the cast-iron frame *C*. In this way the center element of the device is flexibly supported and free to move in any direction, adapting itself to the "threading" of the bar stock. The frame should be rigidly supported from the floor by two pipes arranged as shown. W. Burr Bennett.

Bridgeport, Conn.

Over-Safetyized Machines

I can appreciate the feelings of H. B. McDermid, as expressed on page 371, and yet there is another side to the question. To my mind a pipe railing is a menace unless the space between is filled with netting in some such way as he mentions and to which he seriously objects. Such open rails are dangerous, as affording only false security instead of the real thing.

Floors often become slippery from oil, and many a man who was neither drunk nor careless has slipped when near a rail of this kind. And if he missed the rail itself, his arm or leg has gone between the rails and been injured by the machine inside.

The drilling machine was a horrible example, but largely because the guard was fixed instead of having a side open to shift the belt. Or better yet, a good belt shifter would have made this unnecessary and have been safer into the bargain.

I do not believe there is a tenth as many intentional injuries as many seem to think. And while many inspectors are doubtless deficient in mechanical judgment, they unfortunately have no monopoly on that—many shop men can give them a good run for their money.

What I object to most is the indiscriminate use of "Safety First" signs, carelessly put up and tending to make the term meaningless. Frank C. Hudson.

New York, N. Y.

Machinist Instruction in the Public-School System

It did my heart good to read the common-sense article by Mr. Prince on page 211. Much is expected of this vocational-school movement (I should have said trade-school movement, as the word trade pins us down to an objective, while the word vocational is a trifle evasive and elastic), and I had begun to fear that the trade school had already started to deteriorate into a manual-training proposition of ultra-shiny work and blue ribbons.

Trade schools are intended to teach trades, and the nearer you make the school shop like the commercial shop the better and quicker will the boy amalgamate with the commercial shop when he leaves the shelter of the school. No boy really knows a trade today unless he has speed as well as accuracy. As his day-rating is fixed according to the amount of work he turns out accurately during his first week in the shop, it is worth 25c. or 50c. a day for him to have speed the minute he enters the factory. Most of us know from experience that once the day-rating is set, it requires months of the hardest kind of plugging to have it raised. Besides, if a boy is slow when he starts on his new job and later acquires the necessary speed, the foreman takes upon himself the entire credit for the boy's whole training and overlooks everything else that he may have known when he entered the factory. It is a big asset for a school to nourish every little bit of school credit that it can.

Trades cannot be taught by educators. Trades can be taught only by men who know their trades thoroughly and in whom the boys have confidence. When I see the number of educators with their raffia-work sort of trade instruction, who have crept into our trade schools, I become alarmed for the future. They seem to fail to grasp the fundamental fact that trade schools were designed to make the boy self-supporting and family supporting. Many trade schools, even as early in the history of trade-school education as this, have declined to the same impractical level, as far as bread and butter is con-

cerned, as the general-course high school, and we all know what the educators have done to our high schools.

There have been so many repeated disappointments in the ability of our high-school graduates to hold down even elementary jobs that the public has come to expect very little from them. In trade-school work each instructor must hold himself, and must be held, responsible for each boy's instruction in his department. When the responsibility is spread out too thinly over an entire system, as in high-school work, then the school deliberately fails in its purpose. The instructor in planing, for instance, should be held directly responsible for the boys that make a specialty of planing, provided of course that he does not have such a large number of boys that he cannot make the instruction individual.

In going through one of our large factories one day a short time ago on a follow-up trip to see how our boys were doing on the job, a foreman pointed out to me a little fellow who was working away like a beaver. "Mr. Spence," he said, "young Nichols, there, took hold of that Norton grinding machine like a veteran from the beginning. You certainly gave him a flying start at the trade school." Immodest, perhaps, but if Nichols had proved to be a dismal failure, what alibi should I have had, as instructor in grinding, to hide behind?

If only responsible instructors are hired—men who have bucked up against shop conditions, who take pains to conscientiously prepare the boys to meet these conditions man fashion, and who instill into the boys the proper spirit toward their work—then the trade school can fulfill its mission.

In certain towns where manual-training work is being given under the guise of trade training, factory managers have no further use for the graduates of the school as a whole. The result is that the boys are forced to leave town to work where they and the school are not known. It is poor economics that permits this condition, for not only does the town lose the money already invested in the boy's whole public-school education, but it loses a future valuable citizen. It might be well for these schools to hire a few instructors whose hands are ingrained with cast-iron dust and drop overboard those whose knowledge extends only to the making of a parlor center-punch, a music rack or a tabouret. In our Worcester school the local demand for graduates has always exceeded the supply, and we always intend to live up to our standard of thorough trade training without any frills.

Worcester, Mass. ROBERT J. SPENCE.

Empirical Design of Piston Pins for Gas Engines

On page 111 Messrs. Lewis and Kessler show different details of piston-pin design, also formulas. On page 254 Mr. Sweet suggests cast-iron pins instead of steel. Gray-iron pins are satisfactory in steam engines, but not, in my experience, in gas engines.

Twelve years ago a plant in the western part of Pennsylvania changed the motive power for driving its hydraulic machinery from steam to gas, and gas engines of the crosshead type were installed. One of the superintendent's hobbies was gray-iron crossheads, and these of ample proportion were fitted to each gas engine. Special care was taken that they were sound, made of charcoal iron and carefully molded. They proved a failure, as they would last only from two to three months and then break. The only remedy was to make new ones, cast of steel instead of gray iron.

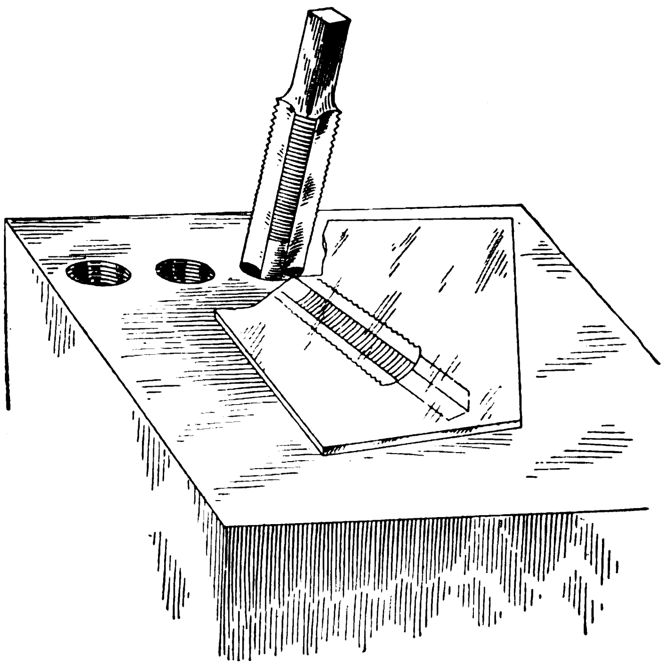
Another gas-engine builder using gray-iron crosshead pins had a similar experience, although he spared neither money nor brains trying to make a go of it. Therefore experience dictates that where hard or continuous operation is required, a high-carbon steel pin tempered and ground as stated in paragraph 3, page 111, should be used. Gray-iron piston pins in open-type pistons would mean a wrecked engine if they should break.

One point should be observed in regard to the taper of piston pins. A taper of 5/8, 1/2 or 1/4 in. per foot is better than 1 in., as given. A smaller taper gives a better grip in the piston bosses and is less likely to jar loose if crosshead brasses or bearing gets loose or pounds. owing to improper taking up for wear. G. STROM.

Titusville, Penn.

From a Small-Shop Notebook

Mr. Van Deventer's interesting pages from a small-shop notebook remind me of a much simpler method of starting a tap straight than any shown there. I occasionally use an old piece of a broken mirror, laid by the



SIMPLE METHOD OF STARTING A TAP STRAIGHT

hole to be tapped. The angle by which the tap deviates from the normal is doubled by the mirror, and the discrepancy is easily noted. When the tap and its reflection are in one straight line, the tap is normal to the work. This may be an old scheme, but I have never seen it described. K. PECK.

Ashtabula. Ohio.

A Beneficial Effect of High-Speed Steel Scarcity

The editorial on page 213, which discusses high-speed steel and the effects resulting from its scarcity, brings to mind a condition that existed in some shops prior to the advent of high-speed steel and furnishes another point to consider when the question of returning to

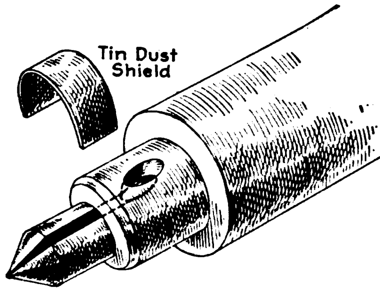
carbon steel presents itself. Many concerns were using cheap grades of steel for tools, and any attempt by foreman or machine hands to get a better grade was futile, because of a difference of perhaps 5 or 10c. per pound in cost.

When high-speed steel came into use, people changed from 10c. carbon steel to 80c. high-speed with scarcely a murmur, when they could not be induced to buy a 20c. carbon steel. It is one thing to strive for improvement in the output of carbon steel and another to strive for a good grade of carbon steel to increase the output.

Cleveland, Ohio. G. W. RICHARDS.

Oiling Dead Centers

Herewith is a sketch of my scheme for oiling centers. A hole in the tail spindle allows oil to flow in a groove on the dead center. Common machine oil ought to work



OILING DEAD CENTERS

all right for high speeds and light cuts on small work; but for large and heavy duty, something with more body to it, like a mixture of white lead, graphite and oil, should be used.

Stockton, Calif. M. JACKER.

Bending Small Tubes Without Rosin Filling

Referring to the article on bending small tubes, on page 118, we do a great deal of this sort of work using the spiral spring method. Instead of removing the spring by the means described, however, we have a cross-handle attached to the wire coil. A twist or two with the hand winds up the spring sufficiently to make it easily removable. This seems to us to be quicker than using the lathe.

At first, various grades of brass wire were tried, but the result was unsatisfactory. Steel wire has been substituted, and no trouble is now experienced, except that it is a little harder to withdraw the spring from a bronze tube than from a brass one. Thanks to Mr. Nemour, we are going to try a different lubricant, having so far used soap.

Jersey City, N. J. H. D. MURPHY.

Power-Press Accidents

On page 231 C. B. Hayward refers to power-press accidents. The operator will most naturally say that the guard failed to work properly and the ram descended the second time. To allow sufficient time between each operation is somewhat difficult, but it is my opinion that the majority of power-press accidents are due to haste and to disobedience to instructions. In the reduction of shells the operator, instead of keeping his fingers on the outside of the work, will invariably, after a time, place one or more fingers in the interior of the shells, as it is quicker to handle them in this way. This action places him in danger, should something go wrong with the mechanism of the press or guard, as the case may be.

With safety devices that compel the operator to use both hands in order to operate the press I have seen men attempt to manipulate the machines with one hand, using a wedge for tripping the other handle.

Some power-press operators do not appreciate the efforts to safeguard them, wilfully disobey instructions and improperly use the devices placed on the machines for their benefit. Regardless of the particular device used, the operator must at all times be alert and ask himself if it is worth while to take any chances.

East Rutherford, N. J. GEORGE F. KUHNE.

C. B. Hayward, in his article about accidents on power presses, page 231, ends by saying "Therefore, as there seems to be no feasible and practical way of preventing the 'falling gate,' it is up to the man running the press to keep his hands out from under the punch as much of the time as possible." In 16 years of experience having to do with a number of power-operated and also a great number of foot-operated presses I have never had a power press in our works repeat, or known of one's doing so.

We had one operator cut off part of a finger under a power press, and this man claimed that the press repeated; but the foreman questioned his statement, as he himself had worked on the same press for several years. Where work had to be put on the dies, we devised fingers, or pick-ups, so that there was no occasion for the operators to run needless risks either in placing or removing the work. It was quite a different story with our foot-press operators. It was a daily occurrence to have them slip their fingers, which would lead us to believe that most press accidents are due to inattention on the part of the operators. I do not mean to say that power presses do not and cannot repeat, but I believe that in many cases when accidents happen this explanation is a press-room fixture.

I have several sizes of presses fitted so that speeds can be varied, and I always start in new help by running the press at a very slow speed, then increasing it from time to time until the operators are capable of feeding at almost any speed.

Waterbury, Conn. THOMAS MCCABE.

Job-Hunting Technical Unions

Your editorial on page 300 points out that all the older national engineering societies are wrestling with the problem of the engineer and public esteem, from which it may be concluded that something is wrong.

In many respects the American engineer is admirable and is even superior to the foreigner; but he stands undeservedly low in the estimation of his fellow-citizens, which fact is known all over the world. Even a German "Herr Doktor" Engineer (I quote from memory) some years ago, after a flying trip through the United States, ventured a long-winded article in the *Zeitschrift des Vereines Deutscher Ingenieure* on the situation of the

American engineer. His parting shot was, "One day America will regret having mistreated its 'draftsmen' so badly." The word "draftsmen" was not translated. It indicated the educated engineer, and then and there is expressed fully and cleverly how lowly the American rates his technical men.

The doctor, however, drew his conclusions from conversations with American engineers. The ungratefulness of the public was pointed out as the cause of the engineers' troubles, but here I am forced to disagree with the doctor and his informers.

Having had the privilege of working ten years in Europe, Asia, Australia and America, I have had opportunity of judging by honest comparison, and I maintain that the public—the employer—is innocent. The guilty man is the American engineer himself. His social standing in his community is lower than that of his brother engineer in any other country, and he alone is to blame.

The American engineer lacks a becoming amount of professional self-respect, or respect for his profession. His recognition of the "just as good as you" principle, however admirable in its proper place, often prevents his "better" knowledge from taking a decided stand against opinions of those who lack proper training.

The American engineer "sees more" in salesmanship than in design or management. How can he expect recognition from laymen where he himself falls short? His desire for direct material gain at the cost of love for his profession has been fatal. Notwithstanding the American engineer's better salary, his foreign brother is better situated. Shorter hours, recognition, a fair salary and no lay-offs form the basis of a comfortable life.

The American engineer, especially the younger one, is less stable and more wasteful than the engineers of other countries, with the result that he usually is poor in pocket and has to accept what comes along.

The national societies alone cannot materially alter the public esteem; but each individual engineer, by word and action, has to prove that, besides the material end, there is something greater and more beautiful in engineering. The layman soon will recognize the "distinctive technical qualities" and his appreciation will be expressed in hard cash, that being the American way.

The small percentage of American engineers who have not jumped around and whose salaries are low on account of a (usually) imagined lack of experience might well study such books as Van Deventer's "Machine-Shop Management." Some of them will discover that they have grown unperceived into full-fledged superintendents or chief engineers. The consequent enthusiasm will have a marked effect on their pay envelopes.

Brooklyn, N. Y. JAN SPAANDER.

A Beneficial Effect of High-Speed Steel Scarcity

I read with interest the editorial on page 213, relative to the present scarcity and high cost of high-speed steel and the economies that are being practiced. This article recalls my own experience when confronted with a similar problem.

About 30 years ago I was employed as master mechanic and general mechanical factotum in a car-manufacturing plant, where the company was in the last stages of financial decomposition. As we could obtain no credit, we could not secure any tool steel.

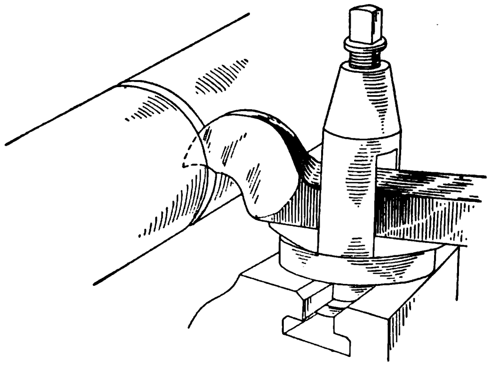
We made our own car wheels, so it occurred to me to experiment with chilled cast iron for tools. I was agreeably surprised at the excellent results obtained from the chilled cast-iron tools we came to use on all our lathes and planers. The greatest difficulty I encountered at first was that the tools would snap off where they were secured in the tool post. I overcame that by making the body of the tool heavier and also by making larger tool posts. During the time I remained with that company no other material than chilled cast iron was used for tools, and this practice was continued in that plant for over 10 years.

I also used chilled cast-iron tools successfully about 15 years ago. We had four locomotives, and all of them had badly worn tires. It was necessary to turn the tires, in order to keep the engines on the rails. I had the misfortune to be detailed for this work. Owing to their hardness, I was unable to find any brand of steel that would cut them. I suggested chilled cast iron and was directed to try it. While I had some doubt, on account of the hardness of the tires, the chilled tool cut everything it came in contact with; and it would stand a heavier cut than any high-speed steel I had previously used on similar work. The chilled-iron tool has the merit of being very cheap as compared to the high price demanded for tool steel, and I am surprised that more manufacturing plants have not used such tools, especially on roughing out work.

Mount Carmel, Ill. G. H. GREGORY.

Cutting Downward in the Lathe

Reading about backward cuts with a lathe, in your editorial on page 255, has led me to describe an interesting method of dividing, or cutting off, shafts. The illustration shows a dividing tool that never fails on any diameter, but the machine must be running backward.



GOOSENECK LATHE TOOL

As an example, I will state that I have parted 6-in. shafts between centers and outside the steadyrest with this design of tool, by throwing in the finest crossfeed and feeding to the center of the piece. The gooseneck is not for spring, but to get the cutting edge elevated to the center of the machine. A. G. BILLINGSLEY.

Sharon, Penn.

Editorials

Copying Machine Tools

The tremendous demand for American machine tools, the entrance of many new firms into this manufacturing field and the insistent pressure for early and still earlier deliveries have brought about a situation that might easily have been predicted. American machine tools are being copied by American designers. This is no new situation, but one that is more noticeable than usual because of its extent. Some comments have reached the *American Machinist* recently to the effect that this practice should receive wholesale condemnation—root, trunk and branch. We have been urged many times in the years gone by to take this same position with regard to German manufacturers who, it has been alleged, have resorted to wholesale copying of American machines. The *American Machinist* has persistently refused to take any such dogmatic position.

There are so many interests and principles involved in any discussion of machine-tool copying that clear thinking, and not opinion or emotion, must determine what is said and done.

The rights and interest of the public in such matters are clearly defined. Under our patent laws an inventor or owner of a patent has the exclusive right to his invention for a period of 17 years. At the end of that time his device becomes public property and can be copied, made, sold and used by anyone. At the end of the monopoly period his invention becomes a part of the great storehouse of mechanical knowledge, from which everyone is entitled to draw and does draw when he seeks to develop a new machine. This expression of a "common storehouse" is peculiarly applicable in the machine-tool field, for there are few machine-tool patents. The art is wide open.

Thus the designer who takes devices and mechanisms from machine tools not protected by patents is clearly within every legal right. Most of the "copying" has been of this nature. There are used on machine tools many constructions and devices that could very properly be considered as standard. In fact, the *American Machinist* has often pointed out that the standardization of machine-tool details promises decided benefits to users and builders alike and that this uniformity could be obtained with ease.

But there is another kind of copying that has been resorted to by a few firms and designers in the United States. There are cases where an attempt has been made to reproduce not only the mechanism, but the outward semblance of a well-established machine, extending in the most aggravated cases to exact copying of catalog illustrations and text. The motive behind this kind of copying is far different from that which governs the one first mentioned. And here, as in most things in life, the final result and effect must be judged by the motive behind them.

The designer or manufacturer who simply takes well-known, tried and tested devices and mechanisms from the common storehouse of mechanical knowledge and fits them together into a machine of his own, behind which he purposes to put his own reputation, is copying, to be sure, but he is acting from a straightforward motive. On the other hand, the manufacturer who not only takes tried and tested mechanisms from others, but designs a machine that has the exact outward appearance of the well-established product of a competitor may be working from a dishonest motive—trying to sell machines on the reputation of another. The most charitable view of such a course is that lack of time or designing ability has prompted a questionable act.

To show that in some cases descriptive circulars have been taken, word for word, the following parallel columns are offered. The items at the left are from a circular of a well-known firm that has been building the machine described for a number of years. The right-hand column consists of quotations from a machine-tool description published in one of our recent issues. This supposedly new matter was offered to the *American Machinist* as the description of a new machine tool. A comparison of the two columns will show any fair-minded man that the language of the second firm came from the circular of the first. The *American Machinist* regrets that it published this material in this form.

Automatic Chuck and Bar Feed are operated by the long lever in front of the head which gives increased leverage for closing the collet. A stepped wedge automatically adjusts the collet for slightly varying diameters. Extra capacity collets can be furnished for holding short-length work larger in diameter than the capacity through the spindle. Taper gibs, fitted the whole length of the saddle on each side, provide means of adjusting the slide sideways.
The hand longitudinal feed, regularly furnished with the cut-off for movement along the bed of facing, necking, etc., is operated by means of a hand-wheel in connection with spiral gears and an accurately milled screw, and is fitted with a graduated dial reading to 0.001 of an inch. Dial indicators are provided to obviate the necessity of making measurements of the longitudinal cuts.	The hand longitudinal feed is operated by means of a hand-wheel in connection with miter gears and a milled screw and is fitted with a graduated dial reading to 0.001 in. Dial indicators are provided to obviate the necessity of making measurements of the longitudinal cuts.
Geared Oil Pump delivers lubricant through an adjustable piping system to the proper place. It operates automatically when the machine is run in either direction. The steel oil pan is large and deep, giving ample space for chips.	A geared oil pump delivers lubricant through an adjustable piping system. It operates automatically.

Of course, the reputation of a machine is not made on its appearance. Beauty is only skin deep. Good material, accurate workmanship and durability have far more to do with the success of a machine than its looks or the words by which it is described. Any manufacturer who has tried to have his product duplicated abroad knows the truth of this statement. The reputable manufacturer has little to fear from his copying competitors, for in Kipling's convincing language:

They copied all they could follow, but they couldn't copy my mind.
And I left 'em sweating and stealing a year and a half behind.

The Business Languages of South America

An instructive incident grew out of the chance throwing-together of a small, energetic North American boy and three or four Spanish-speaking South American children of about his own age. After only a few days of romping and playing, the children's elders noticed that English was being used almost exclusively in the games. The North American lad was interviewed, and with rather an imperious toss of his head, he said: "Course, they use my names for things. I call things by their right names. If they didn't do the the same, we couldn't play."

The unwillingness of one who speaks English by right of birth to give up his mother tongue and the courtesy of the South American in adapting himself in gracious fashion to the wishes of another—these two traits are illustrated by this little happening. Because such a thing could happen, it is necessary to point out the languages of South America to North American business men and the attendant conditions which they must meet if they would do business on that great continent.

There are two business languages used in South America, and neither is English. The language of Brazil, with about 20,000,000 people, is Portuguese. The language of the rest of South America, comprehending an equal number of people, is Spanish. Portuguese and Spanish—these are the business languages of South America. The North American business man must not play the part of the imperious small boy, but must use in his correspondence and through those who represent him the language of the people he wishes to reach.

Under no conditions should a letter addressed to South America be written in English, unless the writer is positive that the person to whom it is addressed reads and speaks English fluently. If the writer does not know that the person he is addressing possesses this qualification, the letter must be in Portuguese if sent to Brazil and in Spanish if sent to any other South American country. On the other hand, it is always safe to answer a letter from South America in the language in which it is written.

The *American Machinist* has previously pointed out the racial traits of courtesy possessed by all South Americans, which tend at once to make them lenient of errors in language, provided the attempt to make oneself understood is genuine. Thus, a letter written in poor Portuguese or poor Spanish is far better than one written in good English. The English letter would probably reach the waste basket without an attempt being made to read it. On the other hand, the letter in understandable, though inelegant, Portuguese or Spanish would be read and its contents grasped.

All business letters written by South Americans are most courteous—in fact, to a North American, overcourteous—in style. They are cordial and even gracious. To us, both the salutation and the closing greetings are effusive. Scattered through the body of the letter are frequent phrases of direct address to the one who is to receive the letter, worded in the most polite terms. When reading such expressions, one can almost imagine the courtly lifting of the hat that accompanies the meeting and parting of business men in South America.

Three examples of common salutations in Spanish business letters are herewith given, each being followed by a rather literal translation into English: *Muy Señor mió*—My dear Sir; *Distinguido Señor*—Distinguished Sir; *Illustrissimo Señor*—Most Illustrious Sir. Three endings for letters, similarly translated, are also given: *Quedo de Vd. atto. y S. S.*—I remain to your Grace your attentive and obedient servant; *Me repito de Vd. atto. y S. S.*—I repeat to your Grace that I am your attentive and obedient servant; *Esperando sus ordenes S. S.*—Awaiting your orders, I am your obedient servant.

It is unnecessary to multiply these illustrations, for any good textbook of the language used will give numerous other examples, with comments as to how they should be employed. From these few phrases it is easily imagined how offensive our brusque North American style of letter writing must be to anyone who naturally, and by association and training, uses most courteous forms in addressing others. Fortunately, it would be impossible to translate into Spanish or Portuguese our slangy, punching, North American business-letter style.

The importance of using the language of the country in dealing with South America has been realized and acted upon by both the British and the Germans. The German has acted from his usual disposition to take advantage of everything that might count; the Englishman has accommodated himself to necessity. The final result is that the salesmen representing German and British houses are well equipped with a knowledge of the language of the countries with which they are doing business, the customs of the people and the niceties and refinements of business intercourse. These qualifications give them a decided advantage over North Americans who have failed to appreciate and learn these important things. In the case of the British, however, it must be confessed that this acquirement is a veneer, for when Englishman meets Englishman, or Englishman meets American, the brusque Anglo-Saxon ways again come to the surface.

This subject of business languages in South America is so important that everyone who is exporting to that continent should see to it that only Portuguese and Spanish are used and that the courteous forms of expression which enter into the daily business intercourse of the peoples of those countries are scrupulously observed.

Munition Manufacture Causes Many Shop Changes

One of the many effects of the making of munitions by the various shops of this country will be the emphasis laid on the advantage of subdivision of labor. Shops that have always done practically a jobbing business have been forced to subdivide the machining of shells, both in order to secure rapid production and to reduce costs.

How far the experience gained in this way will influence their work in the future, it is difficult to determine. But it is hardly conceivable that it will not affect the methods used on much of their work.

Cutting speeds will also probably be increased in many cases. Then too, more knowledge will be available as to what taps and dies can and cannot do. This of itself may have a wider influence on future machine work than we are apt to think of during the rush of the work itself. If different shops will keep notes as to the changes in methods it will make interesting and instructive reading.

Shop Equipment News

Heavy Manufacturing Lathe with Geared Head

The chief consideration in the design of the lathe shown was the manufacturing conditions for which it was intended, with the result that the spindle speeds have been limited to eight changes and the general features developed along what have come to be considered single-purpose lines.

Aside from the headstock the machine requires little description. All the parts are heavily proportioned, and the materials used follow the best accepted practice.

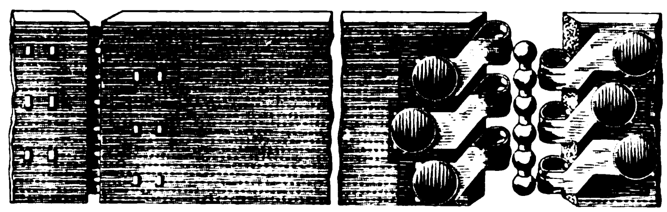
The headstock is of the selective sliding-gear type. It permits four spindle speeds from a single pulley drive, and a two-speed countershaft provides an additional four speeds. The sliding gears are mounted on the initial drive shaft directly above the lower shaft, carrying the gears keyed fast to it. The lower shaft carries a pinion that meshes with the large gear on the lathe spindle. As the sliding gears are operated by a single lever, it is impossible to engage opposite gears. Only the gears at work are in mesh. The lever operating the friction clutch in the drive pulley is interlocking with the gear-shift lever, making it necessary to release the clutch before the gears can be shifted and also to have the change gears properly meshed before the clutch can be engaged. Lubrication of change gears is taken care of by a reservoir in the headstock, permitting the gears to revolve in a bath of oil.

The machine is a recent product of Robert H. Snider & Co., Philadelphia, Penn., and is made in the one size.

Flexible Steel Belt Lacing with Ball-Bearing Joint

In addition to the noiseless and easily attachable features of the form of metal belt lacing shown, the main claim is the strength of the joint gained by the use of bifurcated rivets that clinch below the surface of the belt.

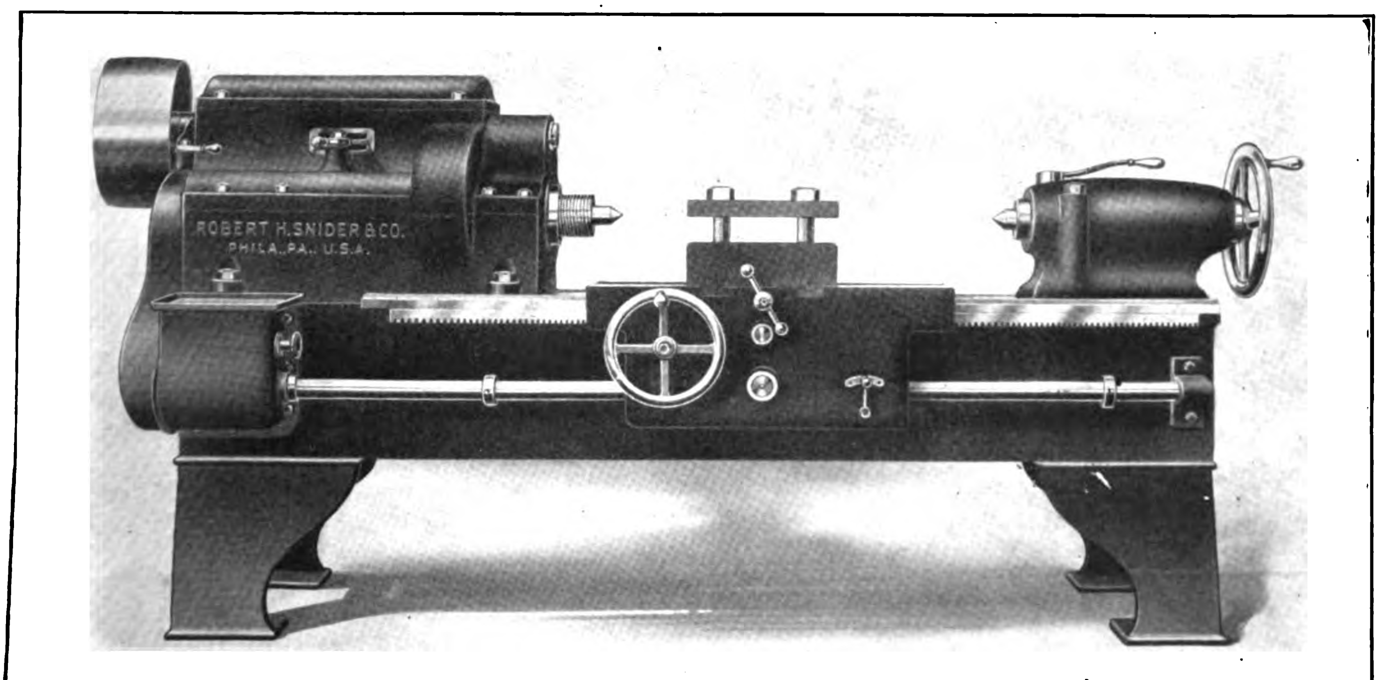
The pulley side of the joint made by this form of lacing is shown at the left, from which it will be observed that the teeth are slightly shorter than the thickness of the belt, thereby preventing any metal coming in contact



FLEXIBLE STEEL BELT LACING WITH BALL-BEARING JOINT THAT REDUCES FRICTION

with the pulleys. The right side of the illustration shows the construction of the fastener, in which the ball-bearing form is designed to reduce the joint friction to a minimum.

The lacing is made in a number of sizes to properly fit standard thicknesses of belt and is a recent product of the Manufacturers' Belt Hook Co., Chicago, Ill.

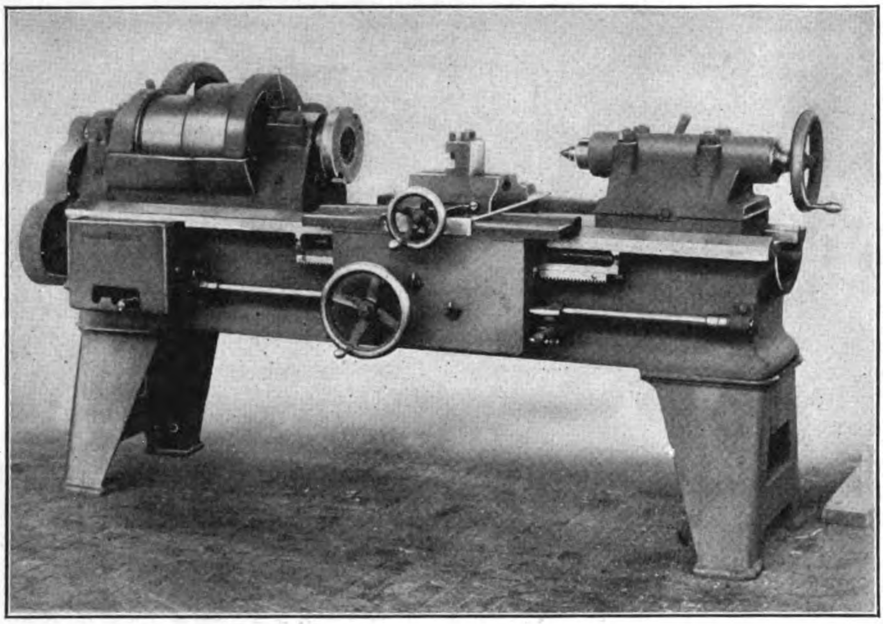


HEAVY MANUFACTURING LATHE DESIGNED ALONG SINGLE-PURPOSE LINES

Swing over bed, 18 in.; swing over carriage, 11¼ in.; distance between centers, 8-ft. bed, 38 in.; tailstock-spindle diameter, 4 in.; travel of spindle, 9 in.; minimum gear reduction, 3 to 1; maximum gear reduction, 15 to 1; driving-pulley face, 8 in.; speed of driving pulley, 250 r.p.m.; feed changes, ⅛ in., $\frac{1}{16}$ in., $\frac{1}{32}$ in.; net weight in 8-ft. bed, 4,100 lb.

Single Back-Geared Lathe

The latest addition to the ever growing list of heavy-duty manufacturing lathes is shown in the illustration. This machine is the product of the Davenport Locomotive Co., Davenport, Iowa, and in general follows the conventional lines in design and construction.



SINGLE BACK-GEARED MANUFACTURING LATHE

Swing over bed, 17¼ in.; swing over carriage, 9 in.; length of carriage, 30 in.; depth of bed, 15 in.; width of bed, 18 in.; distance between centers (7-ft. bed), 31 in.; weight, 3,500 lb.

From the illustration it will be observed that the design has been planned along what have come to be considered single-purpose lines. The main idea has been heavy-duty turning, for which driving cones of 11 and 14 in. in diameter, accommodating 6-in. belt width, are provided. The ratio of the back gearing is 6.25 to 1; the feeds, ⅛, $\frac{1}{16}$ and $\frac{1}{32}$ in., and the countershaft speed, 135 r.p.m.

Friction Surface Facing

As the result of successful application in the automobile field the Royal Equipment Co., Bridgeport, Conn., is offering its friction facing material, known as "Raybestos," for general machinery service. Various applications, such as friction clutches, hoisting drums and brake rings, will suggest themselves. The base of the material is long-fiber asbestos, so woven, rolled and treated as to possess maximum wearing qualities. The long-fiber base presents fraying, when drilled or otherwise cut.

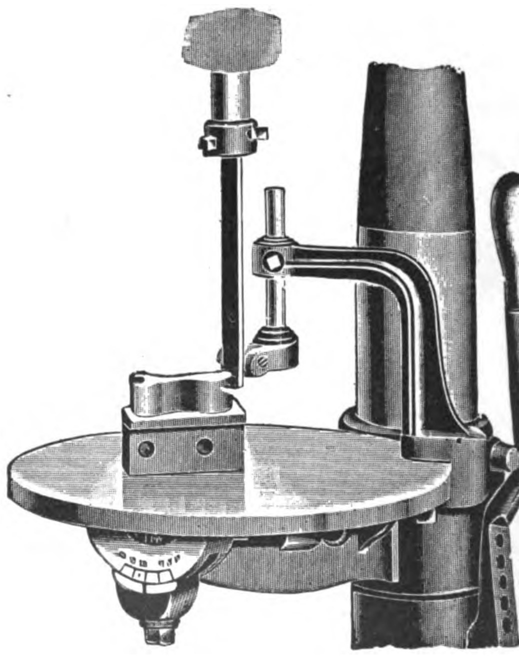
The material is claimed to be heatproof, oilproof and waterproof and can be obtained in various forms and sizes for special applications.

Combination Bench Filer and Hacksaw Machine

While the machine shown was designed primarily for die work, it is adapted for a wide variety of other applications where hand filing and preliminary drilling are usually performed.

Adjustment of the table to the right or left and forward or backward, to provide for practically any angle, is controlled by a single nut, with graduated plates on the table supports showing the angle to which the table is adjusted. It is also possible to adjust the elevation of the table for different lengths of files or changes in the stroke. A handle bolted to the base of the machine and attached to the work-table support enables the operator, by pushing the handle backward, to lower the table and remove the work from the machine without changing the position of the file or the roller guiding it.

The driving shaft at the top of the machine drives either the file or the saw in a vertical position, the cutting being accomplished on the down stroke; a quick return is provided. The range of stroke can be varied from 0 to 6 in. by loosening the nut on the crankpin and moving the latter toward or away from the center of the disk on the end of the driving shaft. The connecting-rod is pivoted on the frame of the machine and also has a pivot connection with the top of the saw frame. The file guide roller is made of soft steel and has a right and left screw to provide an adjustment for accommodating different thicknesses and shapes of files. When a saw is employed, a guide roller of hardened steel is substituted. For use when small circles are being filed or sawed or when the saw has a tendency to lift the work on the return stroke, a hold-down, consisting of a steel finger projecting in front of the file, is employed. This can be attached to any part of the work-table edge and is adjustable for any thickness of work up to 3 in.



COMBINATION BENCH FILER AND HACKSAW MACHINE

A punch-filing attachment is also provided. It is shown in the illustration and is designed for fitting work on blanking punches when they are being filed to fit a die.

It consists of an auxiliary guide roller supported by an adjustable bracket clamped to the edge of the table, as shown.

The main support for the file is provided by a roll under the table, which keeps the file in rigid contact with the work at all times.

The machine shown is the latest addition to the line made by the Extensive Manufacturing Co., 90 West St., New York City.

Shop Eye Guards

From a material known as "micalite," which possesses all of the qualities of celluloid and in addition is fireproof, Strauss & Buegeleisen, 489 Fifth Ave., New York, N. Y., are manufacturing shop eye protectors.

The material is made up in the form of eye-shields for shop workers and two colors are available in one piece without seam or pasted joint so that the line of vision is not impaired.

Spur-Gear Selection Chart

By E. E. Landahl*

The accompanying logarithmic chart is for readily determining the size of a gear when the horsepower to be transmitted and the shaft speed are given or, conversely, the horsepower that can be transmitted by a given gear running at a known speed. The table is based on the Lewis formula as given in Kent's "Handbook," using stresses for S as there tabulated for cut cast-iron teeth, one-half of these values for plain cast-iron teeth, one and one-fourth times these values for plain cast-steel teeth and two and one-half times for cut cast-steel gears. The table is based on a gear face three times the circular pitch. For other faces divide the determined horsepower by the face on which the table is based and multiply by the one to be used.

In using the table there are certain further factors of vital importance that must be carefully considered. One of these is the peripheral speed. Authorities differ as to the limiting speeds for safe usage, but good practice has determined 700 ft. per min. for rough teeth and 1,500 ft. per min. for cut teeth as the limits to be used. Another point that should be borne in mind is that the horsepower of the pinion should be traced out when the same material is used in both of the mating wheels.

As an example of the use of the chart, let us trace out a problem. Assume that we desire to determine the proper size for a gear to transmit 25 hp., the shaft speed being 45 r.p.m. This problem is traced out with a heavy line on the chart. The procedure is as follows:

Find the horizontal line corresponding to 45 r.p.m. and trace to the right until this line intersects an imaginary diagonal corresponding to 25 hp. between the lines given for 20 and 30 hp. From this point go directly up or down the table, depending on the kind of gear tooth desired. Assuming a plain cast-iron tooth, the downward direction is taken. It will be noticed that the vertical path intersects the horizontal line representing 15 teeth midway between the curved diagonals for 2½ in. and 2¾ in. This means that 2¾-in. circular pitch should be used for a 15-tooth pinion. For a 17-tooth pinion a 2½-in. pitch is satisfactory. Gears of other types can be similarly determined from the tables above the r.p.m. section, notice being made that circular pitch is plotted for cast teeth and diametral pitch for cut teeth. For example:

1. If we wish to use cast-steel cast-tooth pinion, 17*T* should be 1¾-in. pitch; 16*T* and below should be 2-in. pitch.
2. In the cast-steel cut-tooth table we could use 19*T*—2½ diametral pitch; or 15*T* to 18*T* inclusive, 2¼ pitch.
3. Passing on up to the cast-iron cut-tooth gears, we could use 20*T*—1¾ diametral pitch or 1½ pitch with any less number of teeth.

For finding the horsepower for a certain gear at a given speed simply reverse this operation.

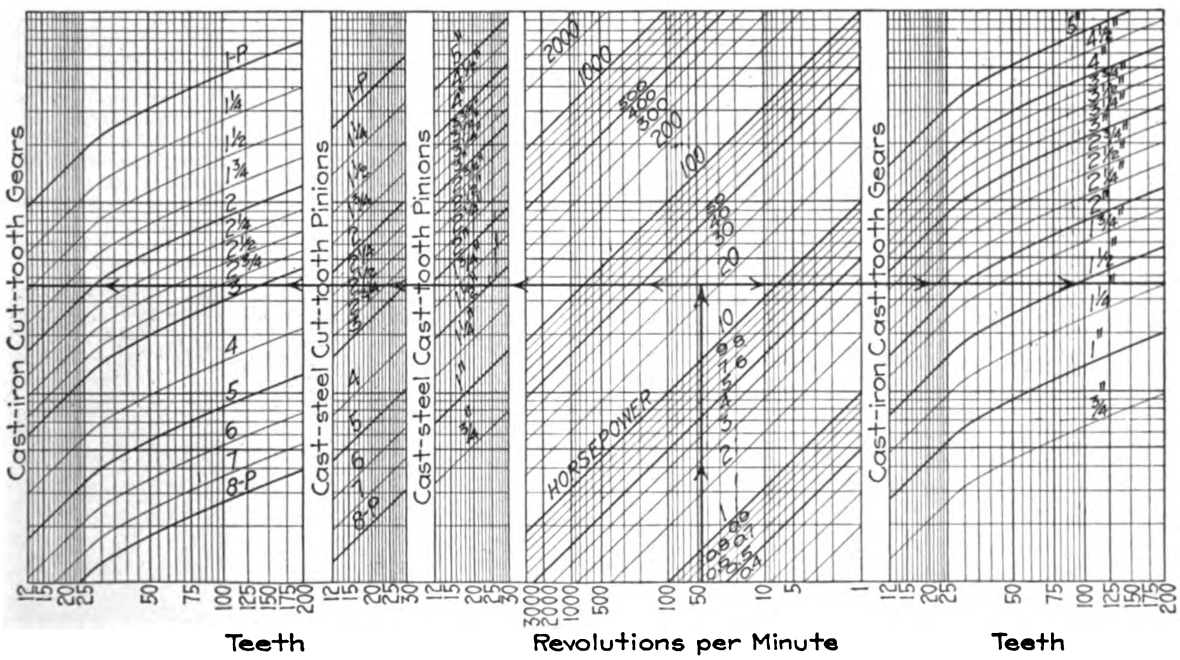


CHART FOR DETERMINING THE SIZE OF GEAR OR HORSEPOWER

*Assistant chief engineer, Webster Manufacturing Co., Tiffin, Ohio.

NEW PUBLICATIONS

THE METALLOGRAPHY AND HEAT-TREATMENT OF IRON AND STEEL—By Albert Sauveur. Second edition. Four hundred and seventy-one 7x10½-in. pages; 438 illustrations; indexed; cloth bound. Sauveur & Boylston, Cambridge, Mass. Price, $6.

Professor Sauveur's "Metallography of Iron and Steel," published in 1912, now appears in a revised and enlarged edition. In its rewriting a large part of the book has been devoted to the study of heat-treatment. Thus the new title is more accurately descriptive of its contents. Fifty pages of new matter and nearly 100 new illustrations have been added. Recent developments in the metallography of iron and steel have been included, as well as the applications of theoretical knowledge to industrial practice in the art of heat-treating.

MACHINE DESIGN—By Albert W. Smith and Guido H. Marx. Four hundred and eighty-three 6x9-in. pages; 277 illustrations; indexed; cloth bound. John Wiley & Sons, Inc., New York City. Price, $3.

In the preparation of this, the fourth, edition of a well-known college textbook on machine design, the former material has been revised and enlarged, as is plainly shown by the references to engineering information as recent as 1913 and 1914.

The original plan of emphasizing fundamental principles and methods of reasoning has been retained, and there has been no effort to make the volume cyclopedic in scope. The task of revision was undertaken and executed solely by the junior author.

INVENTIONS AND PATENTS—By Philip E. Edelman. Two hundred and seventy-eight 5x8-in. pages; indexed; cloth bound. D. Van Nostrand Co., New York City. Price, $1.50.

The author's preface states, "This volume is intended particularly for all persons interested in patents, either as inventors, investors or manufacturers. It is intended that the layman also will find considerable matter of interest."

It is difficult for the reviewer to believe that all the space occupied has been used to advantage in carrying out this purpose. The two opening chapters are historical in character, dealing with the development of the patent system and the United States Patent Office. Then follow 12 short chapters, which outline patent procedure and contain much information and good advice. The two final chapters, a number of blank pages for memoranda and an appendix, occupying in all 85 pages, do not seem pertinent or in keeping with the purpose of the volume. The lack of an interesting literary style also tends to make the reading of the book drag.

Numerous volumes have been brought out, dealing with various phases of our patent system, patent procedure, inventors and inventions. Thus a new book, to attract attention and make a place for itself, must either approach the subject from a new angle with an abundance of fresh material or develop a style of its own that will make old matter fresh and readable. In neither respect does this volume seem adequate.

MECHANICAL DRAFTING—By Charles B. Howe. One hundred and forty-seven 8¼x11-in. pages; 166 illustrations; indexed; cloth bound. John Wiley & Sons, New York City. Price, $1.75.

Reviewed by A. L. Ormay*

Although the subject is undoubtedly overwritten, the book under review immediately justifies itself in a manner with which, unfortunately, only a few of its predecessors can be accredited.

The noteworthy features are, first, thoroughness, and, secondly, the practical exclusion of all nonessentials to the subject of mechanical drawing. The book forms an excellent manual for teachers, in that it supplies all the conventions and problem sheets likely to be found necessary in any course. The treatment of orthographic projection is splendidly conceived and thoroughly worked out.

The book is divided into ten chapters under the following headings: Materials and Instruments, Principles of Drafting, Geometry of Drawing (two chapters), Working Drawings, Machine Drawing, Plan Drawing, Plot and Map Drawing, Pictorial Representation and Sketching, Blueprinting.

The treatment is well proportioned to the importance of each subject, and it is a relief to find that less than ten pages are devoted to materials and instruments, which is in marked contrast to most of the works on the subject of drafting.

In the chapter on the principles of drafting, all the operations necessary in the execution of any drawing are clearly set forth and explained. The two chapters on geometry of drawing, primarily devoted to orthographic projection, the intersection of surfaces and the development of surfaces, are simply and comprehensively worked up. A marring feature here, as well as throughout the volume, is that the wax illustrations not only present a somewhat stiff appearance, but in some instances account for misplaced shade lines and still further produce a rather amateurish effect in the surface shading.

The chapter on working drawings is essentially complete, from the manual point of view, while the chapter on machine drawing contains all the conventional screw threads, bolts and stock parts, with a number of excellent examples showing the method of dimensioning the layout of holes, ordinary and standard tapers, shafts, long screws, etc.

Individually, the chapters on plan drawing and plot and map drawing are calculated to be of value, although the elaborate treatment of architectural drafting is slightly afield in a manual on mechanical drawing. Likewise, the chapter on plot and map drawing—well written but poorly illustrated—is scarcely well classified.

In the chapter on pictorial representation and sketching the construction of isometric, perspective and cabinet drawings is taken up and the rules formulated for making working sketches.

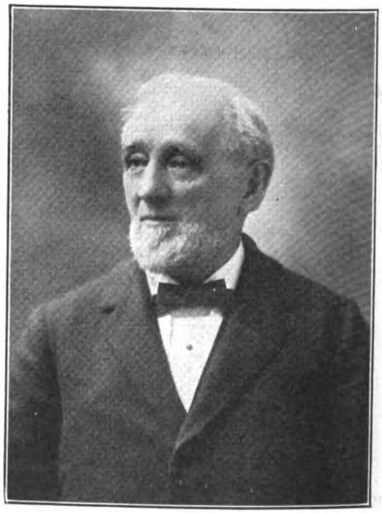
The book as a whole reflects a conscientious effort to make the treatment comprehensive, lucid and simple and conspicuously avoids the crowding in of minor details. Especially commendable features are the elegance of the typography, the arrangement of the cuts and the pleasing effect obtained by the use of an unusually good quality of paper.

*Chief Draftsman, Hill Publishing Co.

Franklin Alter

Franklin Alter, founder and president of the American Tool Works Co. and for many years a conspicuous figure in the machine-tool building industry, died at his home in Cincinnati on Feb. 23, after a long illness. Throughout a business career of more than 60 years Mr. Alter had exhibited an exceptional capacity for organization and administration. Although he had passed his eighty-fifth year, the fact that he did not live to see the completion of the new American Tool Works building now in the course of erection caused additional regret to his closest former associates.

Franklin Alter was born in Carlisle, Penn., October 28, 1831. His boyhood was spent at Hagerstown, Md., where his father was proprietor of a large farm and flour mill. When 19 years old he journeyed to Pittsburgh where he boarded a steamer for the lower Ohio and Mississippi Rivers, with the intention of going to New Orleans. The boat arrived at Cincinnati and remained several days to complete its cargo for Southern points. Mr. Alter took a look at the Queen City, was impressed with its natural advantages and decided to establish himself there.



FRANKLIN ALTER

He obtained a position as clerk with the L. Booth Co., wholesale hardware dealer. His business ability won repeated

promotions for him until he became vice-president and finally sole owner of the concern. There then followed a period of several years in which Mr. Alter devoted his energies to the establishment of several shoe-manufacturing plants. Then came his contact with the machine-tool industry, the first conspicuous step being the purchase of the Davis-Egan Co. in 1900, which was soon organized into the American Tool Works of which he remained the head until the time of his death.

During the past 15 years Mr. Alter took an active part in many of Cincinnati's civic organizations and movements and was an influential figure in the financial circles of that city. He gave unsparingly of his time to local government welfare work, and through his zealous and discriminating inspection of civic appropriations he earned the characterization of "watchdog of the treasury."

Mr. Alter is survived by his wife, three daughters and two sons. The latter, Robert and L. W. Scott, are respectively secretary and foreign trade manager, and production engineer of the American Tool Works Co.

PERSONALS

W. S. Chase, for thirteen years at the head of the sales department of the National-Acme Mfg. Co., Cleveland, Ohio, has retired from active business and for the present will devote himself to personal affairs. Mr. Chase expects to spend much of his future time on his ranch at Meridian, Idaho.

F. C. Mason, a frequent contributor to the columns of the "American Machinist" for many years back, and for the past 15 years superintendent of the metal departments and master mechanic of the Bissell Carpet Sweeper So., Grand Rapids, Mich., has accepted the position of works manager of the Houk Mfg. Co., Buffalo, N. Y.

Benton Hopkins, representing the Samuel Austin & Son Co., Cleveland, Ohio, and the Morgan Engineering Co., Alliance, Ohio, sailed for Russia on Feb. 22 for the purpose of formulating plans and supervising the initial construction of a string of automobile plants in Russia. A group of influential Russians are behind the project.

H. L. Wadsworth, inventor and designer of the sand-blast apparatus bearing his name, has become factory manager of the new plant in Cleveland of the combined American Foundry Equipment Co. and the Sand Mixing Machine Co. Charles L. Benham, an old employee of the Sand Mixing Co. has been appointed factory superintendent.

OBITUARY

Frank Thompson, until recently assistant general manager of the American Car & Foundry Co., Chicago, Ill., died in Miami, Florida, Feb. 27. Mr. Thompson joined the American Car and Foundry Co. when the Wells & French plant was absorbed.

Edward I. Leighton, who at one time or another was identified with a number of Cleveland machinery-building firms, died in St. Augustine, Florida, Feb. 26, aged 66 years. Mr. Leighton was one of the founders of the Van Dorn & Dutton Co., and up to the time of his death retained a financial interest in it and several other Cleveland firms, including the Acme Machinery Co., the Van Dorn Electric Tool Co. and the Reliance Machine Co. Besides his widow, Mr. Leighton is survived by one son, Thomas E. Leighton who is purchasing agent of the Van Dorn & Dutton Co. and the Van Dorn Electric Tool Co.

BUSINESS ITEMS

The report of a recent fire at the plant of the Cleveland Twist Drill Co. was much exaggerated. The plant was not destroyed—only a small unused building was slightly burned.

The Eagle Stamping Co., Buffalo, N. Y., has opened a New York office at 114 Liberty St., which will be in charge of J Prescott Gage.

The American Foundry Equipment Co., Cleveland, Ohio, and the Sand Mixing Machine Co., New York City, have combined interests and moved into a new plant, located at No. 1111 Power Ave., Cleveland, Ohio. The executive offices will be maintained at 52 Vanderbilt Ave., New York, N. Y., and will be in charge of V. E. Minich, vice-president and general manager.

FORTHCOMING MEETINGS

A course of free lectures on military engineering will be given under the auspices of a committee representative of the four national engineering societies, by Captains Robins, Coiner and Ardery, Corps of Engineers, U. S. A. This course will be under the direction of Major-Gen. Leonard Wood and is designed to assist those who desire to enter the engineering battalion which will be formed at Plattsburg next summer. All engineers interested in preparedness will be welcome, but attendance at these lectures does not imply obligation to subsequent camp duty. Through the cordial attitude and coöperation of the United Engineering Society, the auditorium of the Engineering Societies Building has been placed at the disposal of the army officers. These lectures will be given weekly, having begun on Feb. 14, under the following divisions:

March 13, 1916—The construction, maintenance and repair of roads, bridges and ferries; the selection and preparation of fords.

March 20, 1916—The selection, laying out and preparation of camps and cantonments; the service of general construction; and the special services, including all public work of an engineering nature which may be required in a territory under military control.

March 27, 1916—The construction, operation and maintenance of railways under military control and the construction and operation of armored trains.

American Society of Mechanical Engineers. Spring meeting, April 11-14, New Orleans, La., Calvin W. Rice, secretary, 29 West 39th St., New York, N. Y.

American Society for Testing Materials. Annual meeting June 27 to July 1, 1916, Hotel Traymore, Atlantic City, N. J. Edgar Warburg, secretary, University of Pennsylvania, Philadelphia, Penn.

American Society of Mechanical Engineers. Monthly meeting first Tuesday. Calvin W. Rice, secretary, 29 West Thirty-ninth St., New York City.

Boston Branch National Metal Trades Association. Monthly meeting on first Wednesday of each month, Young's Hotel. W. W. Poole, secretary, 40 Central St., Boston, Mass.

Providence Association of Mechanical Engineers. Monthly meeting fourth Wednesday each month. J. A. Brooks, secretary, Brown University, Providence, R. I.

New England Foundrymen's Association. Regular meeting second Wednesday of each month. Exchange Club, Boston, Mass. Fred F. Stockwell, 205 Broadway, Cambridgeport, Mass.

Engineers' Society of Western Pennsylvania. Monthly meeting third Tuesday; section meeting, first Tuesday. Elmer K. Hiles, secretary, Oliver Building, Pittsburgh, Penn.

Rochester Society of Technical Draftsmen. Monthly meeting, last Thursday. Secretary, R. H. Barnes, Taylor Instrument Companies, Rochester, N. Y.

Superintendents' and Foremen's Club of Cleveland. Monthly meeting third Saturday. Philip Frankel, secretary, 310 New England Building, Cleveland, Ohio.

Western Society of Engineers, Chicago, Ill. Regular meeting first Wednesday evening of each month, excepting July and August. J. H. Warder, secretary, 1735 Monadnock Block, Chicago, Ill.

Philadelphia Foundrymen's Association. Meetings first Wednesday of each month. Manufacturers' Club, Philadelphia, Penn. Howard Evans, secretary, Pier 45 North, Philadelphia, Penn.

Technical League of America. Regular meeting second Friday of each month. Oscar S. Teale, secretary, 35 Broadway, New York, N. Y.

Prices--Materials and Supplies

IRON AND STEEL

Pig Iron—Quotations were current as follows at the points and dates indicated:

	Mar. 3, 1916	Feb. 4, 1916	Mar. 5, 1915
No. 2 Southern foundry, Birmingham	$15.00	$15.00	$9.50
No. 2 X Northern foundry, New York	19.75	19.75	14.25
No. 2 Northern foundry, Chicago	18.50	18.50	13.00

Talks With Our Readers

By the Publisher

DRY ROT is the deadliest of the species. It begins at the heart, and, unseen, saps the life blood.

The leaves remain green, and the trunk and boughs, to all intent and purposes, as strong as ever. But the strength is only apparent—the tree is just a shell —a victim of dry rot.

Dry rot is a very common disease in commercial and industrial life.

Ten years ago a firm was the big "It" in its field—and is still living on the glory of by-gone days.

Dry rot has got it—its product is not as good as that turned out by the young, growing house; its cost of production is 10-years-ago high; its selling and distributing methods outrageously antiquated.

And the man who buys from the house of faded glory runs a very big chance—to put it bluntly—of being "stung."

Advertising is the great vaccine for dry rot.

A firm which advertises consistently and successfully rarely suffers from it. The advertiser has to turn the search light of self-examination upon himself too ruthlessly to labor under any false impression of superiority.

If this superiority is false, he has to make it real before his advertising campaign will be successful.

The whole tendency of a vigorous, well-worked-out advertising campaign is invariably to make sound both the company advertising and the product advertised —to keep the dry rot out—to keep the old firm young.

BUY *advertised equipment and supplies, and make sure that you are getting the best that the best has to offer.*

Standardized Machine-Tool Drive

By W. L. Schellenbach

SYNOPSIS—The complete design of a machine-tool drive in the form of a lathe headstock, giving speeds in a geometric progression with the ratio 1.4142. Both cone and geared types are shown. The drive can be adapted to any machine tool in which speed variations are necessary.

The standardization of machine-tool drives is always an interesting subject for discussion, and it has been my experience that the more thought one puts into it the more advantages can be seen. For some time past I have had a thorough knowledge of Carl G. Barth's ideas of speed ranges for machine tools and am quite sure that many designers are not entirely familiar with what Mr. Barth is endeavoring to accomplish. One's first impression of Mr. Barth's ideal speed range does not have the force that comes from better acquaintance with him and his arguments in trying to bring order out of chaos.

A short time ago an engineer who had recently designed a machine-tool drive was quite confident that his speed range was in accordance with Mr. Barth's idea, simply because the range was in geometrical ratio. The *American Machinist* has presented Mr. Barth's method, and there should be no excuse for misunderstanding the chromatic speed range at this time. For those who have not followed the matter closely and may yet fail to understand it—and I am sure there are some—I will repeat it briefly.

The Barth chromatic speed range is based upon the square root of 2, which is 1.4142. This increment can also be reduced to the smaller increment of 1.189, which is $\sqrt[4]{2}$. The logarithmic scale gives a number of values, which Mr. Barth is endeavoring to have established as standard practice in designing speed ranges. They are approximately as follows: 4.75, 5.67, 6.75, 8, 9.5, 11.3, 13.5, 16, 19, 22.6, 26.9, 32, 38, 45.2, 53.8, 64, 76, 90, 108, 128, 152, 181, 215, 256, 304, 362, 430, 512. It is my understanding that all speeds must come somewhere within this list and correspond with the values given, although the increment of change may be any power of 1.189.

After becoming thoroughly familiar with this system, the designer will find it a simple and easy method of laying out his speed range. We may all just as well as not decide on some standard speed range and apply it generally. Mr. Barth does not take the arbitrary stand that his method is best, but that something should be adopted alike for all. This plan can in no way affect individuality or limit the designer in other directions. I am favorable to Mr. Barth's range and think it the best yet proposed. The principal reason is because the back-gear ratios are 2, 4, 8 and 16, according to the range used. This point looks good to me, because on some classes of machines—especially lathes—the back-gear ratio can be utilized for conveniently obtaining coarse leads, something which I believe has not before been claimed for it.

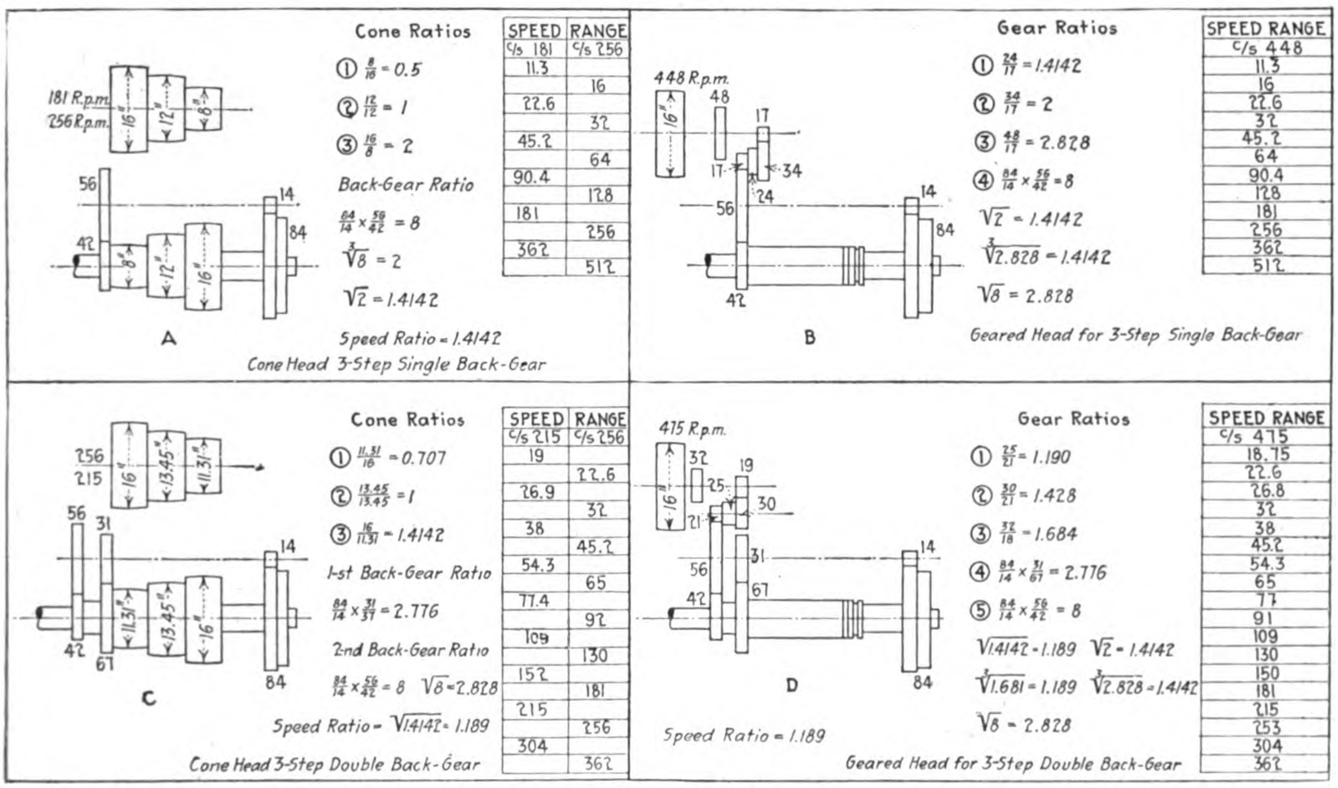

FIG. 1. CONE AND GEAR DIAGRAMS FOR THREE STEPS AND BOTH SINGLE AND DOUBLE BACK GEARS

I used the Barth chromatic speed range in designing a lathe headstock that forms the basis of this paper. I show the device as a headstock, although those familiar with machine-tool designs will readily see that this method slightly modified can be used on almost any machine tool requiring speed changes. The general method of obtaining

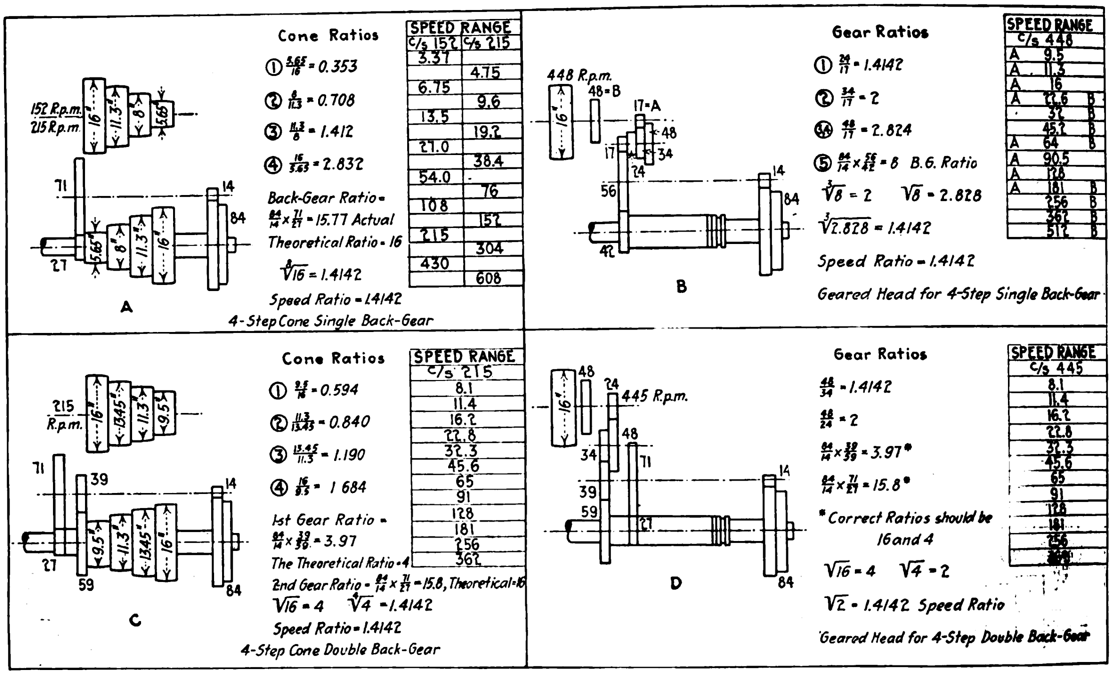

FIG. 2. CONE AND GEAR DIAGRAMS FOR FOUR STEPS AND BOTH SINGLE AND DOUBLE BACK GEARS

the speed ranges is the simplest I have ever seen. The geared and cone drives can be arranged so that the speeds are identical in either case. Very few gears are used in the transmission of the power, and it requires but few gears to do the actual speed changing. This fact obviates the necessity of using so many hardened gears.

I have adopted the chromatic speed range and submit a number of gear diagrams covering all existing types of headstocks of the cone and geared design. Referring to *A*, Fig. 1, it will be noticed that with a two-speed countershaft running 181 and 256 r.p.m. 12 speeds are obtained. This is a three-step cone single back-geared drive. The corresponding geared drive is shown at *B*, Fig. 1. It will be seen that the same speeds are obtained as with the cone drive, but with a single speed of 448 r.p.m. for the driving pulley. Referring to the diagram *C*, Fig. 1, the well-known type of three-step cone double back gear is shown. The countershaft in this case has speeds of 215 and 256 r.p.m., giving a speed range of from 19 to 362 r.p.m. with the increment of speed change at 1.189. Diagram *D*, Fig. 1, shows the same speed range obtained with the geared headstock. In this case it will be seen that 11 gears are used for obtaining 18 speeds, while in the single back gear 9 gears are used for obtaining 12 speeds.

The gear diagram of *A*, Fig. 2, shows a four-step single back gear, and diagram *B*, Fig. 2, shows the same headstock with gearing arranged for obtaining 13 spindle speeds with a single speed of driving pulley. It will be observed in referring to the table *B*, Fig. 2, that two combinations of gears are used for obtaining three of the speeds. This is done to keep the speed range from exceeding the necessary limits. It will be noticed that 10 gears are used for obtaining the 13 speeds, but it would be possible, if the speeds were needed, to obtain 16 speeds with this number of gears.

Diagram *C*, Fig. 2, shows a four-step double back-gear cone headstock giving a speed range of from 8.1 to 362 r.p.m. with a single speed of countershaft. Diagram *D*, Fig. 2, shows the necessary gearing for obtaining the same speeds in the geared head. Ten gears are used in this construction.

On diagram *A*, Fig. 3, a five-step single back gear is shown, giving 20 speeds with a two-speed countershaft. Diagram *B*, Fig. 3, shows the geared headstock to match

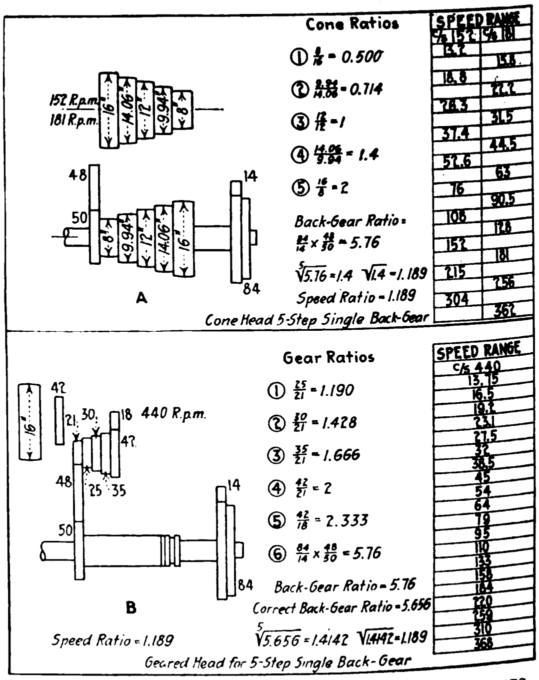

FIG. 3. CONE AND GEAR DIAGRAMS FOR FIVE STEPS AND SINGLE BACK GEARS

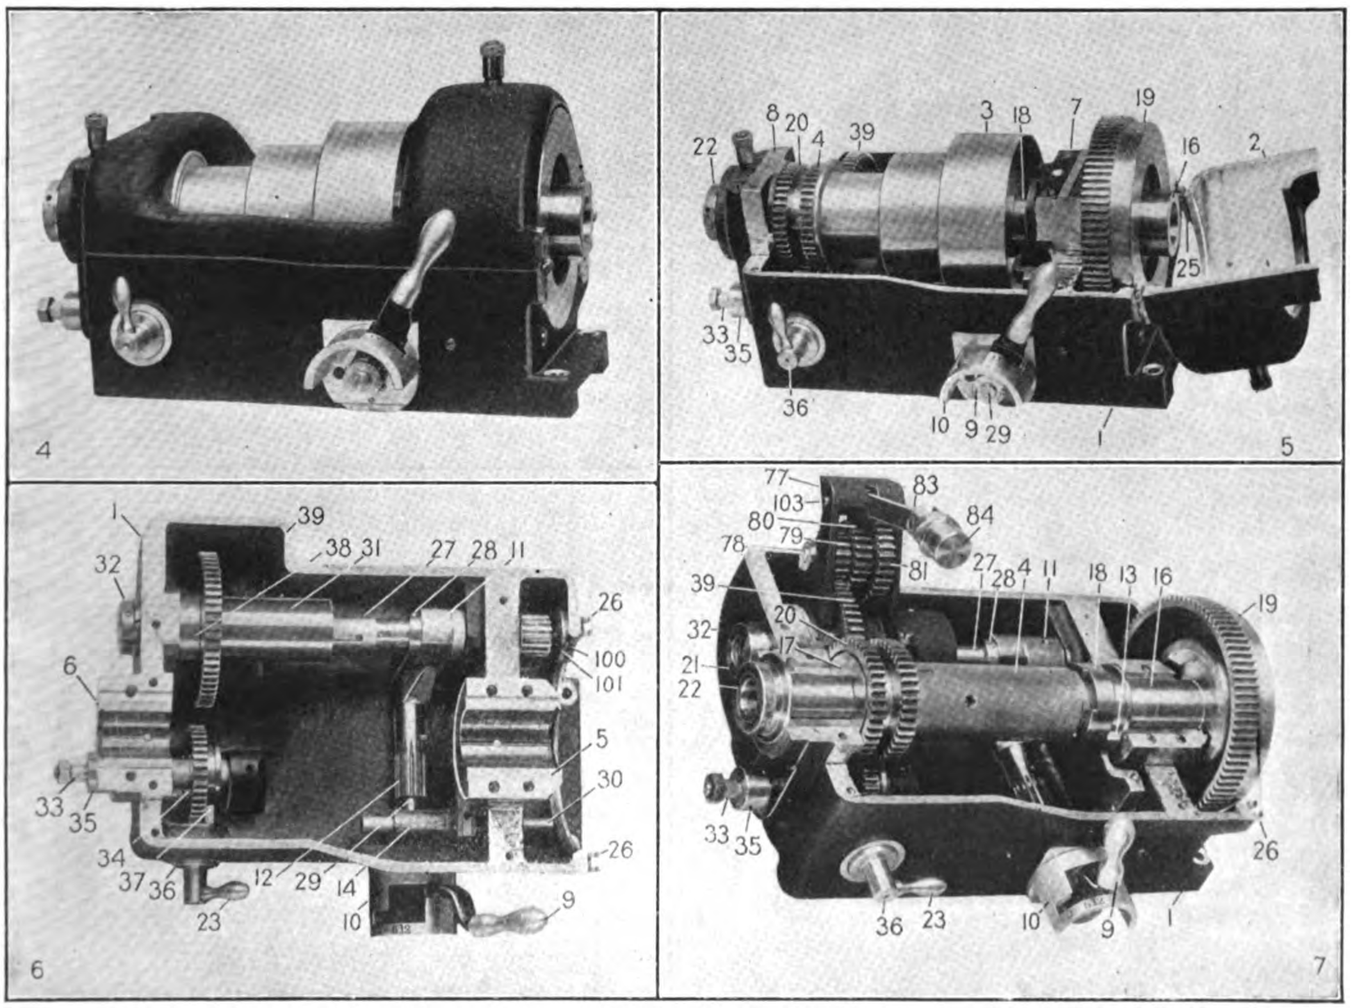
this, which gives approximately the same speeds. In the last-named diagram 20 spindle speeds are obtained **with but 11 gears and with but a single speed of the driving pulley.**

Other combinations of gearing may be used for obtaining similar results, but the simplicity of this drive and its flexibility in being adaptable for both the cone and geared heads make it the simplest I have seen. For the purpose of reducing this idea to practice a complete headstock was built and operated under power, and this fact should overcome the too frequent objection advanced when plans only are shown. In the design of this headstock the following points were considered as being vital: (1) Simplicity, or few and easily machined details; (2) standardization or interchangeability of cone and geared head parts; (3) anti-friction bearings; (4) hardened gears where clashed or meshed under power; (5) oil immersion for the geared drive; (6) few gears in mesh under pressure; (7) outside or direct drive to the faceplate or chuck; (8) accessibility of parts; (9) convenience of obtaining speed changes; (10) a fundamental headstock unit for both types; (11) optional reverse or brake.

A general view of the cone type of headstock with the cover in place is shown in Fig. 4. In Figs. 5, 6 and 7 the head casting 1 receives the hinged cover; the face gear 19 is mounted at the outside of the front spindle bearing, but still within the main headstock housing. The spindle 16 has a flange, the outside diameter of which receives the face gear 19, which is threaded to receive the faceplates or chuck. A pilot at the front end of the spindle is made to receive the bore in the faceplates or chuck, and the threaded part of the gear does the driving. This arrangement insures a solid drive direct at the dog or chuck and overcomes the tendency of the spindle to vibrate under heavy back-geared cuts. The cone-gear sleeve 4 is bronze bushed and runs loosely on the spindle, except when the splined clutch 18 engages it and locks it with the spindle. The cone gear 4 has a key near its gear, and the cone pulley is bored and keyseated to fit the outside diameter of 4. A feed gear 20 is keyed to the spindle and forms a bearing for the hardened thrust washer 17. The rear end of the spindle has a collar 21 splined to it and a nut 22 for taking up end thrust. Fig. 6 shows the spindle removed and exposes the back gear and the method for shifting.



FIGS. 4 TO 7. THREE-STEP CONE HEADSTOCK AND DETAILS OF SPINDLE AND GEARING

Fig. 4—Cone-type headstock with cover closed. Fig. 5—Cone-type headstock with cover open. Fig. 6—Headstock with spindle removed. Fig. 7—Headstock showing spindle and speed arm

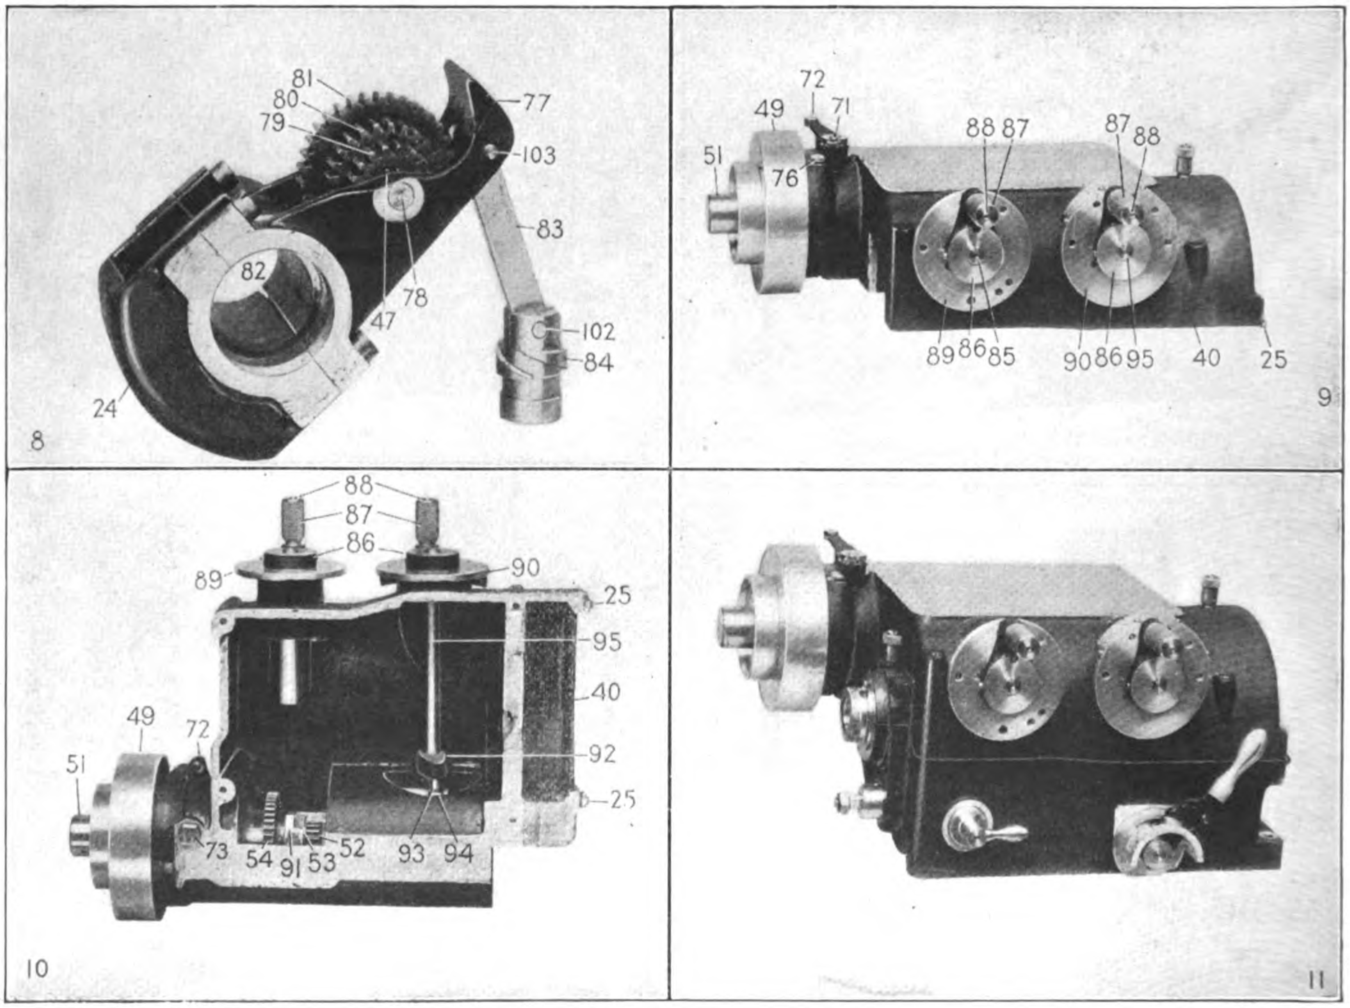
The back gear 27 revolves in the bearing 11 and is confined to it longitudinally by a collar 28. The back-gear pinion is splined to slide in the sleeve 31, to which is keyed the back gear 39. The sleeve 31 takes its bearing in a bronze bushing 38. The collar 32 confines the sleeve 31 against end movement. The cross-shaft 29, Figs. 5 and 6, has the arm 12 pinned to it, one end of which engages a

bushing 11, the other end having teeth cut upon it to engage the rack 14 sliding upon the rod 30. The rack 14 has a shoe, or fork, 13 fitted to it, to engage the spindle clutch. A guard 10 insures the proper engagement and disengagement of the direct and back-geared speeds. It will be noticed that these speeds are stamped upon the guard.

Fig. 7 shows the spindle again in place, with the cone pulley removed and the speed arm 77 taking its bearing on the bushing 38 and on the sleeve 31. The speed arm itself is more clearly shown in Fig. 8. This arm is provided with a cap 24 secured with screws and contains a cone of gears 79, 80 and 81. This cone of gears is hardened and runs on a roller bearing 47 and a pin 78. The headstock was built in accordance with the diagrams of A and B, Fig. 1, and is arranged to provide 12 speeds in the geared head lathe with but a single speed of driving pulley. The arm 77 spans the gear 39, Fig. 6, and this gear meshes with the pinion 79 of the arm. The pins 102, 103 and the link 83 form a connection between the threaded plunger 84 and the arm 77. This arm has only a swinging action around the back-gear shaft, for the purpose of meshing its cone of gears with either of the gears 52 or 54 on the top cover 40, as shown in Fig. 10.

Figs. 9 and 10 show clearly the cover used for the geared-head construction and the drawing, Fig. 12, shows a section through the bored portion of the cover. The outer end of this cover has a flange 42 secured to it by screws. This flange receives ball bearing 44, held by nut 43. The driving pulley 49 is keyed to the internal gear 50 and held in place by the nut 51. A support 74 provides a seat for the ball bearing 44′. This ball bearing supports the sleeve 56 at the inner end, and the sleeve at the outer end is supported by a ball-bearing 45 mounted on the stem 99, which is fitted into the sleeve. A ball bearing 46 supports the internal gear under the friction.

The tapered part of the internal gear fits into the tapered part of the sliding friction gear 66, which is keyed to the sleeve 56. The sliding of gear 66 is accomplished by the toggles 67 and 68. A loose ring 65 is fitted to the gear 66 and carries the pinions 61, which transmit motion from the internal gear 50 to the sliding friction gear 66 when the ring 65 is held stationary by the contracting band 75. The sleeve 56 has four keyways, which receive the sliding shaft of the pinion 52, mounted in a roller bearing 48 and also carrying the gear 54. Both gears 52 and 54 are arranged to mesh with any one of the three gears 79, 80 and 81 on the arm 77. The shaft 52 is arranged to slide longitudinally by means of the carrier 91, which has a groove turned in it to receive a block 94, mounted on the pin 93 of the crank 92, which is pinned to the shaft 95.



FIGS. 8 TO 11. THE SPEED ARM AND COVER CONSTRUCTION OF THE GEARED HEADSTOCK

Fig. 8—Headstock speed arm. Fig. 9—Cover for geared-head construction. Fig. 10—Inside of cover for geared-head construction. Fig. 11—Geared-head construction complete

Referring now to Fig. 10, it will be seen that the shaft 95 is revolved by the crank 86, which has a knob and pin to determine its proper angular position on the index plate 90. Secured to this index plate is a speed with an adjusting screw 71, which engages the plunger 76 bearing against the contracting ring 75.

Fig. 13 shows the device with the reverse omitted and a brake provided. The same method for operation is used

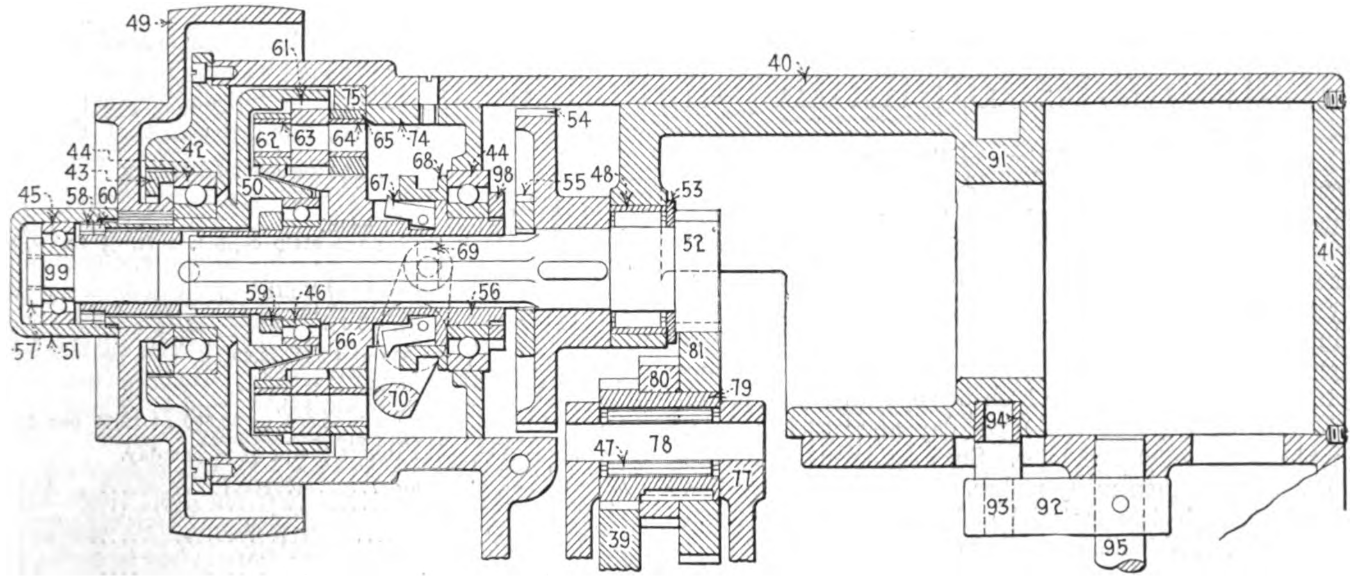


FIG. 12. SECTION THROUGH BORED PORTION OF THE GEARED-HEAD CONSTRUCTION COVER

plate giving a list of speeds. The swinging movement of the arm 77 (see Figs. 8 and 10) is obtained by the engagement of the threaded plunger 84 into the sleeve 85, which also carries a crank 86 engaging the index plate 89.

Fig. 9 shows a lever 72, which is keyed to the shaft 71 passing down into fork 70, the function of which is to slide the collar 68 and depress the toggles 67 (Fig. 12).

Referring now to Figs. 9 and 12, it will be seen that when the friction is engaged the drive will be direct with

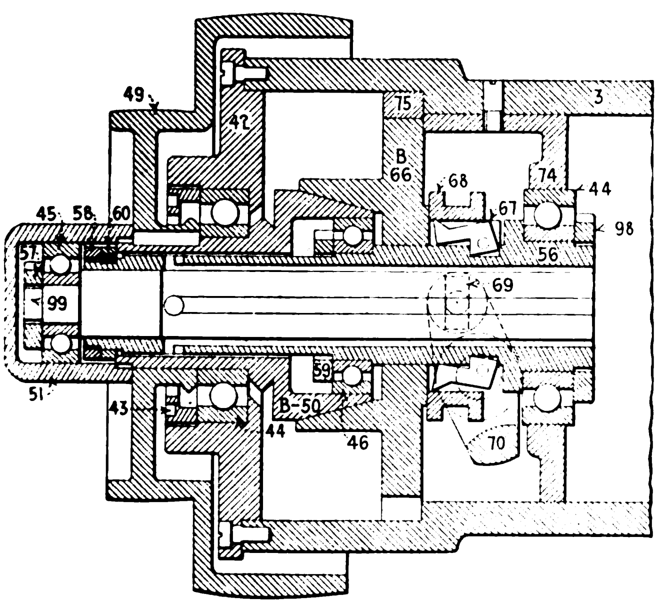

FIG. 13. SECTION OF FRICTION PULLEY AND BRAKE

the pulley, but that when this friction is released and when the contracting ring 75 holds the pinion carrier 65 against rotation the power is then transmitted from the internal gear to the gear 66 in the opposite direction and at an increased speed. This method is used for reversing. Fig. 9 shows the extended end of the lever 72 provided in both cases, *B* 66 having a disk integral with it for engaging the contracting band 75 in the regular way.

Fig. 11 shows the geared head complete, the top planed off to receive a motor. The center of the pulley shaft has been kept as nearly to the top of the headstock as is possible, in order to drive from the motor without more

TABLE OF PARTS IN SCHELLENBACH HEADSTOCKS

	Castings	Steel Cut Off from Bar	Anti-Friction Bearings	Screws	Pins	Nuts	Keys
Cone type	18	18	..	29	13	1	6
Geared type, total	41	56	6	49	22	2	12
Parts interchangeable with cone type	15	18	..	28	13	1	6
Additional for geared type	26	38	6	21	8	1	6

than one intermediate gear. An accompanying table lists the parts used on the cone type, the additional number of parts required for the geared type and the parts that are interchangeable on both types of head.

Why Munition Contracts Have Been Delayed

By A. B. Hazzard

There has been much speculation as to why some of the old-line concerns that have always been successful in former years have lost large sums of money by taking contracts for munitions. In the majority of instances it was a case of trying to do the impossible—trying to equip a plant with machinery, in 60 to 90 days, to manufacture a high-class product with a class of mechanics who had little or no experience in precision work. Some companies went so far even as to buy badly worn second-hand machine tools and lost time and money in overhauling them. In a number of cases the banks absorbed plants, took on war contracts, placed inexperienced men in the management and manipulated the stock to suit.

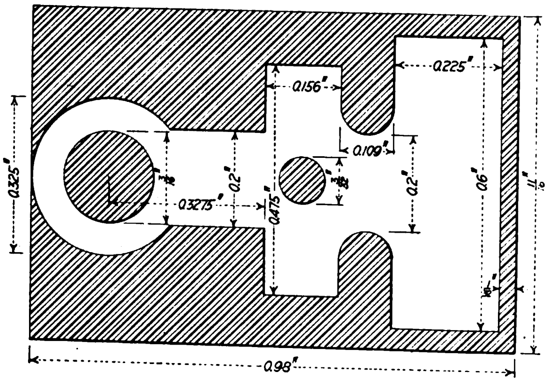
Estimating from a drawing, without giving the proper consideration to the material, has been a very serious drawback. The automatic-machine time on standard bar stock was found to be from 50 to 75 per cent. faster than was possible with the special stock necessary to make munitions. This is due to its being much harder, especially where bar brass is used. As a result, in many cases it was necessary to purchase more modern tools—a fact that was discovered only after serious loss of time, which proved very expensive.

Consider the true conditions of the plant before taking on the war contract; realize that every man was thoroughly familiar with the line-up of tools, knew where all fixtures were located and how to help himself with the usual accessories. It took a long time to get this organization—years, in some cases. Then imagine calling in the superintendent and foreman and telling them that they must prepare to make munitions; that orders for so many hundred thousand shells have been taken, with a guaranteed delivery of 4,000 or 5,000 per day after such a date, probably 60 to 90 days later. Such action presents more of a problem than many realize. It involves a new line of work, high-class material and a refined product—an impossible combination in many cases.

How to Estimate Die Work

By R. W. Johnson

In many factories handling punch and die work in more or less limited quantities the cost of the punch and die has to be written off on the first contract received for the parts for which these tools are made. Further, many times no systematic attempt is made with reference to the preparation of the estimate, with the result that some jobs are taken at an actual loss instead of at a profit, as



THE PART TO BE MADE

would be the case if the estimating had been done in such a manner as would place before the proper official all the information on the subject for which the estimate was prepared. This question is of particular importance when the metals worked are brass, copper or silver.

A concern handling a considerable quantity of miscellaneous work of the above character, generally in limited quantities, was having trouble with its estimating methods and decided to place all estimating in the hands of the engineering department, but arranged so that details of each estimate made would become a matter of record to which reference might be made, should future occasion require. With this end in view the purchasing department was instructed to prepare and send to the chief engineer on the first of each week a memorandum giving in detail the prices of all materials used in the production of the various articles, so that the matter of material costs would be on a safe and sure footing and no errors on this score would creep in.

The chief engineer then worked out a method of making and recording his estimates, such as is shown in the accompanying table. This gives full and explicit details of every step to be taken, from the cost of the raw

DATA AND ANALYSIS OF DIE WORK

Area of blank, 0.328 sq.in.
Area of waste, 0.366 sq.in.
Area of whole piece, 0.694 sq.in.
Material, No. 17 B. & S. gage strip copper, soft, 11/16 in. wide, to be bought in rolls.
Weight, 2.05 lb. per sq.ft.
Material per 1,000 blanks, 84.27 lin.ft.
Material per 1,000 blanks, 9.635 lb.
Weight per 1,000 blanks, 4.5 lb.
Weight of waste, 5.2 lb.
Cost of material per 1,000 at \$0.28, \$2.69.
Credit for 5.2 lb. scrap at \$0.19, \$0.99.
Material cost per 1,000 blanks, \$1.70.
Estimated cost of blanking die, \$65.
Daily production, estimated, 50,000 to 60,000 at \$2.50 per day.
Estimated cost of forming die, \$25.
Daily production, estimated, 6,000 at \$1.25 per day.
Cost per 1,000:

Actual labor, blanking	\$0.042
Actual labor, forming	.20
Total direct labor	\$0.242
Factory expense at 100 per cent.	.242
Material cost	1.70
Total	\$2.184

Percentage of labor to material, 15 per cent.
Remarks—From the above analysis it will pay to study the cutting weight of the blank in order to make any substantial cost reduction.

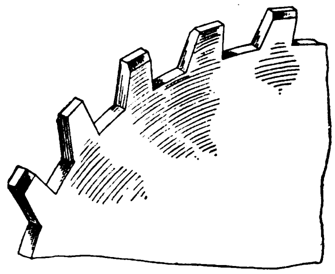
material, including the making of the tools, to the overhead to be charged on getting out the product. In the illustration is shown a detail of the part to be made.

The success that has resulted from the introduction of this improvement in the concern's estimating methods and the measure of satisfaction that has resulted from its use for some time past, not only on the part of the engineering staff, but on the part of the office as well, show that accurate, reliable and permanent records are well worth their preparation and careful filing, in the small factory as well as in the large plant.

Grinding Cold Cutting-Off Saw

W. J. Wells

When a saw jumps and kicks and refuses to cut as it should, it is not always dull, as might be suspected. We had a saw that did this when it was quite sharp. After



CORNERING COLD CUTTING-OFF SAW TEETH

trying several different ways of grinding, we tried cornering each alternate tooth, and the difficulty was ended. This was five years ago, and I have never seen saws ground like this give trouble.

Hardening and Softening Steels in the Small Shop

BY JOHN H. VAN DEVENTER

SYNOPSIS—This article throws light on some right and some wrong ways to harden and anneal carbon and high-speed steels. The use of lead baths, cyanide of potassium and various quenching compositions is treated in detail.

To take his diploma as an all-round small-shop machinist, a man must, in addition to many other requirements, be a fair blacksmith and a first-class tool hardener. The average small-shop owner cannot afford such a luxury as a tool specialist and may perhaps consider himself lucky that he cannot. The idea of specialization has been carried too far. If specialization were the real and ultimate object of man, we should be built differently. Some of us would have nothing but noses—we should do the smelling for the community; others would be exclusive specialists at seeing, and others at hearing. As it is, we are all constructed very much alike and evidently intended by nature to do many things well, although the teachings of the "superspecialists" would make us believe to the contrary.

Judging by the number of inquiries received by the *American Machinist* for information, the hardening and annealing of steels is a matter that is worth presenting to small-shop readers. Like a good many other subjects, different parts of it have been presented from time to time, dispersed over a number of volumes and a number of issues—each one bearing its share of information. In one or two articles on this subject I will try to gather together the most important things to be known and done in connection with hardening and annealing, especially from the viewpoint of practicability for use in the small shop.

METHODS OF HEATING FOR HARDENING AND TEMPERING

The various ways of heating steels group themselves into three distinct divisions: First, in the open fire, in which the piece to be heated is exposed directly to the fuel. This scheme, the oldest, the best known and the commonest, is the one followed in ninety-nine shops out of a hundred. The blacksmith forge as a hardening and tempering appliance is as well known in the large shop as in the small one, and provided care is taken to use fuel free from sulphur and phosphorus and to build the fire deep enough so that the heated metal is not exposed to the direct blast, good results can be obtained. In using the open fire the degree of heat must be gaged by color, which is a disadvantage of this method of heating. While it may give best results some of the time and good results most of the time, it will not give best results all of the time, such as are assured when the degree of heat can be accurately measured and controlled.

The second classification of heating devices may be described as closed retorts or furnaces, in which the piece is protected not only from drafts, but also from attacks by the gases and chemical elements in the fuel. The size of such an outfit may vary from a muffle capable of being juggled about in one hand to a gigantic furnace. When a furnace of this type is fired by oil or gas and is provided with a pyrometer, such as described on page 95, the heat may be closely regulated. I must not forget to mention in this class the electrically heated furnace, which is no doubt the most accurately controlled of any and which is largely used by makers of high-grade small tools as a means of heating their product.

HEATING THE WORK IN A HOT BATH

The third class of heating appliances may be indexed under the name "Bath," although quite different from the Saturday night bath of the small-shop man. It may consist of a pot of melted lead, of melted salt, of potassium cyanide, of sand or of heavy oil. These are of course hot baths, as distinguished from the quenching or cooling baths, which will be mentioned later. The advantages of a bath of this kind are easily obtained in the small shop by placing upon the forge a crucible or an iron kettle containing the bath material. A better way to heat it and one that allows for regulation is by means of a gas or crude-oil burner.

The reason for uniformity of temperature in hardening steels may not be fully understood; and when not, it is difficult for one to realize the importance of maintaining a uniform temperature. In its action, when heated, steel somewhat resembles water. Just as heated water reaches a point where it boils and changes into steam, steel heated sufficiently reaches a point where its particles are changed in their nature and relation. On being cooled to a temperature a little lower than the first the particles will change back again.

These temperatures are called the "critical points" of the steel and vary with different percentages of carbon. The proper hardening temperature is from 30 to 50 deg. above the first critical point. The ideal temperature would be exactly at this point, but allowance must be thus made for cooling in the interval of time before quenching. A table showing these temperatures is given for various percentages of carbon, and it will be noticed that the higher the carbon of the steel the lower this critical temperature becomes.

Steel has a peculiar property of losing its power of attracting a magnet when the critical point is reached, and this fact is taken advantage of by some small-shop owners who do not have pyrometers. A magnetic compass is applied to the piece of heated steel; and when the needle ceases to be attracted by it, the shop man knows that the critical point has been reached.

HARDENING AND ANNEALING TEMPERATURES FOR CARBON STEELS

Per Cent. Carbon	"Points"	Deg. F.
0.10	10	1,616
0.20	20	1,562
0.30	30	1,535
0.40	40	1,508
0.50	50	1,492
0.60	60	1,481
0.70	70	1,476
0.80 to 1.5	80 to 150	1,472

The nearer to the critical point that the small-shop man is able to quench a piece of steel, the finer will be its grain. Its hardness and toughness will also reach a

maximum under these conditions. Over and under this point the grains become gradually coarser, and the hardness decreases.

One thing to remember in heating steels for hardening is to keep the temperature "going up" until the critical point is reached. In other words, it will not do to go above this point and let the temperature drop before quenching. Apparently it is necessary to keep the temperature moving in one direction, in order not to impede traffic among the busy molecules of the heated bar. While this is true, it is equally true that fast heating must be avoided. A piece of steel is often heated so quickly that the outside only is in its proper critical condition.

Every mechanic who has had anything to do with the hardening of tools knows how necessary it is to take a cut from the surface of the bar that is to be hardened. The reason is that in the process of making the steel its outer surface has become decarbonized. This change makes it low-carbon steel, which will of course not harden. It is necessary to remove from $\frac{1}{16}$ to $\frac{1}{4}$ in. of diameter on bars ranging from $\frac{1}{2}$ to 4 in.

This same decarbonization occurs if the steel is placed in the forge in such a way that unburned oxygen from the blast can get at it. The carbon is oxidized, or burned out, converting the outside of the steel into low-carbon steel. The way to avoid this catastrophe is to use a deep fire. Lack of this precaution is the cause of much spoiled work, not only because of decarbonization of the outer surface of the metal, but because the cold blast striking the hot steel acts like boiling hot water poured into an ice-cold glass tumbler. The contraction sets up stresses that result in cracks when the piece is quenched. The next time you harden a milling cutter and have some of the teeth crack off, keep this suggestion in mind.

Preventing Decarbonization of Taps and Reamers

It is especially important to prevent decarbonization in such tools as taps and form cutters, which must keep their shape after hardening and which cannot be ground away on the profile. For this reason it is well to put taps, reamers and the like into pieces of pipe in heating them. The pipe need be closed on one end only, as the air will not circulate readily unless there is an opening at both ends for a "draft," so to speak.

Even if used in connection with a blacksmiths' forge the lead bath has an advantage for heating tools of complicated shapes, since it is easier to heat them uniformly and they are submerged and away from the air. You must remember, however, that unless the metal is stirred, the temperature of such a bath is not uniform. And always remember to use powdered charcoal as a covering for the top of the lead pot. Some may ask why it is necessary to repeat such a simple precaution, but a prominent firm making shrapnel incurred much expense for wasted lead until someone suggested the use of charcoal. A lead bath may be used at temperatures between 620 and 1,150 deg. F. Beyond this there will be much waste by evaporation.

To secure proper hardness, the cooling or quenching of steel is as important as its heating. Quenching baths vary in nature, there being a large number of ways to cool a piece of steel in contrast to the comparatively few ways of heating it.

Plain water, brine and oil are the three most common quenching materials. Of these three the brine will give the most hardness, and plain water and oil come next. The colder that any of these baths is when the piece is put into it the harder will be the steel; but this does not mean that it is a good plan to dip the heated steel into a tank of ice water, for the shock would be so great that the bar would probably fly to pieces. In fact, the quenching bath must be sometimes heated a bit to take off the edge of the shock.

Brine solutions will work uniformly, or give the same degree of hardness, until they reach a temperature of 150 deg. F., above which their grip relaxes and the metals quenched in them become softer. Plain water holds its grip up to a temperature of approximately 100 deg. F.; but oil baths, which are used to secure a slower rate of cooling, may be used up to 500 deg. or more. A compromise is sometimes effected by using a bath consisting of an inch or two of oil floating on the surface of water. As the hot steel passes through the oil, the shock is not as severe as if it were to be thrust directly into the water; and in addition, oil adheres to the tool and keeps the water from direct contact with the metal.

The old idea that mercury will harden steel more than any other quenching material has been exploded. A bath consisting of melted cyanide of potassium is useful for heating fine engraved dies and other articles that are required to come out free from scale. One must be careful to provide a hood or exhaust system to get rid of the deadly fumes coming from the cyanide pot.

Easing Off the Internal Stresses

Work quenched from a high temperature and not afterward tempered will, if complex in shape, contain many internal stresses, which may later cause it to break. They may be eased off by slight heating without materially lessening the hardness of the piece. One way to do this is to hold the piece over a fire and test it as Mrs. Small-Shop Man tests her hot flatiron—with a moistened finger. Another way is to dip the piece in boiling water after it has first been quenched in a cold bath. Such steps are not necessary with articles which are afterward tempered and in which the strains are thus reduced.

In annealing steels the operation is similar to hardening, as far as heating is concerned. The critical temperatures given in the table are the proper ones for annealing as well as hardening. From this point on there is a difference, for annealing consists in cooling as slowly as possible. The slower the cooling the softer will be the steel.

Annealing may be done in the open air, in furnaces, in hot ashes or lime, in powdered charcoal, in burnt bone, in charred leather and in water. There is surely some range of choice for the small-shop man when it comes to doing this work. Open-air annealing will do as a crude measure in cases where it is desired to take the internal stresses out of a piece. Care must be taken in using this method that the piece is not exposed to drafts or placed on some cold substance that will chill it. Furnace annealing is much better and consists in heating the piece in a furnace to the critical temperature and then allowing the work and the furnace to cool together.

When lime or ashes are used as materials to keep air away from the steel and retain the heat, they should be first heated to make sure that they are dry. Powdered charcoal is used for high-grade annealing, the piece being packed in this substance in an iron box and both the work and the box raised to the critical temperature and

then allowed to cool slowly. Machinery steel may be annealed in spent ground-bone that has been used in casehardening; but tool steel must never be annealed in this way, as it will be injured by the phosphorus contained in the bone. Charred leather is the best annealing material for high-carbon steel, because it prevents decarbonizing taking place.

Water annealing consists in heating the piece, allowing it to cool in air until it loses its red heat and becomes black and then immediately quenching it in water. This plan works well for very low-carbon steel; but for high-carbon steel what is known as the "double annealing treatment" must be given, provided results are wanted quickly, as is usually the case with water or oil-bath annealing. The process consists of quenching the steel in water or oil, as in hardening, and then reheating it to just below the critical point and again quenching it in oil. This process retains in the steel a fine-grain structure combined with softness. Large pieces of steel should be rough-turned before annealing. It will not be necessary to say anything about color tempering, this being a subject familiar to all. In drawing temper, however, the color is not the only gage that can be used. One of the best is a thermometer in a bath of heavy oil having a flash point between 500 and 600 deg., which will take care of all the tempers up to that corresponding to dark blue. The steel is first preheated slowly in a fire or furnace, as it might crack if plunged immediately into the hot oil.

In hardening high-speed steel the main requirement is to get the cutting edge hot enough. The air blast for cooling is going out of fashion and an oil bath is taking its place, which will be good news to the small shop that has no air compressor. Lathe and planer tools are usually left in their quenched condition for use, not being tempered or drawn. More complicated and expensive high-speed steel cutters are somewhat insured against breakage by drawing the temper slightly. Milling cutters are drawn to 400 deg. F., drills and reamers to 450 deg. and taps and dies are let down a little farther, not, however, reaching 500 deg.

Boring Pump Chambers in the Drilling Machine

By A. N. Patterson

In the illustration, Fig. 1, is shown a pump-chamber pocket that was bored in a drill press. The top flange was faced, drilled and tapped before the boring was done. This was permissible, as the pockets had no relation one to the other, and the distances between centers of the chambers did not have to be absolutely accurate.

In Fig. 2 is shown the arrangement of tools for all operations. *A* is a plate to hold the guide bushing *B*; this plate was secured to the top flange by capscrews in the tapped holes. The method of operation is as follows: The boring bar in the spindle of the drill press is raised clear of the work, the guide bushing *B* is slipped over the bar and the cutter inserted and secured. The bar is then lowered to the work, the bushing being pushed down in the plate, and the boring commenced.

A roughing and finishing cutter was used for each diameter to be bored. The dimensions of the bar and bushing were such that the bushing would enter the plate before the cutting commenced, so that the bar was always guided when boring.

The tool used for chamfering the bottom of the hole is

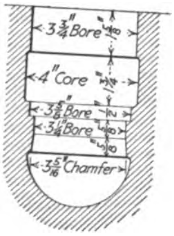


FIG. 1. THE HOLE TO BE MADE

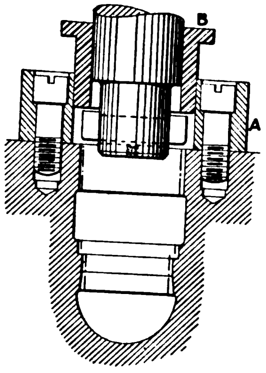

FIG. 2. ARRANGEMENT OF TOOLS

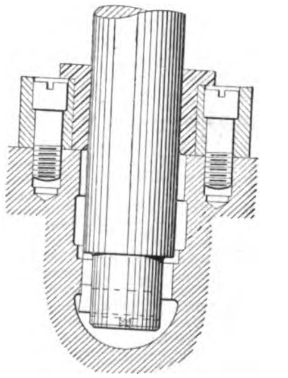

FIG. 3. THE CHAMFERING TOOL

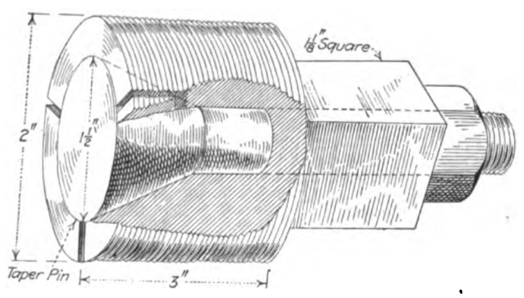
shown in Fig. 3. In doing this operation the bushing was raised clear of the plate and the boring bar and tool inserted eccentrically in the hole, to permit it to enter. The bushing was then forced into the plate, centering the bar, and by feeding upward the hole was chamfered.

A Handy Driver for Removing Shell Sockets

By John Dunn

The accompanying sketch shows a very handy driver for removing the brass socket from an 18-lb. shrapnel shell in order to correct the weight or put on a new socket.

The shell is first heated to break the solder joint between the brass socket and the tube. The plug is then screwed



SHELL-SOCKET REMOVER

in. Tightening the nut on top expands the plug; then by the use of a large wrench the socket may be backed out. This driver will not harm the socket, which may be put back in the ordinary way, and it makes an otherwise nasty job very easy.

Jigs for Machining Detail Parts of a Talking Machine

By Robert Mawson

SYNOPSIS—The jigs here shown and described are of a simple character, but are giving satisfaction. Those used in drilling the top and bottom plates are designed for a multiple drilling machine, thus enabling quick production of parts. In the jig used for the winding crank an adjustable stop plate makes possible any necessary adjustments.

In this article are shown some of the jigs used by the Rex Talking Machine Corporation, Wilmington, Del., in manufacturing its machines. It will be observed that the tools are of somewhat simple design, as the parts machined are not of a complicated nature. However, these tools have been found to give satisfaction both as regards the quality and quantity of work produced.

It will be observed that when machining the top and bottom frames, Figs. 1 and 6 respectively, the operation is performed in a multiple-spindle drilling machine. This enables the machining time to be cut to the lowest limit, and at the same time accurate results are obtained, as after the drill spindles have been once set correctly the drilling operation is of the simplest and requires a minimum of attention.

In drilling the holes in the edge of the top frame a simple yet effective jig is used. After the casting has been located in the jig by means of dowels fitting in previously machined holes a swinging strap and screw bearing on the piece holds it securely. The jig for the winding crank is provided with an adjustable stop, so that the hole may be kept in the correct position in the event of the length of the crank forging varying in any degree.

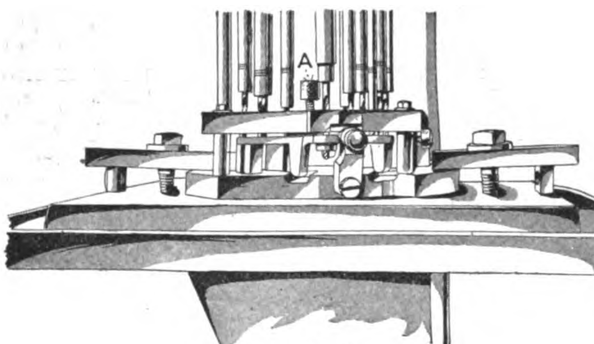


FIG. 2

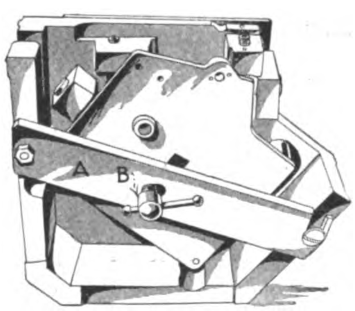

FIG. 3

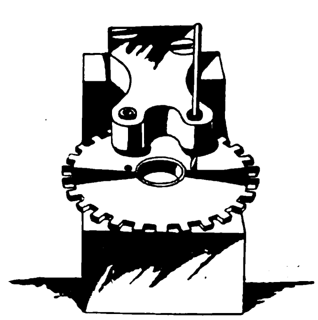

FIG. 5

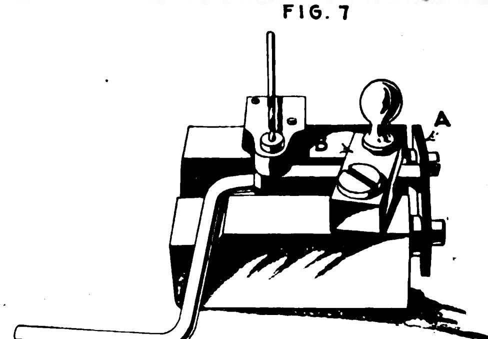

FIG. 9

JIGS USED IN MACHINING DETAIL PARTS OF A TALKING MACHINE, WITH WORK SHOWN IN POSITION

FIGS. 2 AND 2-A

Operation—Drilling holes in face of top frame, Fig. 1. The casting is located by stop pins, being forced against them by knurled-head screws on the opposite sides. The screw A holds the casting down securely. Two straps hold the jig rigidly on the drilling-machine table.

Holes Machined—Four No. 12 drilled, two No. 24 drilled, three No. 15 drilled, one No. 33 drilled, one 17/64-in. drilled and one 15/64-in. drilled.

FIGS. 3 AND 3-A

Operation—Drilling holes in edge of top frame, Fig. 1. The casting is located by dowels that fit into holes drilled in the previous operation. Cover A is then swung over and the screw B, being tightened, holds the casting securely in the jig.

Holes Machined—Two No. 33 drilled, one ¼-in. drilled, one No. 32 drilled, one 19/64-in. drilled and one 15/64-in. drilled.

FIGS. 5 AND 5-A

Operation—Drilling holes in winding gear, Fig. 4. The piece is located in the jig by fitting it into a machined hole. After one hole is machined, a drill is put through the bushing into the hole, as shown, to hold the part in alignment.

Holes Machined—Two No. 43 drilled.

FIGS. 7 AND 7-A

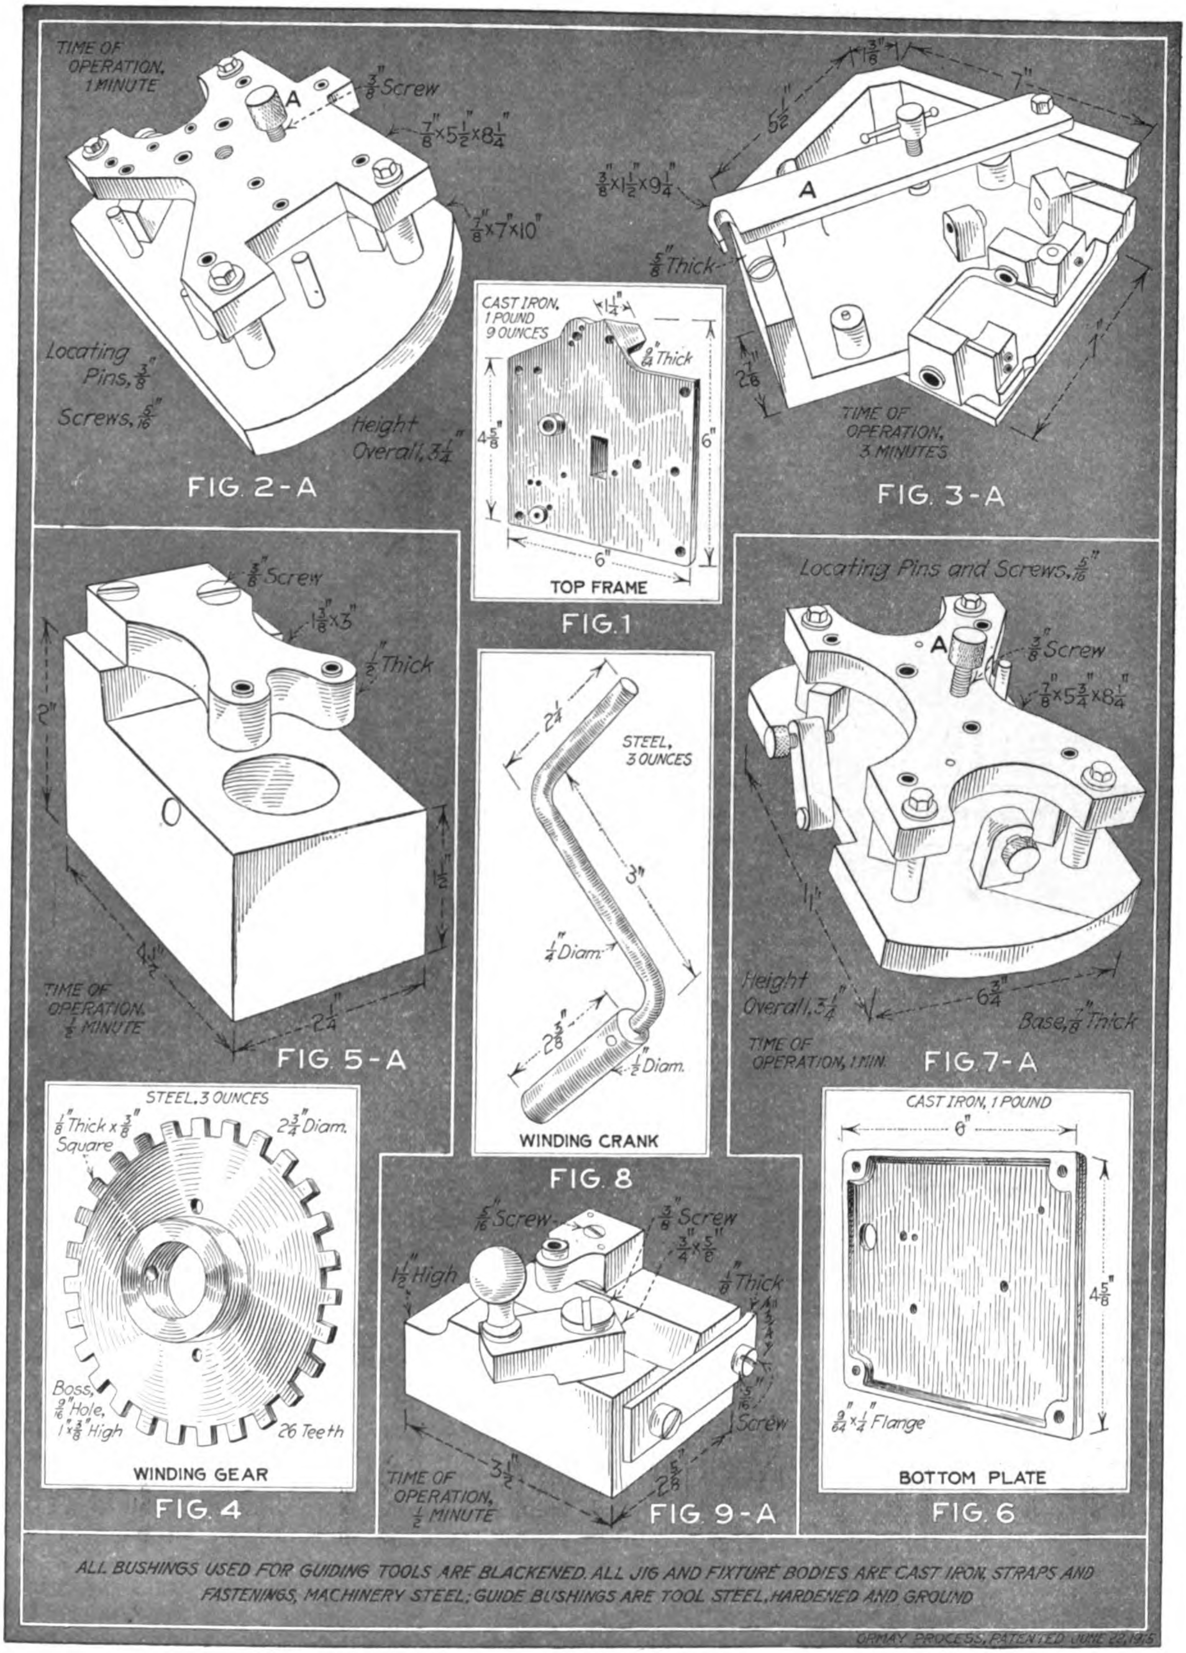
Operation—Drilling holes in bottom plate, Fig. 6. The rough casting is located against pins, being forced against them with knurled-head screws on the opposite side. The screw A is then tightened to hold the casting securely.

Holes Machined—Four No. 12 drilled and three No. 24 drilled.

FIGS. 9 AND 9-A

Operation—Drilling hole in winding crank, Fig. 8. The part is pushed back against the plate A and held in position by the plate B, which is swung over.

Holes Machined—One No. 43 drilled.



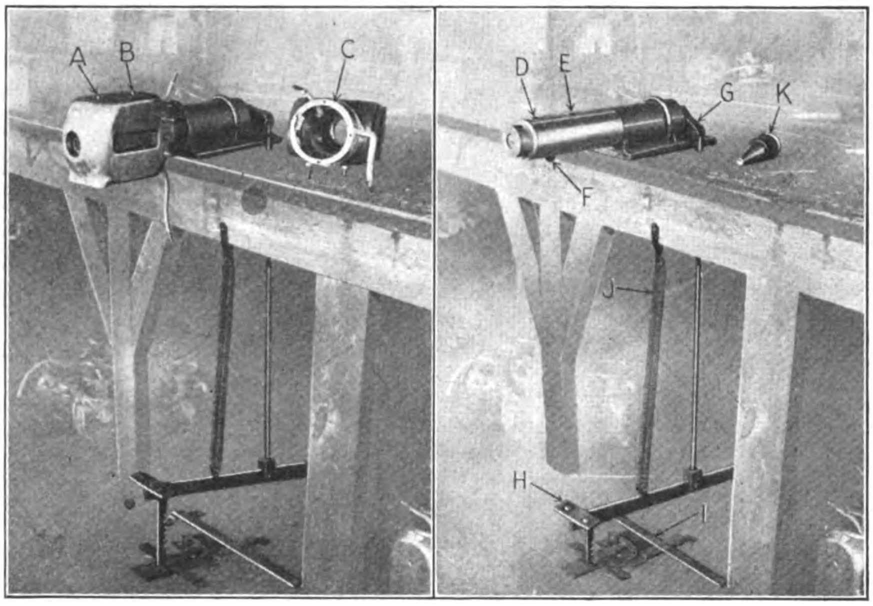
DETAILS OF JIGS USED FOR MACHINING PARTS OF A TALKING MACHINE

A Riveting Mandrel

By E. V. Allen

A special riveting mandrel, used to hold motor starting bodies while riveting in the field plates, is illustrated in Figs. 1 and 2. This device is used in the shop of the Disco Electric Starter Co., Detroit, Mich. Fig. 1 shows a body in place, with two of the rivets to be headed over at *A* and *B*. One of the bodies, turned to show the inside, may be seen at *C*.

Fig. 2 shows the mandrel with the work removed. Here two steel plugs are set in at *D* and *E* for the heads of the rivets to rest on. The body is slipped over the mandrel until the rivets rest on these plugs, then the plug *F* is forced downward by means of the short lever *G*, operated by the foot treadle *H*. As the foot treadle is forced down, it is held from flying up by a ratchet and dog on the floor. When it is desired to release the treadle, the lever *I* is kicked back, and the treadle is carried up by the springs *J*. The plug *F* is backed by an eccentric that forces it out as the lever *G* is moved downward. At *K* is shown a heavy rivet set for rounding over the ends of the rivets after they have been hammered down.



FIGS. 1 AND 2. RIVETING MANDREL WITH AND WITHOUT SPECIAL MOTOR WORK IN PLACE

Canada's Position with Regard to War Materials

With the exception of recruiting soldiers and financing the war there is nothing that has concerned the Canadians to a greater degree than the production of ammunition and the other necessities of war. In the actual manufacture of munitions Canada has done far more, and far better, than was expected. The manufacturers have accommodated themselves to entirely new conditions and lines of manufacture with a facility that is a surprise to mechanics who are familiar with labor conditions on both sides of the international border.

Great credit is also due to the financiers. There has been no difficulty in obtaining money from them in almost any amount for legitimate manufacturing enterprises. It is all very well to say that the financiers are looking to their own interests. Of course they are; but there are many cases where the backers of such concerns have, after writing off a moderate profit, voluntarily given the balance to the Government. There are so many such instances that this order of things can be considered the rule. The successes of these enterprises may have the salutory effect, after the war, of making the men with money less timid and much more willing "to take a chance" than they have been in the past.

The men who have done the actual work have benefited materially in more ways than one. They have earned good wages, for which they have turned in much and good work; but beyond this there are many so-called unskilled men who have learned at least some of the rudiments of trades that call for skill—and skill is an asset of value to any nation.

Just how much has been done by the Canadians in the way of munitions manufacture is not known to the general public, but a few of the facts will at least help to a better understanding of the matter.

The Imperial Munitions Board has issued orders in Canada for 22,800,000 shells of various sizes, chiefly from 3 in. to 6 in. in diameter. In the aggregate these shells have a value of $282,000,000. If the orders for cartridge cases, primers, forgings, frictions tubes, etc., be added, the total will reach $303,000,000. For this work, up to the end of 1915, $80,000,000 was paid out. The monthly output is now valued at more than $30,000,000. At this writing there are 422 plants working directly on war orders. How many more plants or how much employment is indirectly due to them is difficult to estimate. The War Purchasing Commission, which is separate from the Munitions Board, is the second largest buying agency in the western hemisphere, if not in the world, today. This body has nothing to do with the purchase of shells, but it does deal in every other requirement of the army. Its purchasing schedules cover over 5,000 different articles. The appropriation for the year just past amounted to $100,000,000.

It is safe to estimate that, if the war continues throughout 1916, there will have been spent on war supplies in Canada in 1915 and 1916 more than $500,000,000.

Makeshift Taper Gage

By A. N. King

In the course of job work we often have brought in broken axles on which there are taper fits. It is rather hard to get them accurate by ordinary measuring, and we seldom have the part with the taper hole in it, so that we can try the two together. The following method is used:

The taper part is laid against one jaw of a planer vise and the opposite jaw brought up against the taper and clamped. The new tapers are then turned until they fit into the opening between the jaws and enter to the proper depth.

Manufacturing 120-Millimeter Serbian Shells--II*

By Fred H. Colvin

SYNOPSIS—Making the ogives, or nose pieces, and the points, as well as the assembly, varnishing and painting, has many interesting features. Threading is done both in Jones & Lamson turret lathes and by hobbing, both methods proving satisfactory. Rethreading by power is also a feature on the points, which are largely the product of the automatic. Turning the shells by power to try the gages introduces a somewhat novel feature in gaging methods, while many of the gages themselves are interesting from their simplicity and effectiveness.

The ogive, which is the French term for the nose, or "pointed arch," comes in the shape of a forging weighing about 15 lb. The first operation is to drill a 1½-in. hole through the ends, a three-spindle Barnes gang drill being used for this purposes, as shown in Fig. 21. One man handles about 5 pieces per hour on this machine.

The second operation Fig. 22, forms the inside, turns the outside, and threads for screwing into the body of the shell. This operation is performed on a Jones & Lamson machine, its threading attachment proving very satisfactory for this work. The production is 20 for a 10-hr. day.

Two alternate methods of boring the ogives are shown in Fig 23. Both are on Bullard vertical lathes, the difference being in the method of using the forming cam. In the first, at the left, the boring was done by the side head, the cam being placed at *A*, as shown. This formed the inside of the ogive as the side head was fed down.

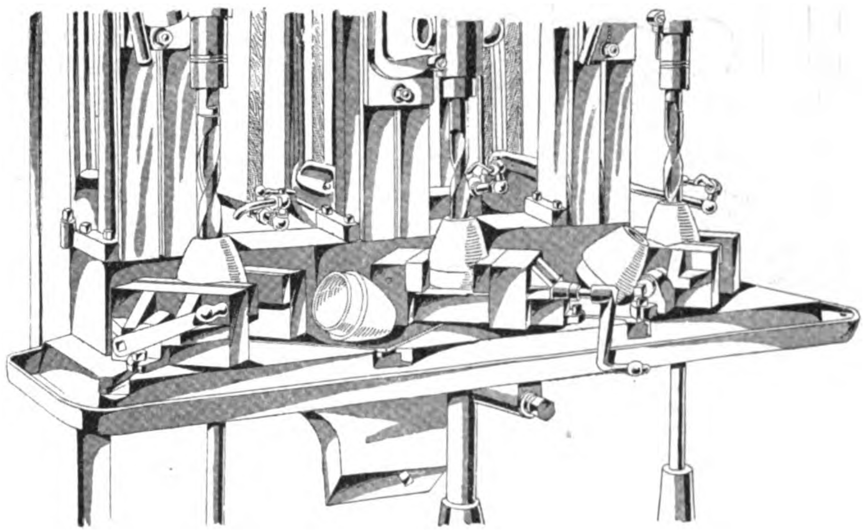


FIG. 21. OPERATION 1: OGIVE—DRILLING

Machine Used—Barnes gang drilling machine. Special Fixtures—Holding chucks. Gage—None. Production—5 per hr.

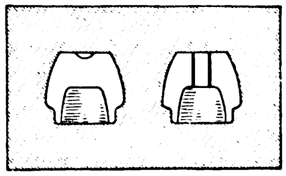
The second method is an improvement over this, as by placing the cam so as to utilize the boring tools in the turret it leaves the side head free to turn the outside for the thread at the same time. The difference in these methods is seen in the production times. For 150-mm. ogives the first way required about 2½ hr. each; and the second, 35 min.

For the third operation, Fig. 24, also performed in a Jones & Lamson machine, the ogive is held in a special chuck having a steel ring fastened to its face and threaded to receive the large end of the ogive. After it is screwed in place, the three inside jaws grip it firmly, while the outer ring not only centers it, but also prevents distortion. The small end is then bored out, enlarging the drilled hole to the proper size; a recess is cut for the end of the thread and the outer end faced to length.

The fourth operation threads the hole in the point, a special thread-hobbing fixture being used, as shown in Fig. 25. The hob runs 225 r.p.m., while the work turns 1 revolution in 2 min. This gives a production of 9 per hr.

The fifth and last operation, Fig. 26, rough-forms the ogive on a Prentice geared head lathe, using a form at the back of the carriage. The inspection is then made before the ogive goes to be assembled for final turning.

The point, or cap, that protects the thread in the ogives so that the fuse can be screwed in without difficulty is made from bar stock. This usage is an interesting variation from the brass, zinc and wooden caps that are now employed for this purpose. These points are turned from $2\frac{7}{16}$ bar steel on Gridley 4¼-in. automatics. The first operation is shown in Fig. 27, together with the tool layout, the production being 5 per hr. The side wrench slots are then milled,



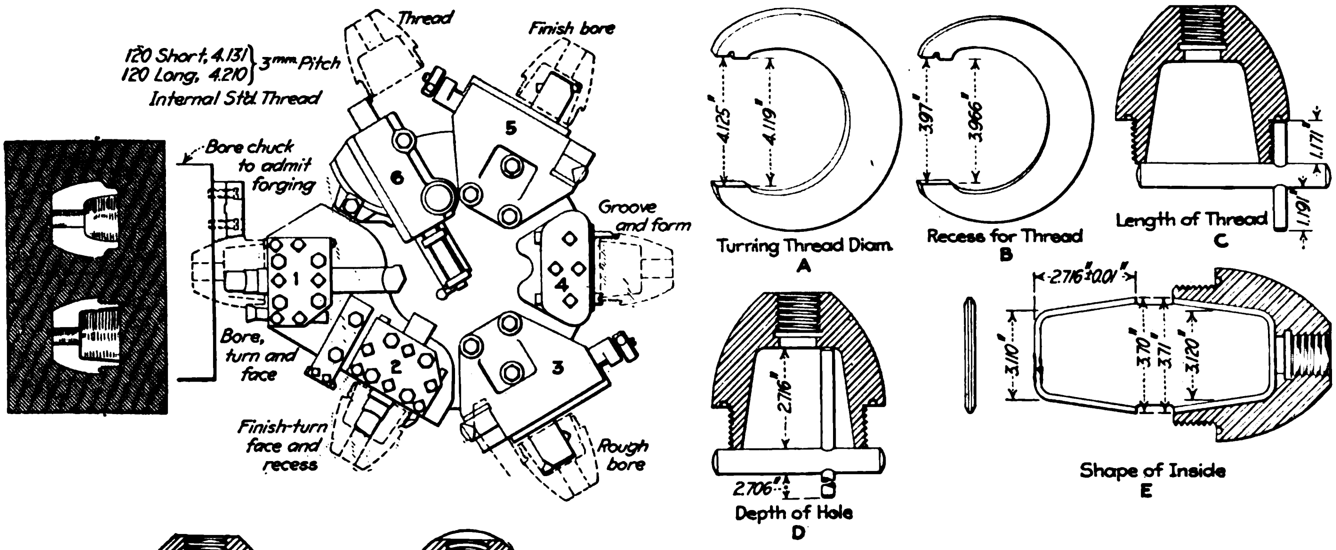
the point being held in a split chuck on a small hand miller, as in Fig. 28, and indexed in two positions, so that the end mill can cut the desired slot, the depth being determined by a suitable stop. The production here is 25 per hr.

The cone end of the point is shaved on a Bardons & Oliver hand turret at the rate of 20 per hr., the point being held in a screw chuck and a single tool used in the cross-slide for this purpose, as in Fig. 29.

Then comes the rethreading, which, instead of being done by hand, as in most cases, is handled on a vertical drill, as shown in Fig. 30 (spring prong) dies are used in the drilling-machine spindle, while the point to be rethreaded rests in a suitable pocket in a holding fixture on the table. The cap is prevented from turning by two studs that fit the wrench slots.

No difficulty seems to be experienced in catching the thread, a tapping head being used for reversal. It is also easy to prevent the die going on too far, by simply lifting

*Previous installment appeared on page 397.



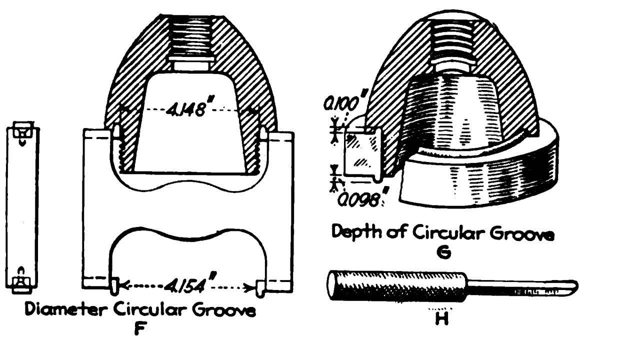


FIG. 22. OPERATION 2: OGIVE FORM INSIDE AND THREADS

Machine Used—Jones & Lamson.
Special Fixtures—Chuck jaws.
Gages—A, thread diameter; B, recess for thread; C, length of thread; D, depth of bore; E, form of bore; F, diameter of annular groove; G, depth of annular groove; H, operation gage for groove.
Production—1½ to 2 per hr.

the whole spindle so that the prongs do not engage, allowing the point to revolve with the die. This method is certainly easier than rethreading by hand, even though the production may not be as much higher as might be imagined. In this case it is 22 to 25 per hr., but it must be remembered that these points are of steel and that the thread is nearly 2 in. in outside diameter. The points are then inspected and go to the assembling department to be varnished inside preparatory to being screwed into place on the otherwise completely assembled shell.

Going back to the shells once more, we find them now ready to have the ogives screwed solidly into place. This work is done by hand while the shell itself is held in the vise of a clamp, shown in Fig. 31, which is mounted on a stand so as to be of convenient height. The shells are clamped in this vise by means of the cam shown, the ogives started in by hand and the assembling plug screwed into the nose of the ogive.

This plug consists of a central stud squared at one end, threaded at the other and having a thrust collar against which the ball thrust, shown, bears. The ball thrust is held in position by the three side fingers with hooked ends so that it is perfectly free to move. The stud is screwed into the nose of the ogive, and the ogive itself is forced into the shell by a large ratchet wrench fitting on the squared end of the plug.

These parts must be forced together very tightly, both on account of the necessity of their being virtually one piece of metal and on account of the difficulty of varnishing in case they are not. The latter difficulty comes from the fact that, if the stud and the ogive are not tight, oil is apt to be forced out when the shells are cleaned by air pressure on the inside, and this makes it difficult for either the varnish or the paint to dry satisfactorily. Two men working in conjunction obtain an average output on this operation of 30 pieces per hour.

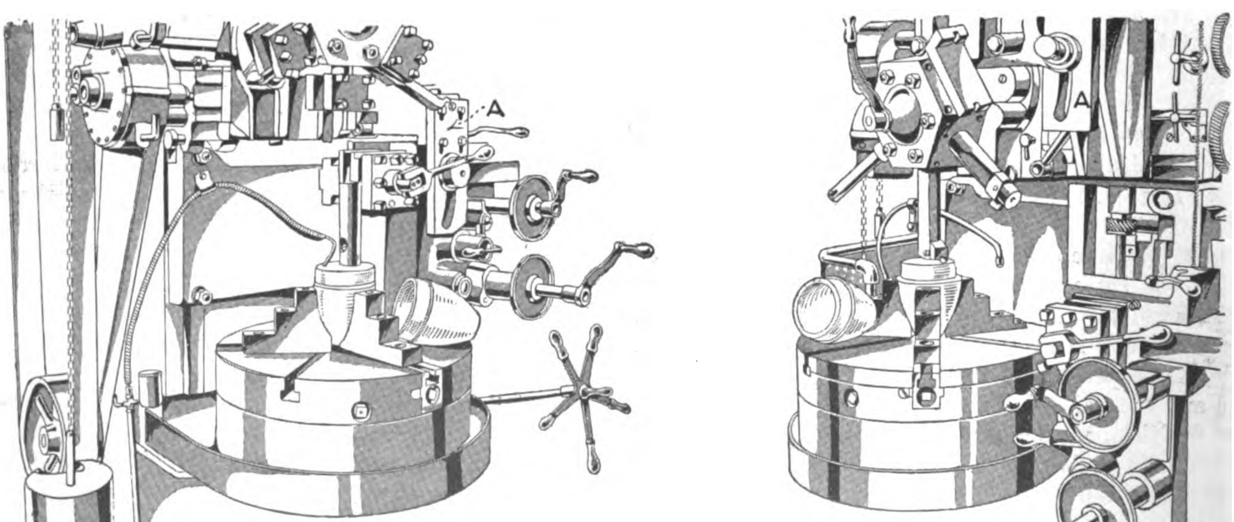

FIG. 23. ANOTHER METHOD OF BORING OGIVES ON BULLARD VERTICAL LATHES

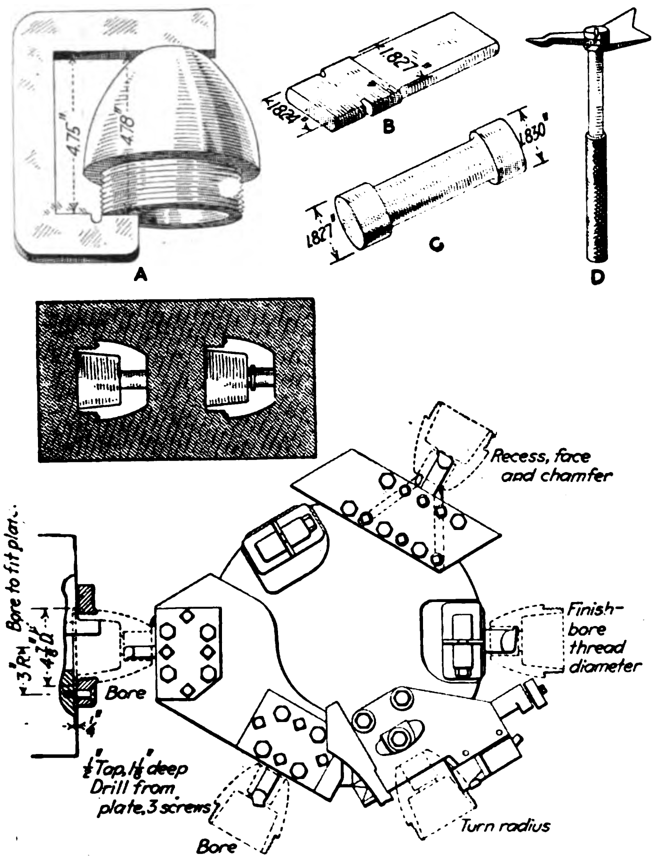

FIG. 24. OPERATION 3: OGIVE—BORE AND REAM NOSE
Machine Used—Jones & Lamson.
Special Fixture—Holding ring on chuck.
Gages—A, length; B, diameter of hole; C, hole for thread; D, diameter of recess below thread.
Production—8 to 10 per hr.

The fourteenth operation, Fig 32, uses the same style of chuck as that shown in operation No. 9 and finishes the curve on the ogive by a form on the back of the lathe-carriage turret. It also finishes the front end of the

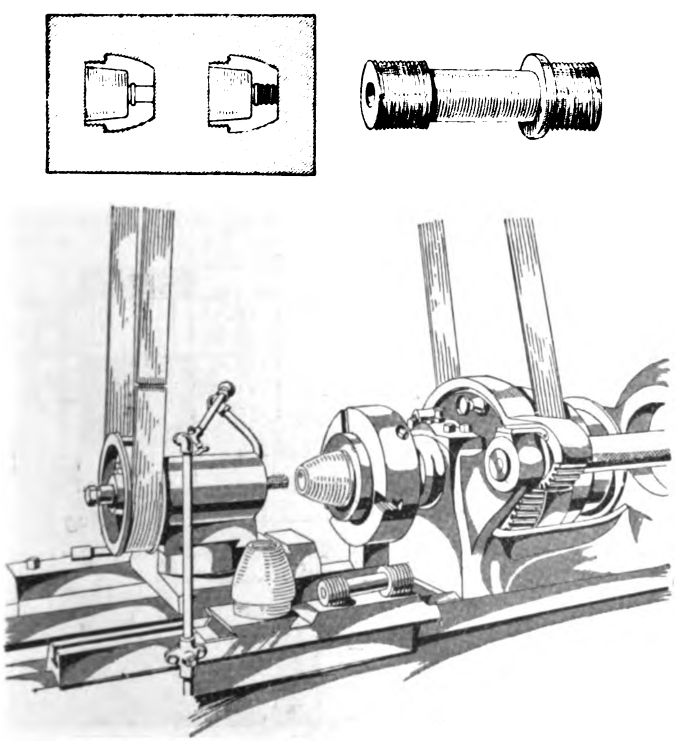

FIG. 25. OPERATION 4: OGIVE—THREADING NOSE
Machine Used—21-in. lathe.
Special Fixture—Hobbing head.
Gage—Plug thread gage.
Production—9 per hr.

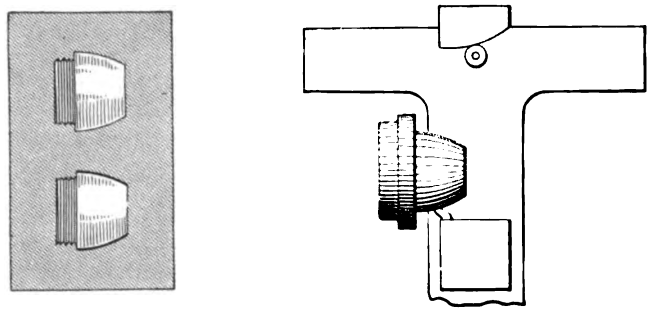

FIG. 26. OPERATION 5: OGIVE—ROUGH TURN OUTSIDE
Machine Used—LeBlond 21-in. lathe.
Special Fixtures—Form on taper slide, chuck.
Gage—None.
Production—15 per hr.

shell body itself, this curve continuing from the ogive back on to the body for about 1½ in. The finishing is done on 21-in. lathes of both Hendey and LeBlond makes, the production being from 2 to 2½ per hr. The gages are shown in Fig. 32.

The copper bands are next swaged on the shells, on a West tire-setting machine, each band being pressed in three positions at 1,500 lb. pressure. This work is handled at the rate of 30 per hr.

Then comes the turning of the band by the use of two tools in a tool post, Fig. 33. The first tool turns the band to the approximate outside diameter, while the second forms both sides and the outside diamter at the same time. The finished band is a trifle wider than the slot in which it is held. This operation uses the same style of chuck as that in operations 9 and 14, and production is 30 per hr. per machine. The whole shell is then cleaned in a tank of heated soda that is blown up into the inside by an air jet at the rate of 50 per hr. Then comes the final shop inspection and at the same time the inspection by the representatives of the Serbian government.

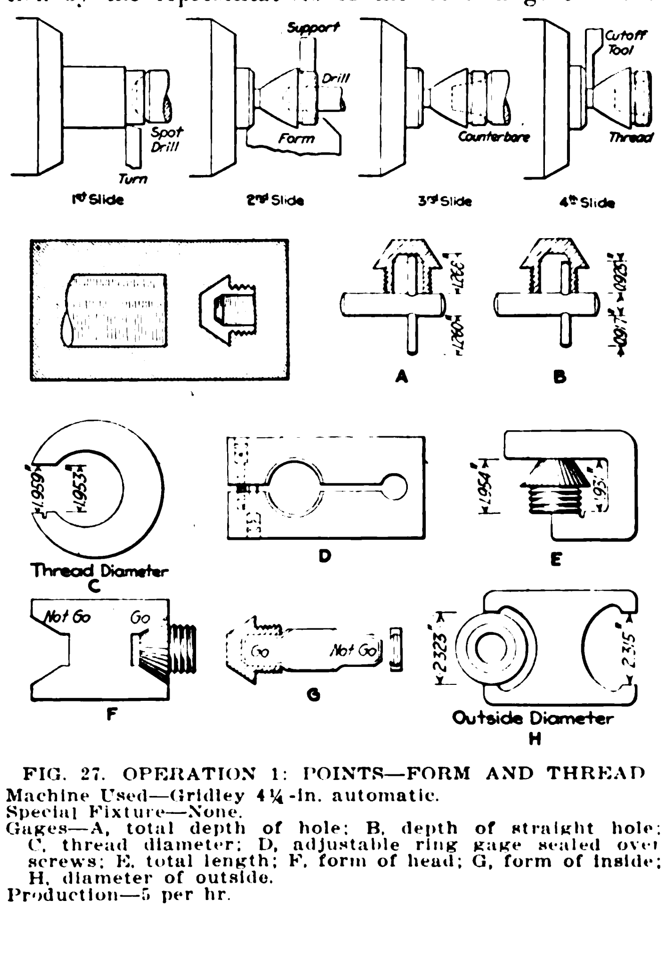

FIG. 27. OPERATION 1: POINTS—FORM AND THREAD
Machine Used—Gridley 4¼-in. automatic.
Special Fixture—None.
Gages—A, total depth of hole; B, depth of straight hole; C, thread diameter; D, adjustable ring gage sealed over screws; E, total length; F, form of head; G, form of inside; H, diameter of outside.
Production—5 per hr.

From here the shells go to the finishing department, where they are again washed in hot soda and also hot water. The tank used for this purpose is shown in Fig. 34, the compartment at the left being for soda water, while the other two compartments contain simply hot water as free from soda as can be maintained as the shells pass from one to the other.

Arrangements are made for a gang of six men, three on each side, each being provided with an upright washing pipe that has radial perforations at the upper end. The central stem controls an air valve, so that by dropping a shell over the upright pipe and pressing down, the air valve at the bottom is opened and a shower of hot water, either soda or plain, is forced all over the interior, cleaning it perfectly and allowing the shells to be handled very rapidly. The exact rate varies of course with the size and weight of the shells to be handled and the strength and agility of the men.

After cleaning, the shells are then ready for the inside varnishing, which forms the twentieth operation and is done on the machine shown in Fig. 35. This consists merely of two pairs of rollers, which are revolved by power and on which the shell to be varnished is laid as at *A*. The varnishing head is seen at *B,* carrying a nozzle that reaches to the bottom of the shell. This nozzle sprays the varnish on the inside, but does not become operative until the head has been pushed into the shell. Then an air valve is tripped, and the varnish is sprayed over the interior of the revolving shell as the varnishing head moves out by power. The spray is cut off at a predetermined point, as it is only necessary to varnish the lower part of the bore in most cases. This limit can, however, be easily varied for any length of shell and to varnish either a part or the whole interior, as may be desired. This inside varnishing can be done at the rate of 120 per hr.

The suboperation is the varnishing of the outside of the shell, which is done under a hood, shown at the right. A revolving spindle supports the nose of the shell and revolves it vertically, while the operator sprays on the varnish with the air-spraying arrangement shown at *C*. The protector *D* is swung in front of the shell to keep the varnish off the band. Inside the hood is a large exhaust fan to keep the atmosphere as clear of the varnish vapors as possible. The outside varnishing of the shells can also be handled at the rate of about 120

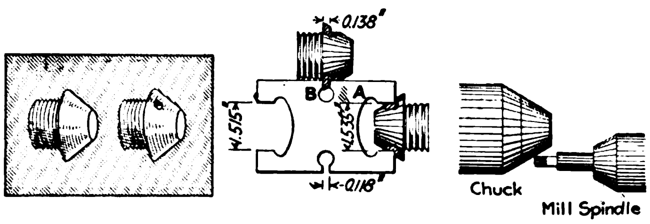

FIG. 28. OPERATION 2: POINTS—MILL KEY SLOT
Machine Used—Hand miller.
Special Fixture—Split chuck.
Gages—A, center distance of slots; B, thickness of metal below slot.
Production—25 per hr.

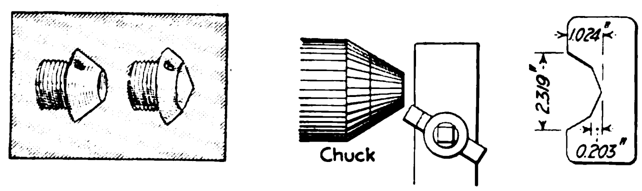

FIG. 29. OPERATION 3: POINT—SHAVE
Machine Used—Bardons & Olive hand screw machine.
Special Fixture—Split chuck.
Gage—Form of head.
Production—20 per hr.

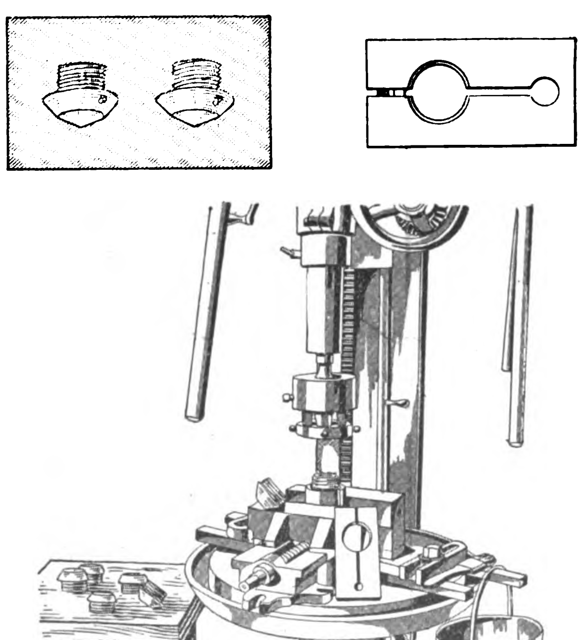

FIG. 30. OPERATION 4: POINT—RETHREAD
Machine Used—Vertical drilling machine.
Special Fixtures—Prong die and chuck.
Gage—Adjustable ring thread gage.
Production—22 per hr.

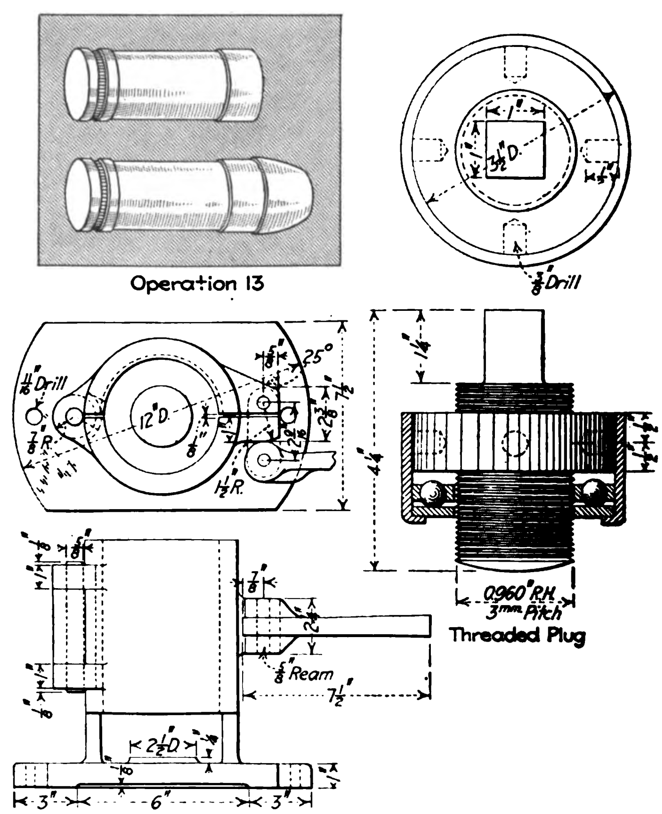

FIG. 31. OPERATION 13: SCREWING IN OGIVE
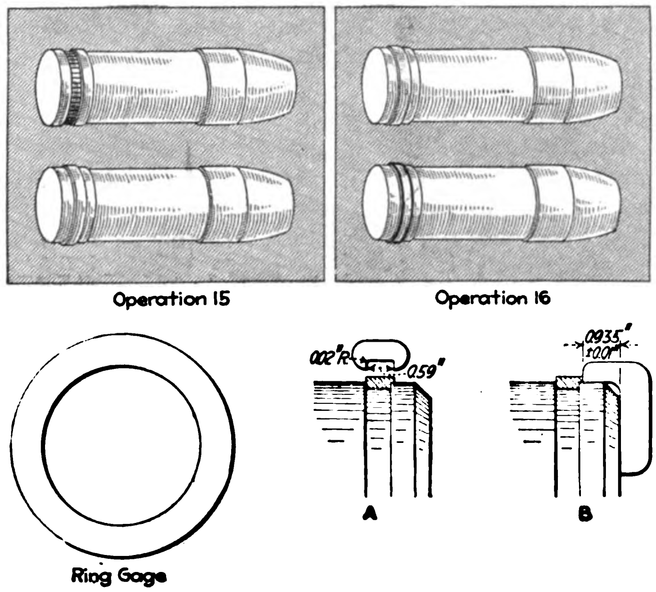
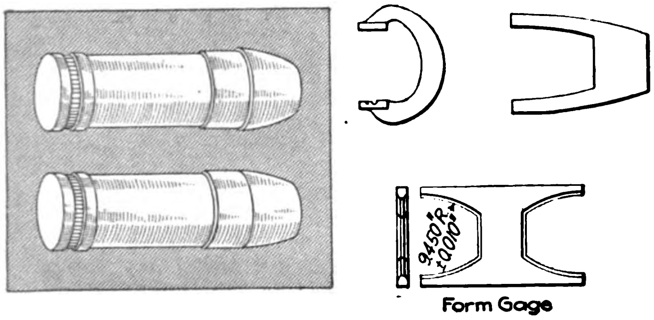
Machine Used—None.
Special Fixtures—Vise and screw plug.
Gage—None.
Production—30 per hr.

per hr. This is done in the De Vilbiss painting machine. The next, or twenty-first, operation is baking the varnish for 8 hr. at a temperature of about 300 deg. F. For this purpose the shells are placed in metal trucks, one of which is shown in Fig. 36. The trucks vary somewhat in construction, according to the size of the shell. The one shown is for the 70- and 75-mm. shells and contains movable separation strips, as shown. The trucks for the larger shells contain permanent divisions formed by crossbars of angle iron.

Operation 22—painting—is shown in Fig. 37. As can be seen, it is divided into stages, according to the number of operators. Four men are generally used, the first painting the end of the shell, the next a band the width of his brush, just below the bronze rifling ring, the third a band at the other end, and the fourth filling in the unpainted space. By working in this way 120 shells per hr. can be handled regularly.

High-explosive shells are painted a bright yellow, while shrapnel are painted a vivid red; but no paint must go on what might be called the bearing surface of the shell—both the copper band and the part just behind the ogive, which is an important diameter, as it fits the gun bore.





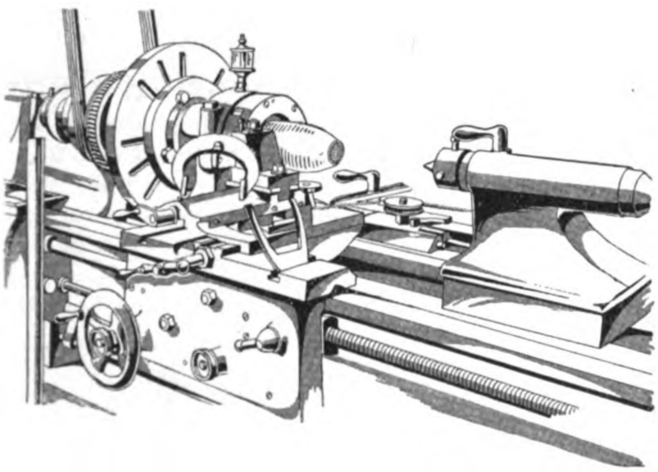


FIG. 32. OPERATION 14: FINISH-TURN OGIVE AND SHELL
Machines Used—Hendey and LeBlond 21-in. lathes.
Special Fixtures—Chuck and formers.
Gage—Form of nose.
Production—2 to 2½ per hr.

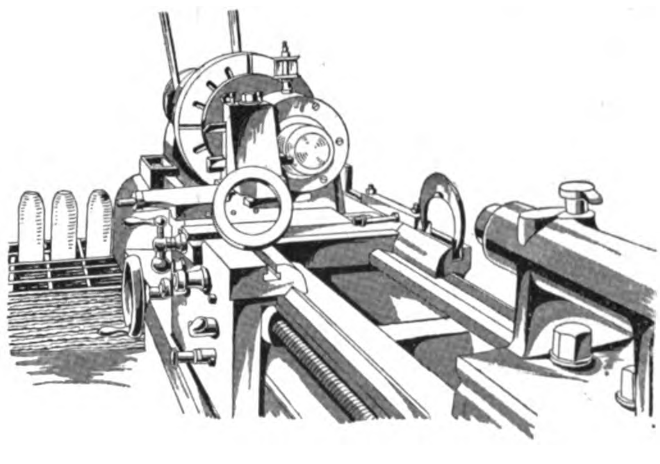

FIG. 33. OPERATION 16: TURN HAND
Machine Used—LeBlond 21-in. lathe.
Special Fixtures—Chuck; tool post.
Gages—A, width of band; B, distance from end of shell.
Production—20 per hr.

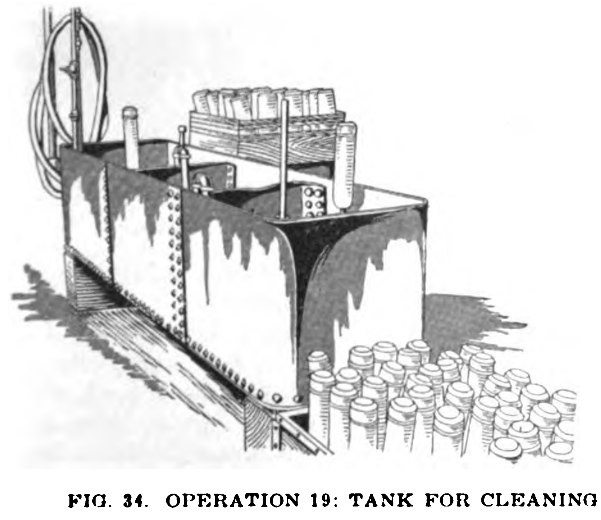

FIG. 34. OPERATION 19: TANK FOR CLEANING

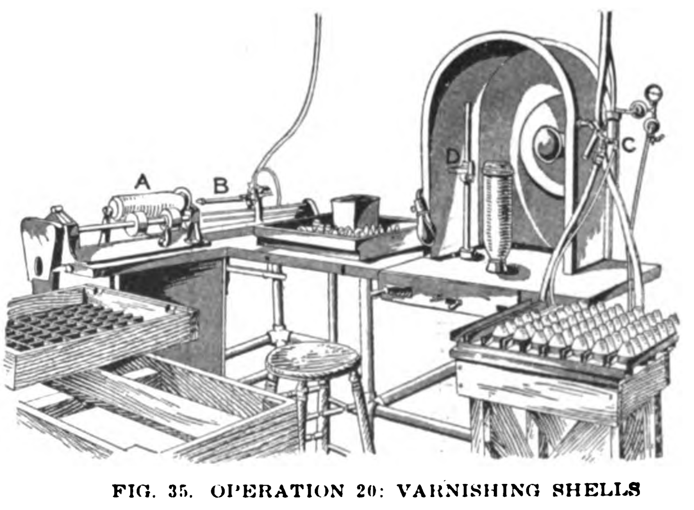

FIG. 35. OPERATION 20: VARNISHING SHELLS

After painting, the shells go to another drying oven at a temperature of 150 deg. F. for 12 hr. They are then ready to have the point screwed into place in the nose as a protector; this is done just before packing. These points have previously been varnished in the same place as the outside of the shell, some being shown in Fig. 35. Each shell is then wrapped in oiled paper and packed four in a box, as shown in Fig. 38. Separators are used to hold the shells firmly in position, and corresponding forms go on top of the shell, so that the cover holds them tightly in place. The construction of the box, the handles of light rope and the marking of the box are clearly shown.

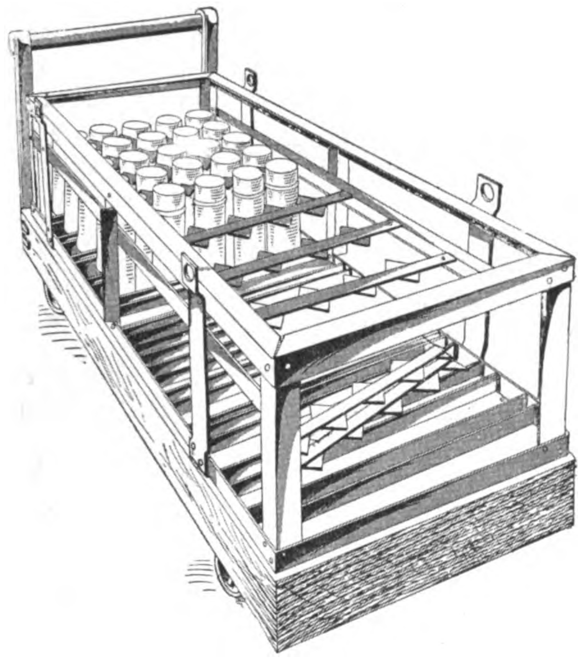

FIG. 36. TRUCK FOR BAKING SHELLS

The covers are screwed in place, and it will be noticed that some of the screw holes A are counterbored to nearly an inch in diameter—before the official sealing. After the screws have been put in place, sealing wax is poured into these holes, and the inspector presses into the wax a seal bearing the Government coat of arms. This is to insure against the shells being tampered with between the last Government inspection at the factory and their arrival at the various points where they are to be loaded.

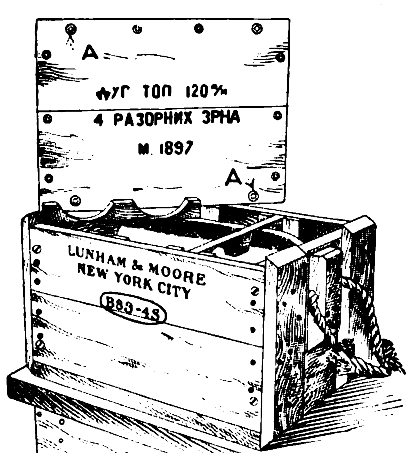

FIG. 38. BOXING BEFORE SHIPPING

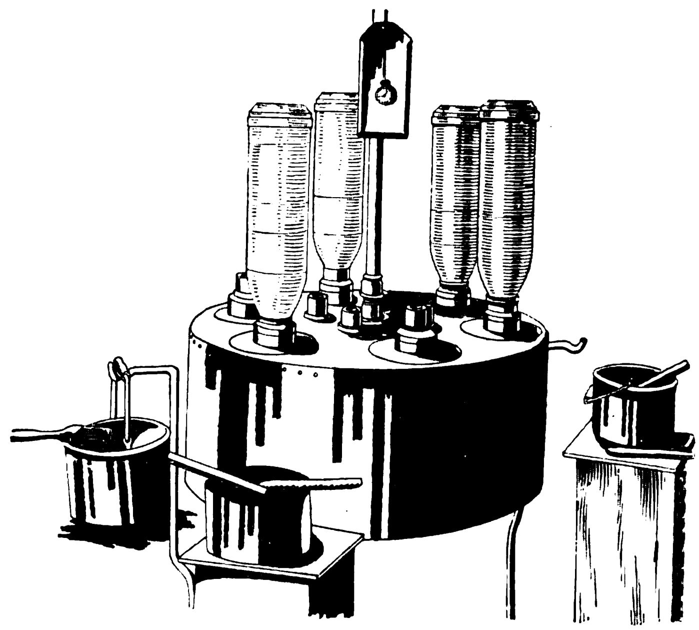

FIG. 37. PAINTING THE SHELLS

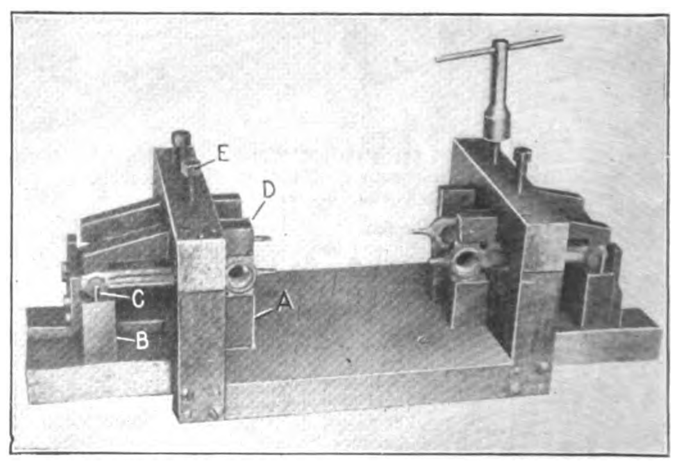
From these two articles it is hoped a good idea of Serbian shell requirements will be gained.

Milling Small Connecting-Rods

What is practically a continuous milling operation on a plain miller is taken care of by the fixture shown, found in use by the Henderson Motorcycle Co., Detroit, Mich.

The fixture holds four connecting-rods—two on each end. The gang of four milling cutters works in between the ends of the rods and machines both sides of two rods at a time. While the cutters are machining two of the rods, the operator removes the milled rods from the other end and replaces them with rough ones.



MILLING SMALL CONNECTING-RODS

The rods are located in the fixture on two blocks *A* and *B*. The front one *A* is a V-block, and the capscrew boss fits down into it. The rear block is flat-topped, with a pin *C* to butt the side of the rod against. The rod is held down by a floating clamp *D*, pressed down by means of a capscrew *E*.

Planning Delivery Dates in a Textile-Machine Plant

By Arthur O. Berry

SYNOPSIS—The method of planning the shop work for some time ahead is outlined in this article applicable to factories where orders for several similar machines are in hand at one time and where the machines are quickly built after being placed upon the erecting floor.

The work-planning sheet shown in Fig. 1 was devised to meet such conditions as those outlined above. The sheet itself is 16x20 in. and is divided into 14 spaces arranged in two columns. These are again divided into two parts, the right-hand column for recording the orders coming in from day to day are immediately cared for on the planning sheets, unless the dates for delivery are too far ahead.

The sheets themselves are made either of a black and white print or the ordinary blueprint paper, in either case produced from a positive made from the transparent paper original. Copies of the sheets are printed from the negatives as required. They are mounted on two light boards and held in position by thumb-tacks. Two sheets are placed one on top of the other on one board, the old sheets being removed when their use is no longer required. Spaces are provided at the top of the sheet for the names of the month and year.

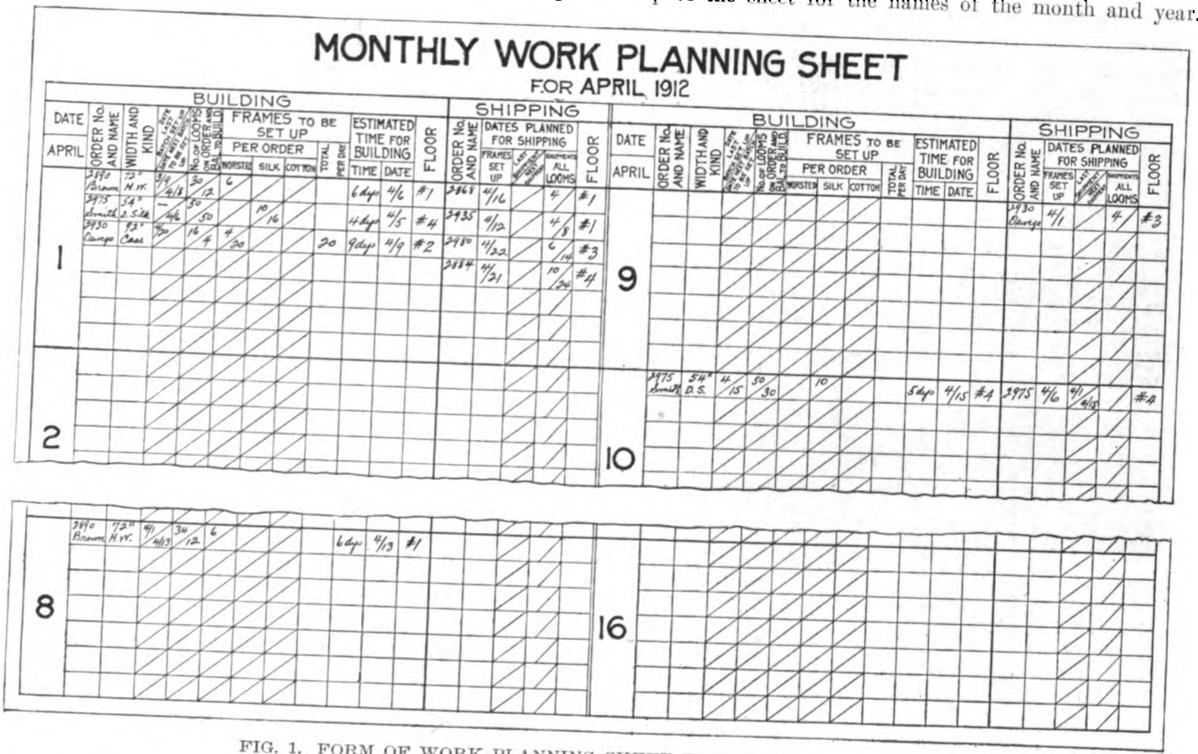


FIG. 1. FORM OF WORK-PLANNING SHEET FOR MACHINERY PLANT

setting up and building of the machine and the left-hand, the day's shipments. Both the setting up and the shipping columns are further subdivided for purposes indicated at the top of each column. Each of the 14 spaces also has seven subdivisions necessitated by the nature of the work and the number of orders running simultaneously. The purpose of the lines running diagonally across and dividing the squares formed by the crossing of the horizontal and vertical lines is indicated at the head of the respective column and will be more clearly explained later.

One of the 14 spaces with its seven subdivisions is allotted to each working day of the month. As only 14 days are provided for on each sheet, four or more sheets are required, running simultaneously. The new

In the first vertical space at the left of the columns the day of the month is placed in conspicuous figures.

A few words may be needed to make clear the use of one or two of the columns and the diagonal lines. It must be kept in mind that the sheet is devised for the planning of work on orders for quantities of machines varying in number from one to several hundred of a kind, and where the shipments are to be made at more or less regular intervals. Therefore, in planning for the building and shipping of an order by installments, it is desirable to be able to make easy reference to the dates previously, as well as subsequently, planned. The fourth column of the sheet is for this purpose, the top left-hand corner of the squares being used to indicate the earlier dates planned, while the

bottom right-hand corner indicates subsequent setting-up and shipping dates. These remarks apply also to the third column of the shipping section and the sheet headed "Last Shipment" and "Next Shipment."

To make the use of the sheet more clear, I will describe the planning of one or two orders. Starting, then, with Order 2890 for Brown, planned to be set up on the first day of April, you find this order to be for a number of 72 "H. W. looms." The fifth column tells you that there are 30 looms in the order and that 12 of these have already been set up, leaving a balance of 18 to come. By reference to shipping data you learn that six looms of this type will make a car load. It is desirable, therefore, to have them set up and built in batches or multiples of six.

From the fourth column of the planning sheet, you see that the last lot was set up on the ninth of the previous month. As the customer is now wanting a shipment every week, you plan to set up another lot of looms on the eighth of the month, and this is indicated in the fourth column. Again referring to the records you find that six days is sufficient to allow for building the looms. You therefore set down the shipping for the sixth of the month, noting this in the tenth and eleventh columns, while the twelfth column is reserved for indicating the floor upon which it is convenient to place the looms. By referring to the shipping section for Apr. 1, you see that there are four looms of Order 2868 and four of Order 2935 going off the floor, thus leaving floor space of sufficient area to accomodate the six looms you are now planning for.

Having decided the date for shipping, you transfer this information to the shipping section of the sheet

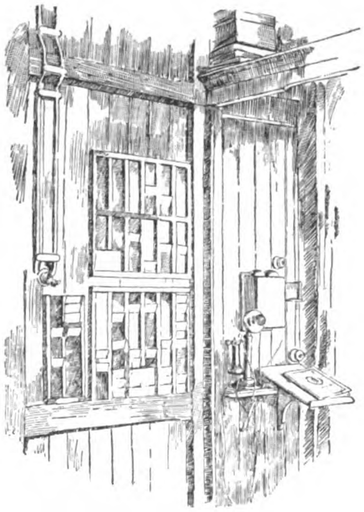

FIG. 2. CONVENIENT WALL BOARD

for the sixth day of the month, noting in the second column by cross-reference the day the looms were set up, also in the fifth column the number of the floor upon which they are placed. The fourth column of the shipping section indicates the number of looms to be shipped, while the third column refers to the dates of previous and subsequent shipments. The fourth column in the building section, headed "No. of Looms in Order and Balance to Build." provides a means for knowing at any stage the balance of looms that have still to be cared for in future planning.

Following the balance of Order 2890, since a lot of looms of the same order will go off the first floor on the sixth of the month, you decide to set up a batch of looms on the eighth of the month, and make the entry for that date, again noting in the fifth column that there are 30 looms in the order, but that a balance of only 12 remains. You plan to ship on the thirteenth

ORDER NO. 2890
NO. OF LOOMS 6
DATE SET UP 4/1/12
DATE TO BE SHIPPED 4/6/12
NAME Brown Co.

FIG. 3. FORM OF CARD FOR WALL BOARDS

of the month, and on this same date can also plan for the balance of the six looms of Order 2890, to go on the floor in the place of the six to be shipped. With the shipping date set down for the nineteenth of the month, this order will be done with, so far as the planning sheet is concerned.

Since it is certain that changes will occur and that rearrangements of the planning sheet have to be made from time to time, it will be wise to use a lead pencil in making all entries.

In addition to the planning sheets are a number of boards, each board representing one of the erecting floors. Fig. 2 shows one of these boards hung in a convenient position on the office wall. The boards themselves are made to any convenient size, but should bear some relationship to the size of the floors that they represent. A number of strips of wood arranged parallel with each other, are attached to the board, and slots are cut at an angle in the strips to allow the small cards, Fig. 3, to be slipped into any position on the board. A convenient size of card to use is 1x2 in. As the new orders are issued and planned, these cards should be placed on the board in the spaces machinery will occupy. The disposition of the machines on the erecting floor as indicated by the cards is checked each day from records supplied by the shop. Information regarding the machines that have been shipped and those that have been placed on the erecting floor is supplied by the departments concerned.

It must not be assumed that the order of work as set down on the planning sheet will be rigidly adhered to. Eventualities are sure to arise from time to time which will necessitate rearrangements of the planning sheet. A customer may "hold-up" an order for one reason or another—his mill may be new and in process of building, and not in a sufficiently advanced condition to allow him to receive the machines at the time he had originally expected to do; or he may call for changes in the construction necessitating the making of drawings and, possibly, new patterns. If the machines have already been placed on the erecting floor, serious inconvenience may be caused through the holding up of floor space planned to receive other machines. If the delay is likely to be protracted, it becomes necessary

to decide whether or not it will be wise to take down the machines and stand them at one side until the new material is ready, or in the case of machines held up on account of the customer not being ready to receive them, to decide whether or not they should be completed and stored away until such time as it is possible to ship them.

Machine Shops in Brazil

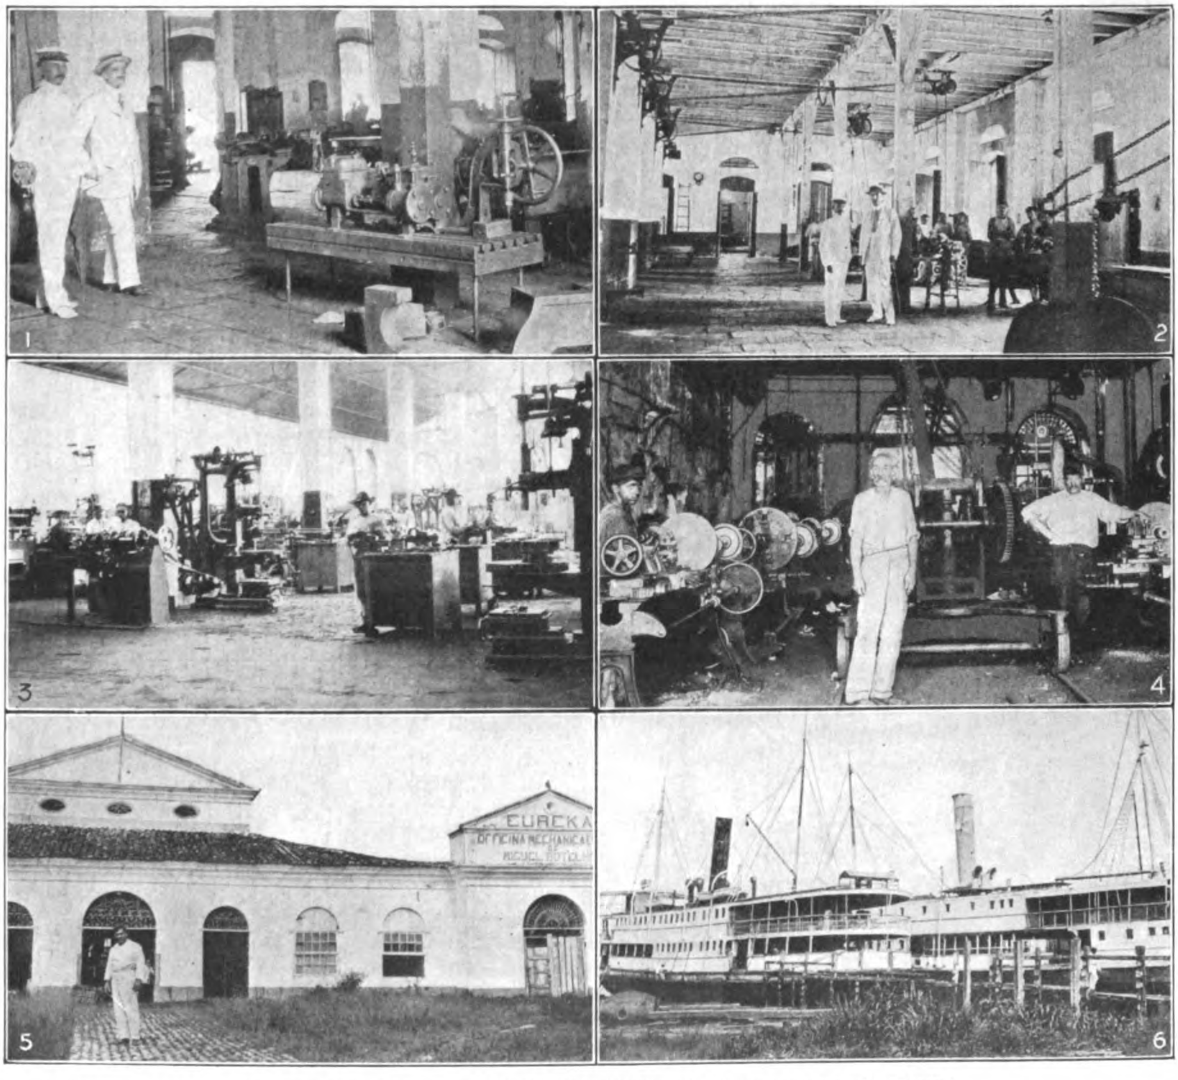
To show still further some of the interesting characteristics of South American machine shops, we illustrate herewith a number of shops in various parts of Brazil.

At Belem, in the State of Pará, is the Officina Arsenal Marinha, which is a small shop devoted to naval repairs. It is in charge of Capt. Tenente Aranha, the force consisting of 18 men in the machine shop and 12 in the foundry, with a total equipment of 13 machine tools, mostly of English make. The commandant is shown at the left in Figs. 1 and 2, the latter also showing the type of shop.

Fig. 3 shows the interior of the shop of the Compania Linha Circular, or Belt Line Railway, at Bahia, Brazil. It is devoted to street-railway repairs and employs about 170 men, of whom 28 are in the machine shop and 10 in the foundry. Nearly all its equipment is from the United States.

The view in the shop of Barão de Suassuna, at Pernambuco, Brazil, is shown in Fig. 4. This shop handles general repairs, employing about 45 men in the machine shop. The majority of the tools are from France.

Figs. 5 and 6 show the shop of Miguel Bothelho, this being known as Officina Mechanica e Naval Eureka. It is also in Belem, Pará, Brazil. The proprietor himself is standing on the main walk in Fig. 5, while Fig. 6 shows some of the repair work which he handles. The two vessels are in "dry dock," which in this locality means that they are run upon the bank of the Amazon at high tide, and work on the hull is done while the tide is out. They are mostly shallow-draft flat-bottom boats, which can be easily handled in this way by the 7-ft. tide.



FIGS. 1 TO 6. A BRAZILIAN NAVAL SHOP AND OTHER REPAIR SHOPS

Fig. 1—Commandant Tenente Aranha. Fig. 2—In the Naval Arsenal at Belem, Pará, Brazil. Fig. 3—Belt Line Tramway Company, Bahia, Brazil. Fig. 4—Shop equipped with French machines. Fig. 5—Miguel Botelho and his shop. Fig. 6—Vessels in "dry dock" at low tide

Probably the largest jobbing shop in Bahia, Brazil, is that of Wilson & Sons, shown in Figs. 7 and 8. It is mostly devoted to ship repairs. The majority of the machine tools are English. Something of the picturesque location can be seen in the view showing the exterior, which also gives the dock and office buildings.

Figs. 9, 10 and 11 are from the Fundicion Geral, this being a combination of Allan Paterson & Bowmans. It is in Pernambuco, Brazil, and is a large shop devoted to general repairs. About 120 men are employed, 100 of them being in the machine shop. Nearly all the machinery is English.

Fig. 10 shows some interesting beam construction, and also the spiral stairs at the back. The grated windows appear very different from our own shop construction. Fig. 11 shows a large double-headed lathe and also the very peculiar partial saw-tooth roof effect down the shop bay. Four angular roofs form the sloping part of the saw tooth, the peculiarity being that there is no glass in the verticals, as with us, the opening between these slanting roofs being without covering of any kind. This construction makes for excellent ventilation, but it is also subject to rain and dust.

Fig. 12 shows the interior of another shop devoted to shop repairs—the Estelleros Port, of Pará. It is also located in Belem and is a good-sized plant, having a regularly equipped dry dock and employing 420 men. Only 42 of these, however, are in the machine shop. The majority of the machines came from England. The shop construction, it will be observed, is quite modern.

Unusual Motorcycle-Muffler Work

By Ethan Viall

SYNOPSIS—The closing-in of the muffler tube in a punch press is of unusual interest and the result of considerable experimenting. Too rapid closing-in means buckling or other troubles. The piercing of the holes in the tubes also presented a number of difficulties, which were successfully solved.

It is a common saying that the man who says a thing cannot be done is constantly being interrupted by someone doing it. When it was first proposed to make muffler bodies from seamless tubing and to close in one end mechanically, the experts said it could not be done so as to be commercially successful. They advanced all sorts of reasons, but Superintendent Parker, of the Henderson Motorcycle Co., Detroit, Mich., believed otherwise. The mufflers in question are used on a four-cylinder, 12-hp. motor, and must not only successfully suppress the noise, but must be able to stand the vibration and hard service to which the average motorcycle is subjected.

It was decided to employ a punch press for the work of closing in one end of the muffler tubes. Considerable experimenting was needed to determine the exact amount that the tube could be closed in at each operation. Consequently the closing dies had to be changed a number of times to meet the conditions brought out by actual use. The final result was the making and using of four closing-in dies, as shown at *A, B, C* and *D*, Fig. 1. The short piece of seamless tubing from which the muffler is made is shown at *E*. The first and last closing-in operations are shown at *F* and *G*. The two intermediate closing-in operations will be readily understood from the description.

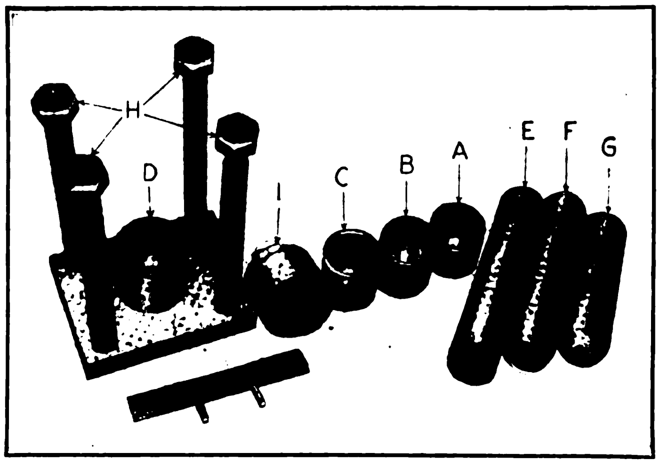

FIG. 1. THE CLOSING DIES AND EXAMPLES OF WORK

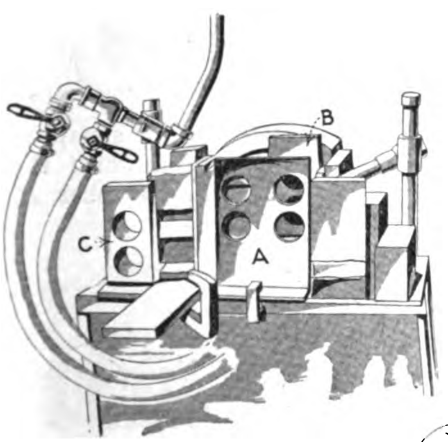

FIG. 2

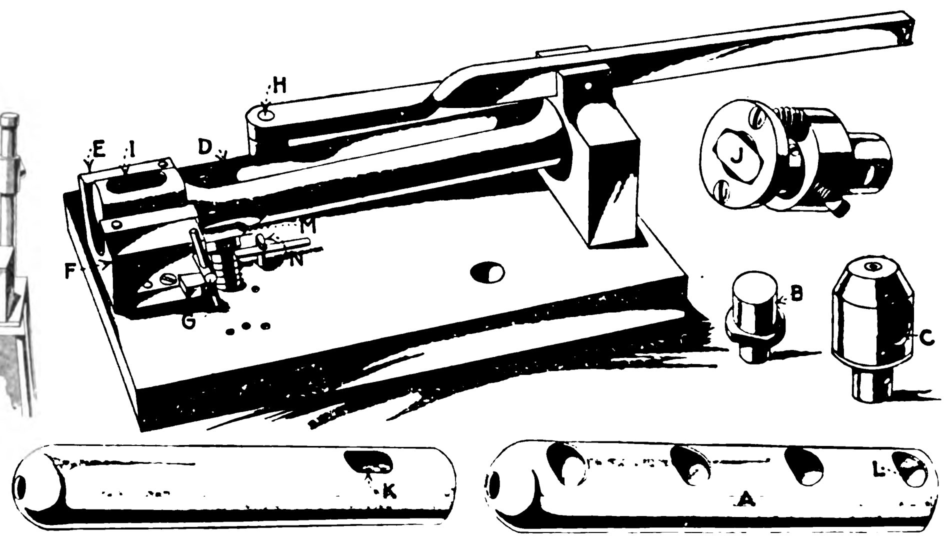

FIG. 3

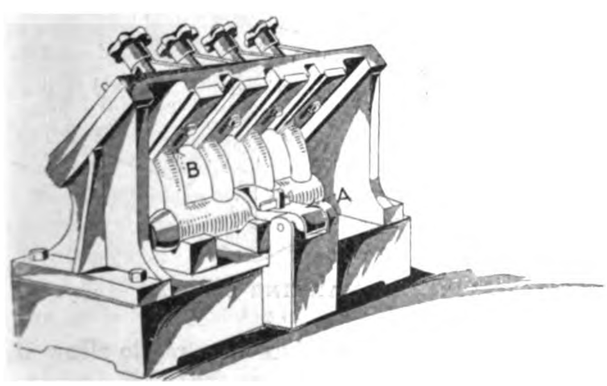

FIG. 4

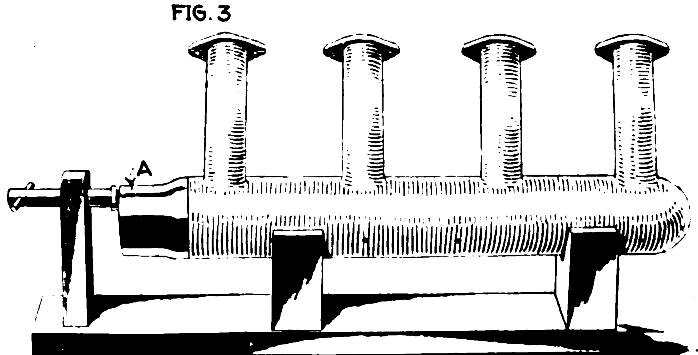

FIG. 5

FIGS. 2 TO 5—DETAILS OF MOTORCYCLE MUFFLER FIXTURES AND OPERATIONS

Fig. 2—Furnace for heating ends of tubes. Fig. 3—Piercing tools and examples of work. Fig. 4—Fixture to hold work for welding. Fig. 5—End-brazing fixture

The tubing used is 13 gage, $1\frac{7}{8}$ in. in diameter and is cut $13\frac{5}{8}$ in. long. To make room for working this length in the press, the dies are carried in a sling that is fastened underneath the press platen by means of four bolts *H*. The punch *I* is carried in the ram and is used to force the tube down into the die. The method of procedure is to set the punch and die for one operation, run through a given lot of tubes, then set up for the next operation, and so on. The first operation is done cold, using motor oil for a lubricant in the die.

The first reduction, or amount of closure, is from $1\frac{7}{8}$ to $1\frac{1}{8}$ in. The second operation closes the tube from $1\frac{1}{8}$ to $\frac{3}{4}$ in., the end of the tube first being heated to a cherry red. The third operation closes the end from $\frac{3}{4}$ to $\frac{9}{16}$ in., and the next and last from $\frac{9}{16}$ to $\frac{3}{8}$ in. Each operation after the first requires the heating of the end of the tube to a cherry red. Starting with a length of $13\frac{5}{8}$ in.,

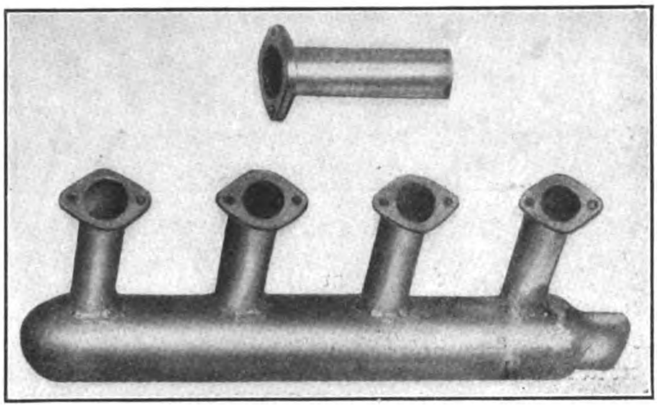

FIG. 6. FINISHED WELDED AND BRAZED MUFFLER

the final operation finds the tube reduced in length to $12\frac{7}{8}$ in., with a $\frac{3}{8}$-in. hole left in the beautifully rounded end.

The heating furnace used is shown in Fig. 2. It is a modified brazing furnace. The tubes to be heated are thrust through the holes in the piece of boiler plate *A* and through holes in the firebrick next to the flame. One of the firebrick referred to is shown in position at *B*, and the other is set on the front of the furnace at *C*. The object of using firebrick with holes in them is that the heat may be applied just where it is wanted. Only a small space is left between these special brick and the back of the furnace, so the flame plays upon only the ends of the tubes. Thus the ends that are to be closed are softened, but the rest of the tube is left hard, to resist the pressure.

Four large round holes and one oblong hole are pierced in the tube after the end is closed. This work is done with the tools shown in Fig. 3. A tube with the four $1\frac{1}{16}$-in. holes pierced in it is shown at *A* and the punch and die at *B* and *C*. The die is placed on the end of the mandrel *D* instead of the one shown. The tube is then thrust on the mandrel between the side guides *E* and *F*. The first hole is located by the stop pin *G*, which is pulled out after the hole has been pierced. The tube is then pushed on the mandrel until the stop *H* will enter the hole, thus locating the second hole. After this hole is pierced, it is used to locate for the next, and so on.

The oblong hole is $\frac{3}{4}$ in. wide and $1\frac{1}{2}$ in. long. The die used is shown in position at *I* and the punch at *J*. The tube is located for the hole *K* by thrusting it on the mandrel until the spring stop *M* will enter the hole *L*, next to the open end. When this stop is not in actual use, it may be locked away from the mandrel by turning the small handle until it catches under the hook *N*. In order to allow the tube to be slipped easily on the mandrel without binding between the end of it and the bed block under the end, about $\frac{1}{64}$-in. play is given. With a mandrel as long as this a spring downward of $\frac{1}{64}$ in. does not materially alter the alignment of the punch and die, yet gives ample clearance for the sliding in of the tube.

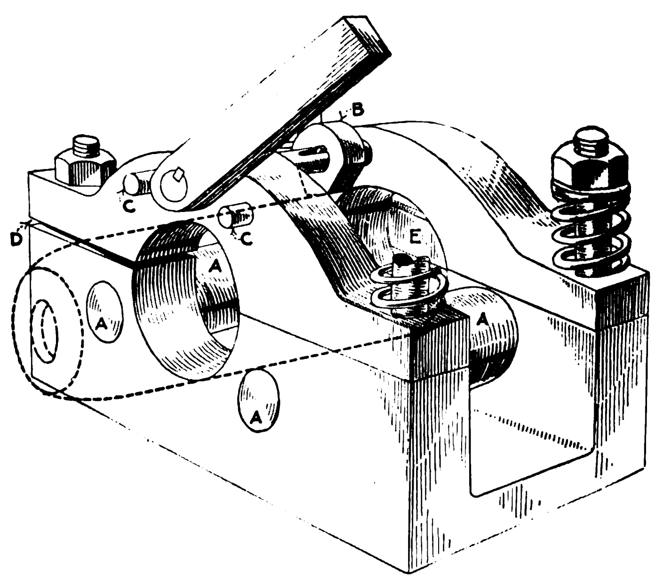
The four flanged tubes that lead from the exhaust valves to the muffler are welded on in the fixture shown in Fig. 4. The muffler tube is laid in V-blocks and is held in place by means of the hinged clamp *A*, which is locked by a taper pin. The four flanged tubes are held in place by means of forked clamps like *B*, the opposite ends simply being thrust through the round pierced holes in the muffler. The parts are then welded together with an acetylene torch and iron filler. A Prest-O-Lite outfit is used, and one man welds (on an average) 34 mufflers in an 8-hr. day, making four welds on each muffler. An 18-lb. tank of gas lasts about 6 days on this work.

An end is next brazed into the open end of the muffler, using the fixture shown in Fig. 5 to hold the parts in place. A regular gas blow-pipe is used to do the brazing, brass wire and a fluxing mixture of the usual kind being worked into the joint. A completely welded and brazed muffler, just as it comes from the fixtures described, is shown in Fig. 6. It gives a good idea of the way the welds around the small tubes look.

A Quick-Clamping Fixture for Marking Shells

By Fred Fruhner

The illustration shows a simple fixture for stamping shells. It consists of two rollers *A*, upon which the shell turns. The stamping is done with the roller *B*.



DEVICE FOR MARKING SHELLS

which is engraved and has the sides cut away to allow the shell to pass when the handle rests on the pin *C*.

The cutout at *D* allows for the difference in the shells, so as not to break the stamp. The springs act as a sort of gage of pressure. The strap *E* locates the shells.

Special Shell and Fuse Drilling and Tapping Machines--I

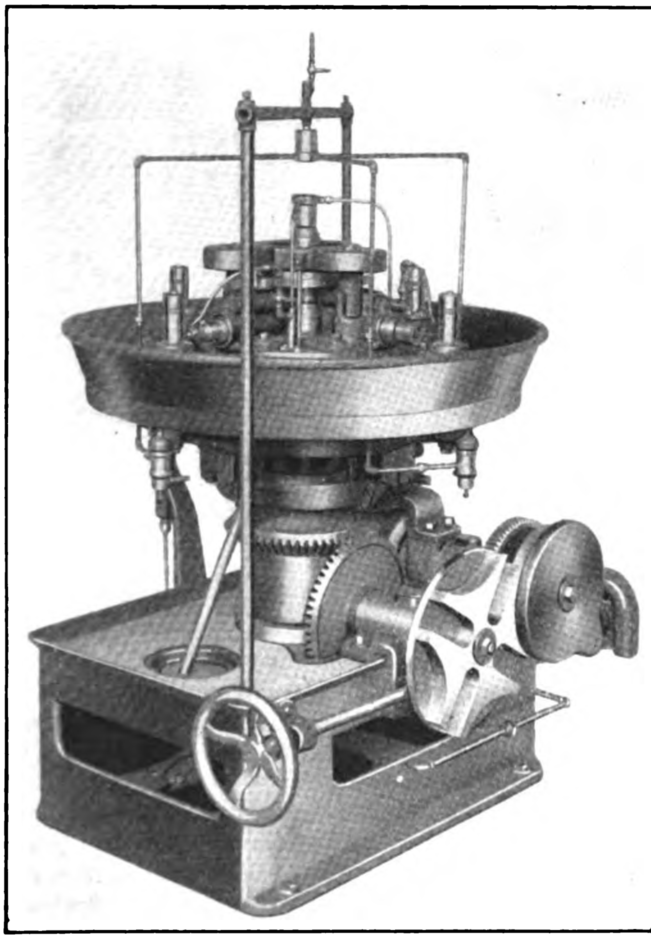
SYNOPSIS—Success in munition work seems to be obtained in two directions—with simple machines and special fixtures or with machines designed and built especially for the work in hand. The machines illustrated herewith are excellent examples of the latter class.

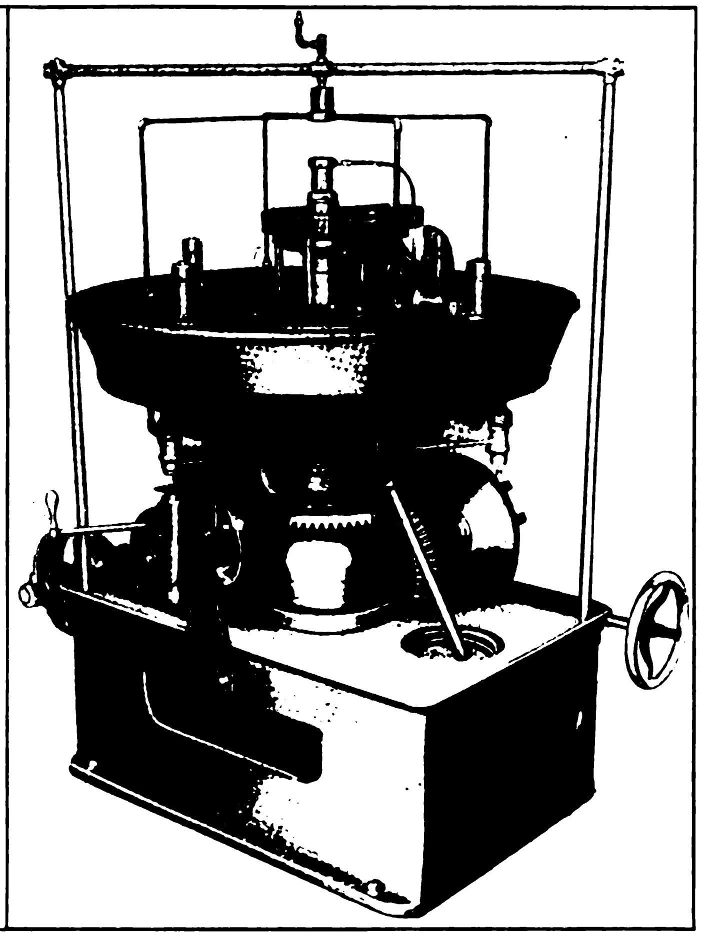
The demand for munitions of various kinds has given rise to many plans for special machines on which they can be manufactured. A number of such machines have been illustrated from time to time, but in no instance have we been able to show such a complete line of special machines for a variety of fuse or shell work as that of the Langelier Manufacturing Co., Providence, R. I. Some of these machines are illustrated herewith, together with the work they perform, the remainder being reserved for a later article.

The first machine is for drilling and tapping the grub-screw hole in the nose of the 18-lb. British high-explosive shell and is shown in Figs. 1 and 2. In Fig. 3 is shown the shell and Fig. 4 illustrates the details of the machine.

It has four work-holding stations, *A, B, C, D,* arranged equal distances apart upon a circular carrier *E,* which rotates around a central vertical post mounted upon a heavy cabinet base. Carrier *E* automatically brings each shell from the loading position *A* successively opposite a stationary drilling spindle *F,* a tapping spindle *G* and finally to the ejecting position *A,* pausing at each index just long enough to allow the drilling and tapping operations to take place. The work-holding stations *A, B, C, D* each have pneumatically operated expanding chucks *H,* in which the shells are inserted and which grip the shells very firmly by their bore the moment the index of the carrier begins.

The air-inlet valve then opens, an air pressure of 70 lb. per sq.in. drawing down the chuck center and forcing out the jaws tightly against the bore of the shell. The chuck is automatically contracted, and its grip on the finished shell is released for quick removal of the shell. At the completion of the cycle the downward projecting knob on the air valve rides up on the short curved rail opposite the ejecting and loading position, the operator depresses the foot treadle, shutting off the air pressure, which releases the grip of the chuck. By keeping the foot treadle depressed the action of the air valve may be rendered fully automatic. Three-point stops permit controlling the distance from the center hole to be drilled to the open end of the she





FIGS. 1 AND 2. TWO VIEWS OF THE CONTINUOUS DRILLING MACHINE FOR SHELL GRUB-SCREW HOLES

This cycle repeats for every shell. Consequently, there is a fully drilled and tapped shell removed at each index, one shell being drilled and another shell being tapped while unloading and loading are taking place.

The indexing of the carrier is accomplished through the intermittent action of the large Geneva motion shown, which is driven through the worm and bevel gearing from

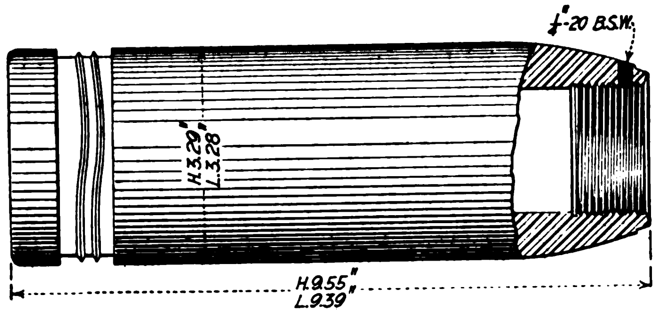


FIG. 3. BRITISH 18-LB. HIGH-EXPLOSIVE SHELL

the jackshaft, shown at the end of the machine and driven from the overhead countershaft. To bring the carrier more positively to stop at each index and lock it rigidly in position for the brief space of time required for the drilling and tapping operations, a locking toe, actuated by a rocker-arm in contact with the edge cam on the Geneva driver shaft, is moved into a slot on the under side of the carrier.

The vertical central post, around which the carrier rotates, houses a vertical sleeve that is intermittently operated by a large cylindrical cam on the Geneva driver shaft, accomplishing the feed and return of the drilling and tapping spindles. This sleeve, in turn, incloses a vertical shaft driven independently by a 12-in. pulley in

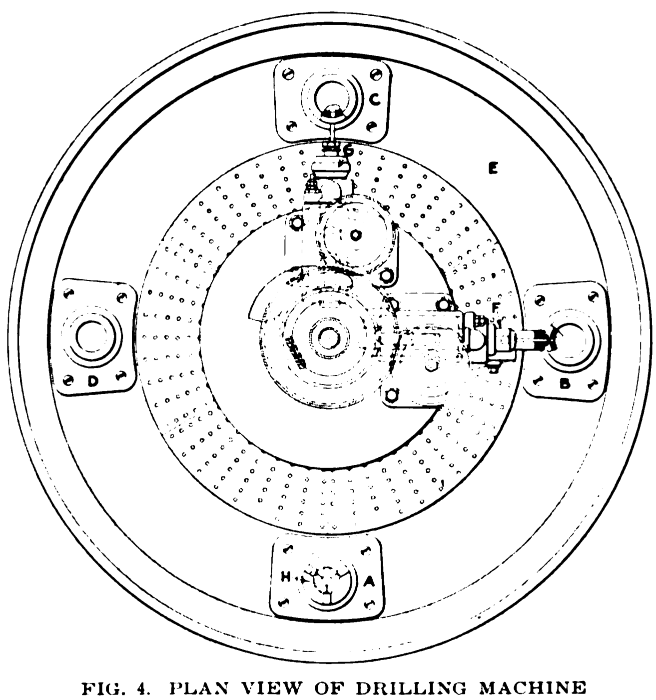

FIG. 4. PLAN VIEW OF DRILLING MACHINE

the base, carrying at its top a 72-tooth spur gear in mesh with two smaller spur gears or vertical shafts, on which are mounted spiral gears meshing at right angles with bronze spirals giving the drilling spindle 1,085 r.p.m. and the tapping spindle 366 r.p.m. The tapping spindle is equipped with a special Jarvis reversing tapping chuck that automatically reverses and withdraws.

The production actually secured with an unskilled operator from one machine averaged five steel shells drilled and tapped with one hole each per minute. This speed is easily maintained, because the machine drills and taps without stoppage for loading or unloading the shells or for securing the shells in working position.

Effective lubrication of the drill and tap is accomplished by an automatic oil feed. The circular pan surrounding the carrier affords ample capacity for catching chips and oil. The perforated false floor allows the oil to run into the base, whence it is pumped back to the work by a circular pump.

The drill is effectively supported and is prevented from glancing off the curved surface of the shell by a rigid steadyrest with long hardened-steel drill-guiding bushings. The feed of the drilling and tapping spindles is effected by a segment cam in contact with rollers mounted on studs and projecting from the sleeves of the drilling and tapping spindles and operating as already described. The floor space occupied by the machine is 44x56 in., and it is 66

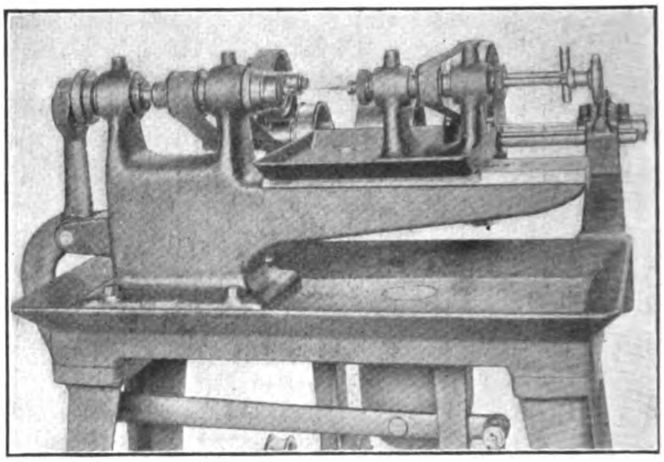

FIG. 5. DRILLING LATHE FOR GAINES AND PELLETS

in. high. It weighs approximately 4,550 lb. All gearing and exposed mechanism is carefully incased, to comply with safety regulations.

The machine shown in Figs. 5 and 6 was designed for drilling the small central hole in the gaine body, Fig. 7, and the graze pellet, Fig. 8. The output for the gaine body is 4 per min., or 240 per hr.; for the graze pellet, owing to the length of hole, 3 per min., or 180 per hr. The gaine body is made of steel and is drilled with a No. 68 0.031-in. drill. The graze pellet is of brass, the drill being a No. 56, of 0.0465 diameter. Both drills are stock sizes, but are specially tempered. The later specifications allow a much larger hole in the gaine and make the drilling correspondingly easier.

The drills being very small, the holes must be drilled at high speeds. To insure the holes being drilled straight and exactly in the center, both the drills and the parts are revolved. The proper speeds for both were determined after much experimenting and were found to be 4,500 r.p.m. for the drill used on the steel gaine body and 800 r.p.m. for the work; for the brass graze pellet, 6,000 r.p.m. for the drill and 1,200 r.p.m. for the work.

The drilling is done by means of a light sensitive floating spindle that is a sliding fit in the tailstock. A ball-bearing hand knob is mounted on the end for the operator, who feeds the drill by pushing. Thus it is easy to feel the cut of the drill and withdraw it when it fills or clogs

with chips. The holes are drilled accurately, and the liability of drill breakage is reduced to a minimum.

The machine consists of a headstock having an extended slide upon which the tailstock is mounted in any position, so that pieces up to 6 in. long can be drilled. For long pieces, such as the gaine body, a quick-operating steadyrest is used, which is adjustable to the diameter and the length of the piece to be drilled. For drilling the graze pellet no steadyrest was required. The headstock spindle is provided with a spring chuck for holding and driving the parts to be drilled. The chuck is opened by a foot pedal. A heavy compression spring inside of the spindle automatically closes the chuck when the operator removes his foot. Both spindles run in adjustable phosphor-bronze bearings, and both are driven from a self-contained

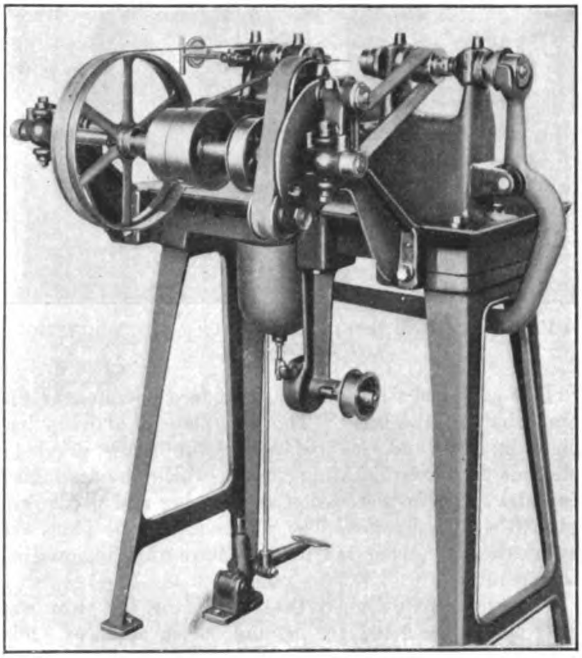

FIG. 6. REAR VIEW OF DRILLING LATHE

countershaft attached to the rear of the table upon which the headstock casting is mounted.

The tailstock-spindle pulley runs upon sleeves that are held stationary in the bearings and that drive the spindle by a double-keyed collar. This construction avoids the running pressure of the pulley upon the spindle, leaving it free so that the operator can sensitively feel the cut of the drill. The drilling spindle is driven by a 1-in. endless woven canvas belt and has a tightener. The headstock drive is unique in avoiding the use of a crossed belt, which would be necessary with a two-pulley drive, because the work must run against the cut of the drill. The open belt drive is obtained by means of a fulcrumed lever carrying two idle pulleys, the lever being mounted on the countershaft hanger at the rear of the headstock. The belt passes around these pulleys in such a manner that the driving pulley on the countershaft drives against the back of the belt. This arrangement secures the same result as with a crossed belt, but without its disadvantages. The headstock spindle is driven by a 1½-in. endless leather belt. The fulcrumed lever with the two idle pulleys also acts as a belt tightener.

An oil pump delivers oil to the drill, when drilling the gaine body. The oil is fed to the drill by a metallic flexible hose, the delivering end being clamped to the oil guard on the steadyrest. The pump is provided with an automatic shut-off valve that permits the flow of oil only during the drilling. It is operated by the foot lever and acts in unison with the opening and closing of the

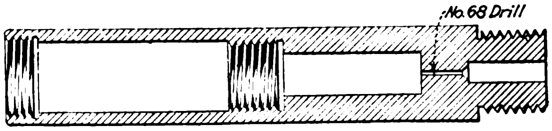

FIG. 7. DETAILS OF GAINE BODY

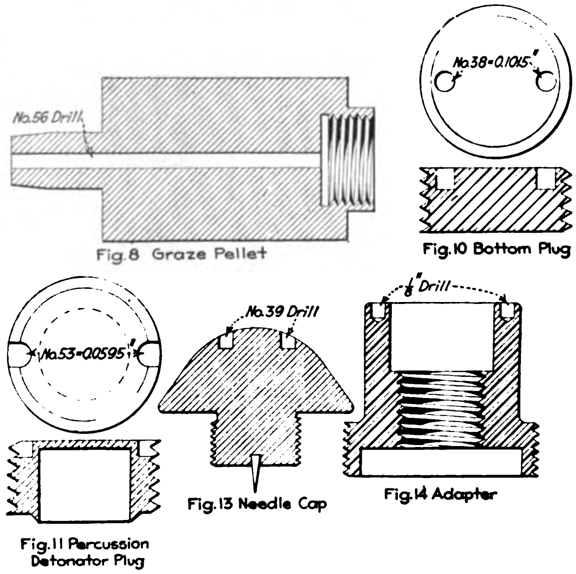
chuck. The pump is belted to the countershaft. The machine occupies a floor space of 3 ft. 1 in. by 2 ft. 7 in. and is 3 ft. 10 in. in height. Its net weight is 500 lb.

One of the standard Langelier drills is equipped with heads for drilling two No. 38 (0.1015 in.) holes 0.50 in. apart in the bottom plug, Fig. 10, and two No. 53 (0.0595 in.) holes 0.260 in. apart in the percussion detonator plug, Fig. 11. The output for the bottom plug, which is of steel, is 7 per min., or 420 per hr.; for the brass percussion detonator plug, 12 per min., or 720 per hr.

Both the plugs are centered with the drilling head by means of a spring steadyrest having a sliding fit on the cylindrical end of the drilling head. In the lower end of the steadyrest are a disk carrying the bushings for accurately starting the drills and also projecting prongs that exactly locate, by contact, the pieces to be drilled. The pieces are approximately located in their drilling



FIGS. 8, 10, 11, 13 AND 14. PARTS TO BE DRILLED

position on the table by means of a shouldered seat fastened to the table.

If the output for any one piece is sufficient to keep a machine continuously in operation, a machine and head are furnished as a unit; if not, one or more heads with different layout of spindles can be made to fit interchangeably in one machine. The drill heads with their steadyrests are self-contained and are easily interchanged.

The heads and drivers are of phosphor bronze and the drilling spindles of a special steel that permits a deep casehardening, so that they can be accurately ground to size, giving a hard surface with a soft center. The feed is actuated by a hand lever in conjunction with a rack and pinion.

The spindle pulley runs on sleeves anchored in the housing of the machine, thus avoiding the belt pull on the drilling spindle. Loose perforated bushings are used in all running bearings, increasing the wearing surface and insuring a free distribution of the oil.

The machine is arranged with a tight and loose pulley drive on the base and a foot belt shifter. The table has a working surface of 9x6½ in. and a vertical adjustment of 6 in. The machine occupies a floor space of 16x24 in. and is 5 ft. in height. Its net weight is 220 lb.

Drilling Caps and Adapters

Fig. 12 shows another standard drilling machine equipped and fitted with heads for drilling two 0.125-in. holes 1.100 in. apart in the adapter, Fig. 14, and two 0.10 holes 0.413 in. apart in the cap, Fig. 13. The output from this machine for the adapter, which is made of steel, is 5 per min., or 300 per hr.; and for the brass cap, 7 per min., or 420 per hr.

Both the adapter and the cap are centered, as are the plugs previously mentioned. The feed is actuated by a hand lever in conjunction with a rack and pinion. The machine occupies a floor space of 24x30 in. and is 5 ft. 10 in. in height. Its net weight is about 450 lb.

The press shown in Fig. 15 was designed for closing the metal around the needles in the percussion needle plug, Fig. 11, and the cap, Fig. 13. It is of the crank and plunger type, with a safety clutch and brake.

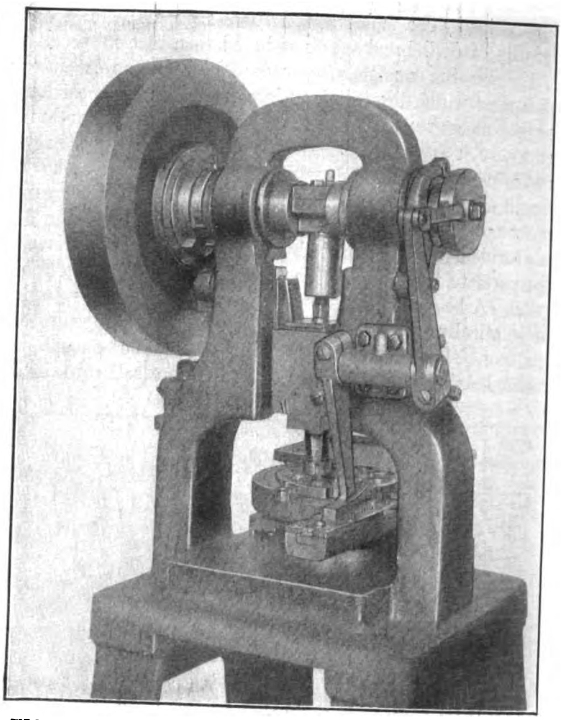


FIG. 15. STAKING NEEDLES IN CAPS AND PERCUSSION NEEDLES

It is equipped with a special dial feed operated by the crankshaft of the press. The dial plate of the cap has eight stations and, for the percussion needle plug, 12 stations that carry locating dies in which the assembled cap and needle or percussion needle plug and needle are placed by the operator. The percussion needle plugs are automatically ejected, but the caps have to be removed by the operator.

As originally designed the output for the caps was 40 per min., or 2,400 per hr. and 50 per min., or 3,000 per hr. for the percussion needle plug.

It has seemed best to the users, however, to use but one operator per machine, reducing the production to 500 per hr. on the needle plugs and to 250 on the caps. The machine has a floor space of 21x23 in. and is 5 ft. in height. Its net weight is 500 lb.

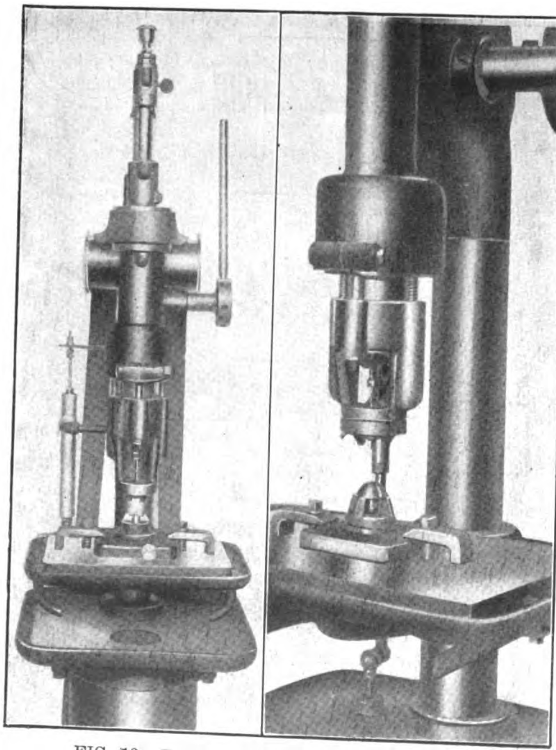

FIG. 12. DRILLING ADAPTERS AND CAPS

Preparation of Pure Iron and Iron-Carbon Alloys

A report on the preparation of pure iron and iron-carbon alloys has been prepared by the United States Bureau of Standards and is given in Scientific Paper No. 266 of the publications of that bureau.

It is shown that previous work on the iron-carbon diagram is unsatisfactory because of the great uncertainty of chemical composition of the materials used. It was therefore thought necessary to produce a series of alloys of great purity to form the basis of a redetermination of the diagram at the Bureau of Standards.

The general method pursued consisted in melting electrolytic iron with sugar carbon in magnesia crucibles. The electrolytic iron was prepared from ingot iron anodes in a chloride bath, with or without the use of porous cups.

Letters from Practical Men

Two Spiral Broaching Jobs

A few years ago, broaching in its simple forms was considered a ticklish operation, while a glance at the illustrations Figs. 1 and 2 gives an idea of the liberties which may be taken with this class of work under present conditions.

Referring to Fig. 1, an adaption of a lathe to broaching a keyway in a bushing is shown. These bushings were required in small quantities and the keyway had to be an accurate spiral.

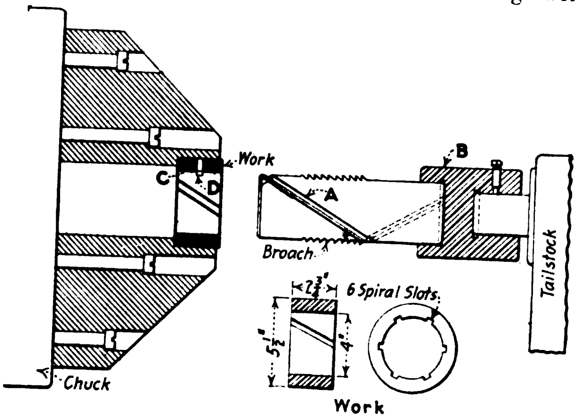

FIG. 1. BROACHING SPIRAL GROOVES IN A LARGE HOLE ON A LATHE

To accomplish this a number of short broaches of slightly increasing diameter were used, one of which is shown in position; and in these broaches a spiral slot *A* was cut.

The work is held in special chuck jaws, as shown, which give clearance in the back to permit the broaches to go through the work. By throwing in the back gears with the bolt that connects the gears to the pulley locked up for direct driving, the spindle of the lathe is locked so that it will not revolve. Over the tailstock spindle a sleeve *B* is placed. In the center of the work to be broached a hole *C* is drilled, and in this hole is driven a pin *D*. For broaching, the shank of the broach is placed in the sleeve *B*, the teat of the broach is guided by hand into the hole of the work, while the slot *A* is caused to engage the pin *D*. Then by turning the handwheel on the end of the tailstock the broach is forced through the hole in the work and made to revolve as the spiral groove travels along the pin. Thus the keyway is a true spiral, following the groove. Each broach will follow the path of its predecessor, as the broach teeth are cut with due regard to their relation with the groove. It is necessary on this work to remove the part from the chuck after each broach has been passed through, in order to withdraw the broach.

A similar job accomplished on a standard type of broaching machine is shown by Fig. 2, the work being smaller and made in large quantities with two spiral keyways cut in it. The piece is mounted in the bushing at *A*, while two broaches are drawn through it—namely, roughing and finishing. The arrangement of the tools for this operation is as follows: In the bushing *A* is placed the guide pin *B*. The shank of the broach *C*, with the work slipped over it, is pushed through the work bushing and gripped by the pin *D* in the broach holder *E*. The work is now held by hand against the work holder and is prevented from turning by the sides *F*. The machine is started and draws the broach through the work, the spiral twist being obtained as the groove necessarily follows the line of the pin.

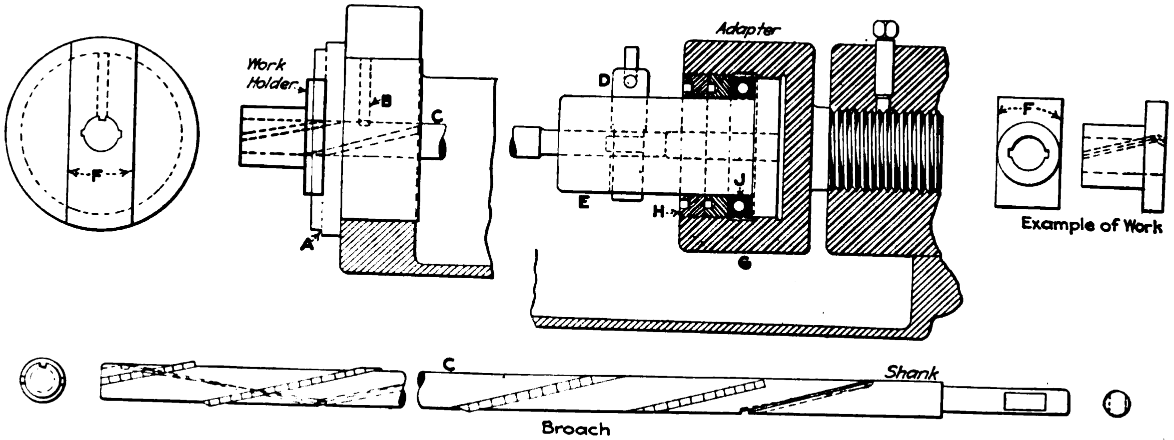

FIG. 2. A GENERAL BROACHING JOB ADAPTED TO STANDARD MACHINERY

As there is no means of allowing the broach to twist in these machines, an adapter is provided. It consists of the broach holder *E* in the adapter *G*, two check nuts *H* and a ball bearing *J*. All these parts are mounted on the drawbar of the machine in a manner similar to that employed for holding broaches on ordinary broaching machines.

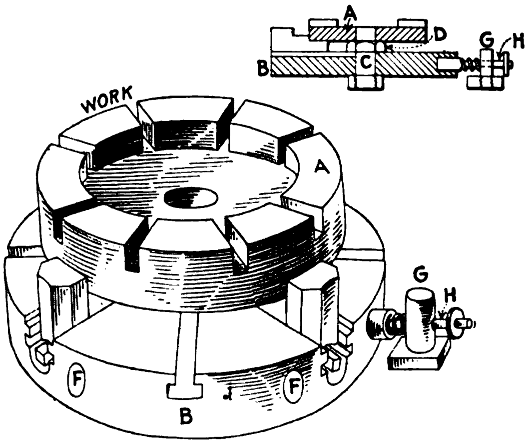
Pawtucket, R. I.

Neat Milling Fixture

In the illustration at A is shown a machine part in which it is desired to mill eight slots. A horizontal milling machine is used, and the work is mounted on a three-jaw universal chuck B so that the top of the jaws is below



A NEAT MILLING FIXTURE

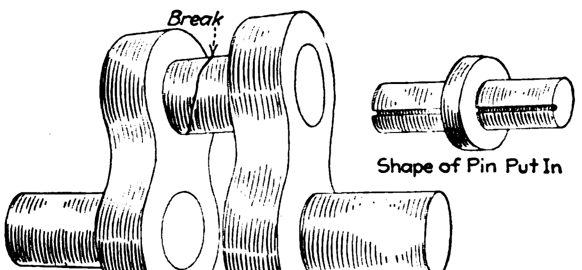
the cutting line. In one of the T-slots in the milling-machine table is placed a head, into which the bolt C is lightly screwed so that it cannot move. On this bolt the chuck is placed and clamped down by means of the nut D, with sufficient allowance to permit the chuck to be rotated about C.

Four holes F are accurately drilled in the side of the chuck. A pin G is screwed up tight in the nut, which is also placed in the same T-slot in the table. The shouldered pin H is put in a hole drilled in the pin G. One end of H fits into the holes drilled in the chuck and locks the chuck and work in position for milling two slots. Then the end of the pin H is removed from the chuck, which is rotated by hand until the end of the pin fits into the next hole, locating the work accurately for milling two more slots. This operation is repeated until the work is finished. W. C. Makley.

Birmingham, Ala.

Crankpin Repair Job

A while ago a forged crankshaft about 5 in. in diameter was brought to our small shop with the crankpin broken. As this shaft was the main drive of the mill, it was imperative that something be done at once. To get



A CRANKPIN REPAIR JOB

a new one forged would take at least several weeks, so it was decided to put a pin through the broken crankpin.

Each half of the shaft was put in the lathe, the broken ends of the pin faced off true and the cheeks centered. We had no horizontal boring machine, so the work was done on a heavy drill press. The shaft was strapped to the box table and also securely tied to the column with a block and bolts. After a hole had been drilled and rough-bored to about 3 in., the work was trued up with a dial indicator, by the surface that had been faced off in the lathe, in order to bring the boring bar parallel with the axis of the shaft. A finishing cut was taken and a generous fillet made. The center of each cheek was used to lay off a shallow keyway in the hole, to hold the parts in line when assembling.

It was necessary to have a collar on the pin to make the cheeks the right distance apart, as about an inch had been removed from the pin in the lathe. Keyseats cut directly in line on the fits of the pin held the parts in line. The collar was made $\frac{1}{32}$ in. larger than the crankpin, to correct any errors in centering the boring bar.

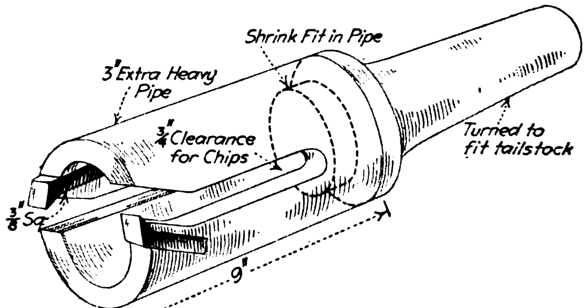
The job was pressed together; and when swung in the lathe, it was out less than $^1/_{64}$ in. The journals were trued, and the collar was filled level with the crankpin, thus finishing the job.

It will be seen that this method of repair weakened the shaft very little, for practically all the thrust came on the crankpin proper, as the function of the pin we put in was merely to hold the shaft rigidly together.

Memphis, Tenn. James Ellis.

Making Lignum-Vitae Bushings

Some time ago I had to make quite a number of lignum-vitæ bushings, $5\frac{1}{4}$x$4\frac{9}{16}$x5 in. long. The method of making these bushings was to drill a 2-in. hole and bore out to size. This seemed both a waste of material



MAKING LIGNUM-VITAE BUSHINGS

and time, so I made the tool shown in the accompanying illustration. It worked satisfactorily, as it saves time, and the center piece may be used to make smaller bushings. Thomas Mulligan.

Winfield, L. I.

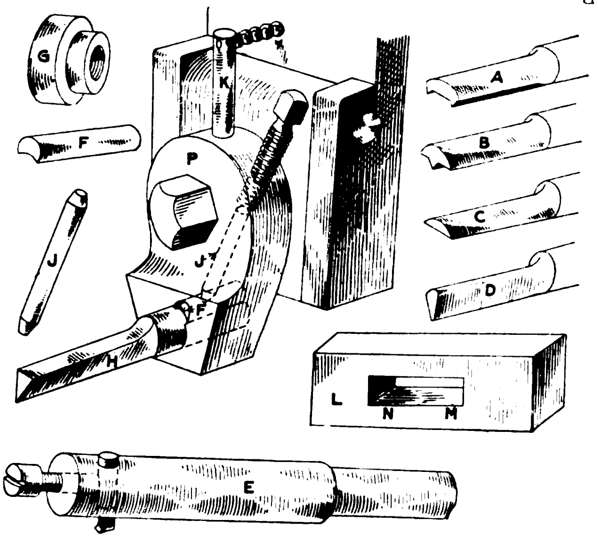
A Tool Holder for Internal Shaping Work

The illustration shows a tool holder that can readily be made to fit any shaper. After the tool post has been removed from the clapper box, the nut G is inserted in its place; and by means of a capscrew the holder P is clamped in position. Several sizes of the nuts G, to fit the various shapers, should be kept on hand.

The cutting tool is held in place by means of the setscrew, which presses the hardened pin J, pressure being transferred from there to F, which has also been hard-

ened, and then to the tool H. The pin K, which is a drive fit in the holder, serves as a means of applying a spring or piece of rubber between the clapper box and head, thereby assuring a steady cut.

A heavy tool holder that can be used in cutting keyways and other heavy work is shown at E. The tools A, B, and C are useful for cutting a rectangular slot, such as is shown in L. The tool B is first used for removing



DETAILS OF TOOL HOLDER FOR WIDE RANGE OF INTERNAL SHAPING

the stock from N to M. Then the tool A is used from N to the corner and from M to the other corner, but the actual corner is shaped with C.

With this tool holder one can shape within $\frac{1}{16}$ in. of the vise. This holder can also be used successfully on work that might project above the clapper box. By means of a socket wrench the setscrew can always be regulated for adjusting the tool. Other features are compactness, rigidity and simplicity. L. E. OLSEN.

Schenectady, N. Y.

Annealing Chains

Considerable discussion has recently arisen as to the advisability of annealing steel and iron chains after they have been in service for a reasonable length of time. In the past it has been considered necessary to anneal chains after they have been in constant use for one year, in order to remove the hardening effect caused by the overstrain or overload that all chains are subject to.

Such overstrain changes the physical properties of the metal, and this alteration may continue for a month, gradually developing greater hardness and decreasing the power of elongation until the metal obtains a permanent set. In this hardened condition the chain is more liable to fracture by shock when a load is suddenly applied or quickly arrested during its descent. If the process of annealing is properly carried out, the metal reverts to its former state as regards ductility, but is generally reduced in ultimate strength.

In addition to hardening, the metal of a chain deteriorates through repeated loading. This result is known as "fatigue," the effect of which cannot be removed by any process of annealing.

The question of whether or not a chain requires to be annealed depends largely upon the material of which the chain is composed and the nature of the work it performs. For example, the heavy hoisting chains used in connection with traveling cranes should be annealed, or "fired," at least once a year, as such a process thoroughly cleans the chain and enables a proper inspection to be made, when excessive wear or the presence of any flaw can easily be detected.

Hoisting chains supplied with chain hoists are usually made of special steel, having greater fatigue-resistance properties than iron chain, and are rarely subject to the severe treatment given to the hoisting chain of a crane or to portable sling chains in general use. Therefore, they should not be subjected to any annealing, or firing, treatment.

The methods applied in some instances in annealing chains have certain disadvantages. The best known is "close annealing," wherein the chain is placed in a gas- or oil-fired muffle furnace, heated to redness and then allowed to cool slowly.

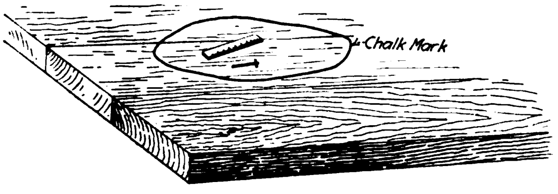
Another successful method is to use an ordinary reverberatory furnace, such as is used for heating plates. If neither of these appliances is available, a very simple and effective way of annealing is to place the chains to be treated over a bar that has been fixed at a given distance from the ground. Then they are covered entirely with a wood fire, which is allowed to remain in position until the ashes are cold. Oak wood is preferable for this purpose, as it is free from sulphur and phosphorus and does not affect the metal injuriously.

If the process of annealing, or firing, is to be successful, one important feature must be considered; namely, the entire mass must be heated uniformly not higher than 1,400 deg. F. and allowed to cool slowly, when very satisfactory results will be obtained. G. H. PLAINE.

Hartford, Conn.

Keeping Track of Small Tools

When using several tools on the bench at once, the fine-measuring tools and small scales can be easily kept separate and in a known place by simply drawing a chalk



METHOD OF KEEPING TRACK OF FINE TOOLS

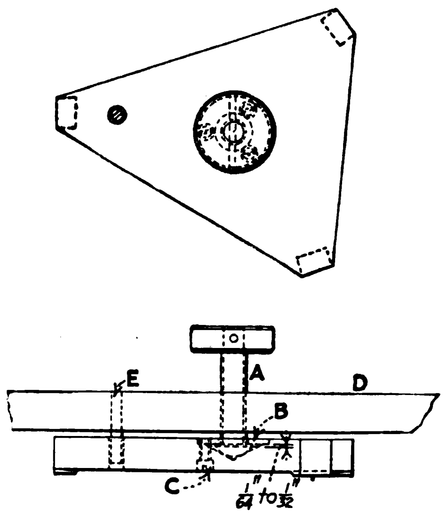
mark around a section of the bench, as shown in the illustration. Always placing the tools inside this line protects them from damage or loss. C. ANDERSON.

Worcester, Mass.

Fastening Clamping Screw to a Large Clamp

The illustration shows a good method for fastening a clamping screw to a large clamp. At a point exactly in the center of the clamp is drilled and counterbored a recess, as shown, to fit around the point of a screw A and washer B. The hole in the washer is drilled a trifle larger

than the screw diameter. There should be from 1/64- to 1/32-in. clearance between the bottom of the washer and the back of the rounded head on the screw. The washer is held fast by the screws *C*. The screw *A*, washer *B* and screws *C* are assembled on the clamp. Then the screw



CLAMPING SCREW FOR LARGE CLAMP

is screwed up in the lid of the jig *D*, after which the knurled head is assembled and pinned to the screw shank. The pin *E* holds the clamp in its right position.

Dayton, Ohio A. M. BOWYER.

The Originator and the Copier

It is always a disconcerting experience to find that designs which were evolved after trouble and difficulty have been annexed without acknowledgment by a competitor. In such cases the feeling of resentment runs high; and even if patent rights are not in question, the aggrieved party has a desire to bring the culprit to justice. There is, however, a crumb of comfort in the reflection that no copy, however close, can equal an original. This much, at least, is a recognized retribution upon dishonesty no less than upon legitimate imitation devoid of fraudulent intent.

The ethics of the subject are obscure. Evolution and improvement are gradual matters. The new of today is the commonplace of tomorrow and is out of date after the passage of relatively short periods of time.

In the matter of patents the state recognizes not merely the inventor's rights, but the question of public service. Protection is afforded for a limited term in return for disclosure of improvement. It is questionable, on the whole, if even patent protection, subject as it must always be to legal revision and confined as it is to narrow limits, is as valuable as is usually assumed. The majority of valid commercial patents are in restraint of trade and are obtained with this single end in view. Those that are of basic character return as a rule very little to their originator. It is reputation, after all, that counts, and this is apt to rest with the progressive firm that is known to originate. Mere copying is detestable to a creative mind, which can usually discover other and equally successful methods of securing the results desired.

National characteristics, like British partiality in favor of solidity and durability and American fondness for simple ingenuity, influence design. It is difficult to act outside of fashion, tendency and tradition. The habit of industries to localize themselves may be cited. It may be assumed that the tendency of like things to get together has a bearing on the question of imitation.

Some things once original are now simply matters of good practice, and resemblance is by no means necessarily imitation. Practice has evolved many standard means of achieving certain results, and such means are based upon origination of past periods.

Little in the way of mechanical invention is basic in the sense that scientific discovery is original, whatever the commercial returns in the former case. Details may be and are improved upon, but the opportunities for radical departure in the mechanical world are rare. This statement is not to deprecate the average invention, but is to say that revolutionary discoveries are far from common. Even when the basic is concerned, reduction to practice is a long and tedious process of evolution, and standard practice is usually the mean between competitors' work.

Modern design in an engineering sense is more selective than creative. First principles are involved in only a few cases; practice in the average commercial tool or machine is rather a settled matter, and we are all so heavily in debt to any predecessor that imitation in this sense is the order of the day.

It is a penalty imposed upon deliberate theft of ideas that imitation is bound to be late in the field. This fact alone affords some measure of protection to honest effort and progressive thought. Reputation follows experimental and original work and is usually found coupled with honest workmanship and first-class, careful system. Its worth can scarcely be over-estimated, and its reward is sure.

Tooting, S. W., England. A. L. HAAS.

Fractions, Decimals and Millimeters

New York City. A. ELTING.

Discussion of Previous Question

Job-Hunting Technical Unions

The statements in the article by J. Spaander, page 431, are not altogether pleasant reading, but are unfortunately more true than they ought to be. The only inconsistent note is where he speaks of the American engineer as too much given to shifting from place to place and then tells of his own 10-year wanderings in Europe, Asia, Australia and America. This shifting has its advantages, however, and I do not believe it is as bad a trait as he pictures.

There can be no doubt about the standing of engineers abroad being better than it is in this country. In Russia, in some cases at least, they rank with certain special layers in the social layer-cake, one of my friends being in the "duke" class and his assistant in the next lower layer, whatever that may be. None of us are anxious for the titles, but most of us would like the respect and the coin of the realm that go with them.

I have discussed this problem in England with both employers and engineers, and the general impression I gathered was that the engineer was there looked upon more as a physician and the case left in his hands. This attitude was apparently due to the fact that the client was either too much engrossed in other business to bother with his engineering work or that he felt he knew nothing of it and left it all to the engineer, just as he would if he called in a doctor to cure the measles.

In this country the average employer is perhaps more of a mechanic than in the older countries, this being probably due to a larger number having come up through the shop than in any other country. And those who do not know about engineering matters fondly imagine that they do, which may be even worse. The engineer should undoubtedly stand for the best engineering practice against the opinions of those who lack training; but when these same individuals happen to be the ones who handle the check-book it is not always easy to maintain one's position.

I cannot agree that the fault is entirely with the engineer, although I am not attempting to excuse him altogether. The general public has much to do with his standing on such matters as may be called public engineering. When the public can be made to see that its good tax money is being wasted by political henchmen who pose as engineers and demands that real engineers be employed, there will be considerable improvement in this direction. This situation is fortunately coming about in many sections of the country and seems bound to grow. With the increasing appreciation of the value of the engineer to the community and the country will come the raised standing of his profession to a par with that of the physician and surgeon.

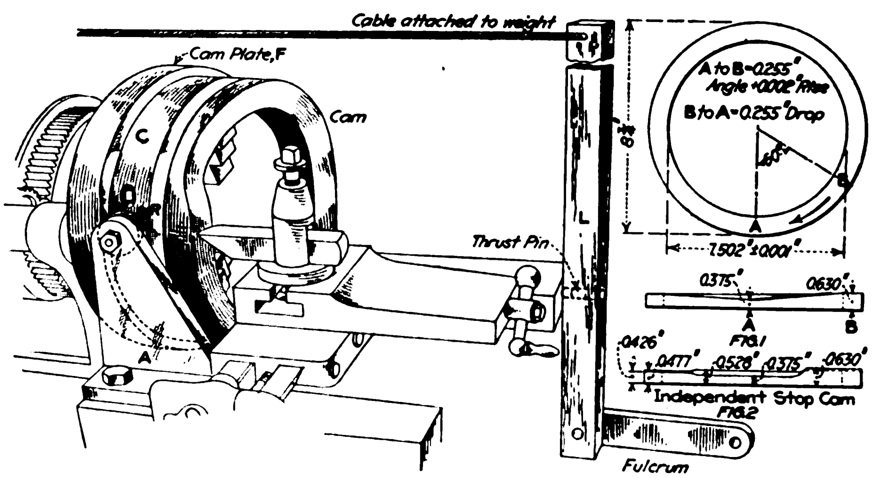
It is important that the engineer himself bear this in mind and be not content with his present standing. On the other hand, he must not become too much impressed with his own importance, but remember that we have little to do with the intelligence with which nature endows us, and that every man must give service according to his ability, if he plays the game fairly.

New York City. FRANK C. HUDSON.

Machining Gear Roller Faces

On page 1085, Vol. 43, was described an excellent method of turning face cams on the lathe. This article was very interesting to me, as we had several hundred cams of the type shown in Fig. 1, to be made at once. They are independent stop cams for the turrets of hand screw machines, and six points, 60 deg. apart, locate the stop finger for each position of the turret. We had been making these cams on the miller, as shown in Fig. 2, chucking them on the dividing head, milling the high point first, then raising the table 0.051 in. for each of the five remaining points. This practice meant turning the dividing head 40 turns by hand for each cam, besides raising the table five times. The best time possible by this method was 20 min. each.

This process was discarded for the method shown in Fig. 3, which proved to be a very satisfactory manufacturing proposition. The cam is held in the 12-in. three-jaw universal chuck C, fastened to the cam plate F, which is threaded to fit the spindle nose of the lathe. This cam plate is about 15 in. in diameter and is recessed about 3/4 in. deep to a diameter slightly larger than the outside diameter of the universal chuck. The chuck is centered by the boss on the back, fitting in a counterbore in the plate F.



FIGS. 1 TO 3. CAM TURNING ON A MANUFACTURING BASIS

The angle plate A, doweled to the carriage of the lathe and held down by two bolts, carries a roller R riding on the cam face. The feed-rack pinions in the apron are disengaged, and the carriage moves back and forth, following the contour of the cam, the roller being forced

against the cam by a weighted lever *L* bearing on the carriage.

This construction was adopted after trying out various springs and was found to be more positive, as it maintains a steady and constant pressure on the cam roller and gives much more uniform work. The work was run 30 r.p.m., so the entire carriage had to "drop back" 0.255 in. in $\frac{1}{3}$ sec., requiring considerable weight.

The power crossfeed was used, reversing in the apron, while the thickness was set by the graduations on the compound rest. A roughing and finishing cut produced the necessary finish. The time for this operation, floor to floor, is slightly under 7 min.

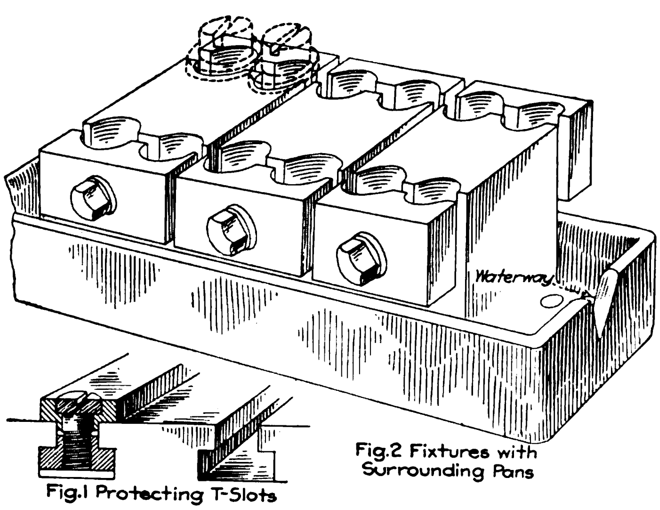
The method of making the master cam plate is deserving of mention. The head is too small to be obtained on the miller without special gearing, so the plate is finished-turned in place on the lathe and a slot cut across the cam face the depth of the low point. A $3\frac{1}{4}$ thread gives a lead of 0.051 in. in 60 deg., so the rise is cut with this thread, the error being less than 0.0015 in. The drop is marked off, roughed down in the shaper and finished by filing, the total time for making the cam plate being about 12 hr. H. B. McCRAY.

Charles City, Iowa.

Making Effective Protectors for Machine Ways

I agree with the article on page 1128, Vol. 43, which says, "Any means that will increase the life of a machine tool or prolong its accuracy and usefulness should be carefully considered."

The usefulness of an effective protector for the machine ways is self-evident, but to me the spring window-



MAKING EFFECTIVE CHIP PROTECTORS

shade contrivance has its disadvantages. For simply keeping chips and dirt out of T-slots a plain strip of the section shown in Fig. 1, held in position by cheese-head screws, is much easier. Although taking more time to arrange, it is not necessary to handle the strips very often, and they give the operator the free use of his table while protecting its surface when heavy or rough castings are being constantly taken on and off.

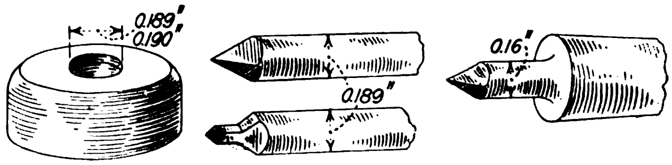
A more common device is a sheet-metal tray in which the jig or work is placed. If a jig is used, a slot is cut in the bottom of the tray to allow the registering pins or tongues on the jig to enter the table. When designing a milling jig, I always try to embody the tray idea in the casting itself, as in Fig. 2. Any extra cost incurred in the pattern and casting is balanced, or justified, in the stiffer casting obtained. The web all around lends strength to the casting in addition to confining the chips to one slot in the table. P. JAMES.

Surrey, England.

Grinding-Operation Kink for Hardened Rollers

On page 185 I notice a grinding kink by W. L. Conklin. It reminds me of a job of similar nature that, to my way of thinking, was handled in a more efficient manner.

Five hundred hardened-steel rolls 0.185 in. in diameter and 2 in. long were called for. A piece of 0.189-in. drill



DRIVING ROLLS BY SQUARE CENTER

rod was cut off to length. Then a bushing was made with a 0.189-in. to 0.190-in. hole in it and slipped on the rod. With a center punch ground four-sided we prick-punched one end of the rod and centered the other end with a small center drill.

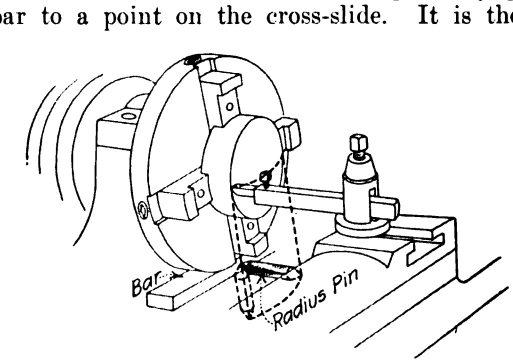
The rolls were then hardened, and when ready to be ground, a center of the grinder was turned down to 0.16 in. and squared on the end to fit the prick-punch square in the rolls. In this way the headstock center revolved the work, which was more efficient than a soldering iron.

Arlington, R. I. GEORGE P. BREITSCHMID.

Turning a Small Radius

On page 865, Vol. 43, was an article on "Turning a Small Radius."

The same principle may be used for convex curves by clamping a bar to the lathe bed between the cross-slide and the headstock, so that the radius pin may go from this bar to a point on the cross-slide. It is then only



TURNING A CONVEX RADIUS ON FACEPLATE WORK

necessary to see that in setting the pin the points where this engages and the point of the tool are in the same vertical plane, the tool in this case being started at the outer diameter, as is also the case in turning a concave radius as described in the preceding article.

Detroit, Mich. GEORGE H. CHENEY.

Manufacturing Rifle Cartridges

The article on page 289 of the *American Machinist* brings to my attention an operation that, as described, is far from being possible. Even if it were, it would be a very poor manufacturing operation. I refer to the following paragraph:

> Cartridges are loaded with many different charges, such as black powder, semismokeless, dense smokeless and the like. These charges differ so much in characteristics—amount used, density, rapidity of combustion, chamber pressure, etc.—that a number of different primers must be provided. Therefore the primer hole, which is pierced through the head of the cartridge during the indenting operation, is of a great variety of sizes, depths and shapes. Tools for this operation will stand up for some 1,000,000 or more cases, with proper care. The only lubricant used is a little lard oil on the punch occasionally.

I also do not agree with that portion of the article which deals with the indenting and piercing in one operation, for the simple reason that in indenting the head of a cartridge the metal is forced down and is flowing before the indenting punch. If it were possible to carry a piercing punch in conjunction with the indenting punch, my experience leads to the belief that the indenting punch would force the metal around the piercing punch in such a way that it would be impossible to strip the shell without breaking the punch.

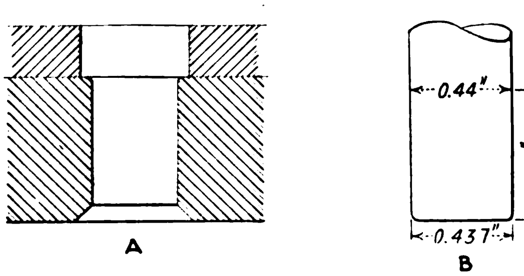
Moreover, the fact that experience has shown how difficult and heartrending it is to try to pierce metal that is thicker than the diameter of the piercing punch makes it hard for me to believe it possible to perform this operation successfully.

As for the machine that does all the operations as stated—I am from Missouri. GEORGE DINGER.

New York City.

The timely article by G. R. Smith, in Vol. 43, page 881, which I read with much interest, calls to memory a few little kinks I used on similar work where large quantities were manufactured, which resulted in a saving in tool steel and time.

The redrawing dies, made as shown at *A*, had a sharp edge at their bottom for stripping, which did away with



SELF-STRIPPING DIE AND TAPER PUNCH USED IN RIFLE CARTRIDGE WORK

the spring detent stripper and enabled us to shrink the dies three times before discarding them as useless.

The shrinking was done by using a shallow pan of water deep enough to reach within $\frac{1}{8}$ in. of the drawing surface of the hole, then heating the die to a cherry red and rolling it in the pan of water until cooled, afterward annealing it and working it over in the regular way.

I have found that the dies will shrink about 0.009 in. the first time and from 0.007 to 0.005 in. the second and third times, but on the fourth shrinking I could obtain no results that warranted the expenditure of time and money.

The punches, as shown at *B*, were straight to within 1 in. of the drawing end, which was made from 0.002 to 0.003 in. small, tapering back to the required size. This made stripping easy.

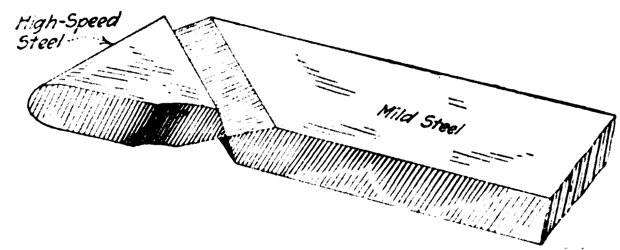
These punches and dies were made for drawing brass shells of 0.044-, 0.380-, 0.320-, 0.300-, and 0.250-in. diameter. Lard oil was used as a lubricant.

St. Louis, Mo. JAMES S. GLEW.

Methods for Making High-Speed Steel Go Farther

Methods similar to those described on page 165 have already been adopted at the Puget Sound navy yard. Our high-speed steel scraps consisted of all sorts of short ends. Owing to the high price of steel we decided to try oxyacetylene welding to utilize the ends on a mild-steel shank. We prepared for the weld as shown herewith and have turned out lathe, shaper and planer tools that give entire satisfaction.

The high-speed points were cut with a hot set and ground to the proper shape, the welding edges being



TOOL PREPARED FOR WELDING

beveled toward the center at about 45 deg. The shank was made in the same way and the weld made with an ordinary steel-welding rod. We figured that making the weld at an angle of 45 deg. from the base would give the welded point a better support from the end of the shank and reduce the stresses at the weld.

The first tool made cost about 35c. excluding the somewhat doubtful value of the high-speed scrap used for the point. Later tools, of course, cost less. After a heavy test lasting an hour on nickel steel, this first tool showed no signs of distress and the cutting edge was still in excellent condition. G. A. HASTINGS.

Puget Sound, Wash.

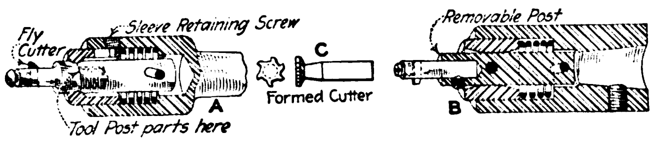
Neat Recessing Tool for Percussion Caps

Mr. Nowalk's article on page 208 showing an eccentric type of recessing tools brings to mind my experience with this and other types of recessing tools, which may be of interest. For recessing the threaded end of percussion pellet hole for steel bodies for the British No. 100 detonator, we found it necessary to design a more rigid tool than was used in the brass bodies.

I first designed a tool substantially as shown on page 208, using the same lead of spiral, but cutting it only 90 deg. of the circle. This gave me the recess required—namely, $\frac{1}{32}$ in., the tool post being $\frac{1}{32}$ in. off center of the body.

We found in practice that this tool was not rigid enough when used on high-speed drills, owing to its length from the drill spindle and on account of the tool post rotating off center. I then designed the tools shown herewith, which are doing satisfactory work. They are simple in construction, more rigid in operation and have the advantage of running in balance, and they allow the use of a larger post to enter the hole.

Both tools shown are substantially the same in principle of operation, but in tool *A* the post is made in two parts,



RECESSING TOOL FOR HIGH-SPEED DRILLS

with a circular groove formed central with the joint where they screw together. The sleeve, which rides on the jig bushing when the tool is in place for recessing, is formed on the inside diameter to fit freely in the groove in the tool post, acting as the fulcrum and its support.

In tool *B* the post is pivoted in the sleeve, as shown, this sleeve being relieved to allow the tool post to rock when thrown over by the cam groove at its bottom end. The pin in the cam groove passes through the body, being located on the center line of tool and riveted in place.

The construction of both tools is clearly shown.

I have shown a small fly cutter held in place by a screw in the end of the tool post. The cutter is made from $\frac{3}{32}$-in. drill rod and is cheaper to make than a formed cutter, with the advantage of setting to the diameter required after grinding.

When the recess is formed in the bottom of the hole, as described in Mr. Nowalk's article, I prefer to use a formed cutter with four or more cutting edges, as shown at *C*. This obviates the necessity for the operator to set the cutting edge exactly in line with the movement of the tool post and gives more wearing surface than the one lip tool. JOHN J. EYRE.

Boston, Mass.

The Machinists' Strap

It gives me great pleasure to find that my ideas of things are shared by so eminent a man as John E. Sweet. When I read his remarks about the farmers' lever and its fulcrum and the machinist and his straps, I went out into the shop where I am in charge and checked up some straps I have had for years, to find, as I expected, that they agreed with the proportions laid down by Professor Sweet.

And now I should like to express a few ideas about straps. We are in agreement as to the lengths from bolt to work and from bolt to block. It is also important, if one is to get the best results, to see that the strap is parallel to the platen on which the work is being held. Inattention to this results in work being distorted, insecurely held and in the breakage of bolts.

The end of the strap that engages with the work should bear level upon it; that is, it should have a surface bearing, not a point, or line, one. To obtain this, packing should be properly prepared of a height equal to the thickness of the job instead of using any old piece of junk from the scrap pile, with irregular surfaces that besides being unsuitable for the job in hand leave their mark on the plane surface of the platen. Where a job is coming through in quantities, it is an easy matter to provide straps embodying in themselves the right height of packing block.

With regard to the straps made by bending a square bar in the middle, I have a number of these and find that they stand up very well, if made of tool steel, ¾ in. square, bent to pass a ¾-in. bolt and of a length, when bent, of about 7 to 8 in. F. R. MANN.

London, England.

Painting Small-Shop Products

Mr. Van Deventer's interesting article on painting small-shop products, in the *American Machinist*, page 183, encourages me to offer a few views on the painting of machine-shop tools.

Architects and engineers have done everything in their power to make the modern factory a healthful, well-lighted, clean place. White walls and ceilings are now the rule, with about 6 ft. of wainscoting of some darker color, say green or brown. How attractive a new shop looks until the machines and equipment are installed! Then we see a mass of dirty, black, moth-eaten units.

Why not finish the machines in keeping with the rest of the building? Finish them white. Finish them white from "stem to stern," except those parts that must necessarily be of polished metal or which are used in actual contact with the work, as chuck jaws, miller tables, ways, lathe centers, etc. Parts that are subject to handling, such as pedals, belt-shipper levers, hand levers, etc., could be finished with a tough coat of porcelain enamel of the kind used on plumbing fixtures. The better grades of this material will not crack off even when subject to the abuse of careless employees. Tools that are subject to heat could not be painted pure white, but could be finished in aluminum paint, which will stand severe heat. This color would blend very well with the general scheme of the shop.

Of course, the objection will be raised that the machines will become stained with oil and look worse than if finished in a dark color. The remedies are better prevention against oil leakage, which is a possibility. Incidentally, in certain classes of tools the ball bearing offers a good solution of this trouble. It goes without saying that the coolant can be properly taken care of.

There is no excuse for dirt in any form in the machine shop. But what is to be gained by all this expense and trouble? First, better work—better because more reflected light will be thrown on the work, which will be of tremendous help to the operator, and the work will stand out in sharper relief, which is also an aid to the eyesight. If you do not believe in the principle of reflected light, just arrange a drop-light over a table top of dark color. Then superimpose a piece of white paper and notice the difference. And last, there is the psychological effect on the operator and everyone concerned. The effect gained is the same as with a finely finished precision instrument—the men will handle the machines with more care, keep them cleaner and do better work with them.

Bridgeport, Conn. W. BURR BENNETT.

[The machinery of the printing plant of the Hill Publishing Co. is finished in white enamel, this practice dating back a number of years.—Editor.]

Editorials

Machine-Tool Descriptions

In one of its aspects the editorial last week on "Copying Machine Tools" brings up the question as to what kinds of machines and appliances are eligible for notice in the department of the *American Machinist* headed "Shop Equipment News." The policy in regard to these descriptions has been in force for many years and is easily and simply stated.

Like every other part of the editorial pages, this department is maintained for *American Machinist* readers and for no other purpose. The readers are interested in every new machine, device and appliance that can be used in machinery building. They have the right to expect that the journal they read will provide them with information about all these things. This the *American Machinist* tries to do. During the last five years 2,139 such items have been printed—an average of over eight each week. This is an unparalleled record.

The test that is applied to each one of these items when it is received for editorial consideration is this: Is the machine or appliance offered a new or improved machine-shop product? That is, is it new to the manufacturer who has produced it? It is not expected that it is necessarily new in principle or mechanism.

It is obvious that any other interpretation would be impossible. Radically new bits of mechanism in the machine-tool field are very hard to find. Every time a lathe is produced with a cross-slide the invention of Maudsley is being copied. Every time a manufacturer designs a turret for a turret lathe he is harking back to the original ideas of Howe and Stone. We might go through many, if not most, of the mechanisms in daily use and such as are shown each week in the "Shop Equipment News" section of the *American Machinist* and name the men who originally developed the devices.

But the readers of the *American Machinist* are not interested in priority or historical credit; they do want to know what machines and appliances can be procured today to carry on their work. Thus the descriptive matter sent by the machine builders is accepted and printed as coming from reputable sources. This confidence is practically never betrayed.

Trade Education in Danger from Its Friends

Vocational education, in common with so many other projects, is in serious danger of disaster at the hands of its friends. Those who believe that it is important to know what to avoid will welcome the report prepared by the National Society for the Promotion of Industrial Education and published by the United States Department of Labor in Bulletin No. 162. The subtitle—Miscellaneous Series No. 7—describes it better, as it is about as miscellaneous a collection of data as we have seen, some of it being excellent information, but much of it being seemingly far outside the realm of a practical survey. The bad feature of this survey is that it will tend to discourage practical surveys, which are so much needed in many cities.

It is difficult to see just why a survey of the industry of a city should be a cyclopedia of those industries, why it should go into minute details of how each operation is performed and just what each tool is used for. Of course it makes a very impressive-looking report; but the same material can be found in the cyclopedia, and it is a fairly safe bet that this pamphlet came from that source. This statement does not mean that a survey should be superficial, but that it should deal with the real fundamentals or underlying principles of the industry rather than with its history in the cyclopedia sense, as in this case.

Taking the metal industries, we find 17 establishments reported, with a total of 4,924 men. The machine shop receives careful attention, all the types of machines being described in dictionary language and occasional gratuitous advice thrown in as to certain machines not being as fully used as they should be. This is about the only trade, however, for which specific recommendations as to school training are given. Nearly all the rest have to be content with a suggestion for more general education.

The bulletin recommends, however, a so-called elementary industrial education that, from the outline given, would be more comprehensive than the apprenticeship now in force in most shops. This step is highly desirable; but it must be remembered that, after such a course, no boy is going to be content with the old form of apprenticeship, either physically or financially. No boy who has absorbed half that is suggested will dote on sweeping the shop for three months at $3 per week.

The ever-changing phases of modern shop practice make proper vocational or industrial training more difficult each year, but they also emphasize the importance of suitable prevocational education. Whether the vocational, or trade, school is to increase, or whether it is to disappear in favor of the shop school, the prevocational teachings of the elementary grades become equally, if not even more, important. This need is particularly clear when we see, in this as in every other report, that the boys and girls begin leaving school in large numbers at 14 years.

The great danger is that people will become disgusted with vocational and other surveys that only put out voluminous reports containing encyclopedia information, but which do not point out how the children can be taught to fit into the industries of their locality. And as it is by no means certain which of these industries will present an opening when the children leave school, their training must be broad enough in fundamentals to be of assistance in whatever line may be open.

This condition is the great educational problem of the day, and a few have seen light and are working toward it. But the problem is made more difficult by both individuals and societies that only succeed in producing at large expense voluminous reports, which may make a show of great activity, but do not point out constructive methods.

Catalogs and Circulars for South America

Like business letters, all catalogs, circulars and publicity matter intended for South American customers must be in the language of the country—Portuguese for Brazil, Spanish for the rest of the continent. The piece of business literature printed in English promptly finds its last resting place in the waste basket. The only exception is when the matter reaches Englishmen or North Americans who are in executive positions in South American shops. But these men are so few in number that their preference for English does not weaken the force of the general rule.

In style and arrangement every bit of business literature intended for South America must be explicit, prepared in great detail and profusely illustrated. The regular type of catalog issued in this country is of little service there. It does not give enough information. The tendency here is to condense everything. We say it is written for the busy man. We realize that the reader will have a more or less intimate knowledge of what is being written about.

But in South America conditions are different. The reader there does not have the extensive mechanical knowledge possessed by executives in North American shops. He does not object to taking time to read long detailed descriptions; in fact, he likes to do so. He wants to know everything that can or should be said about the machine or appliance in which he is interested and does not wish to have points left to his imagination or to interpretation from his general knowledge.

For the reason that illustrations are a universal language that does not need translation or interpretation the cuts in catalogs and circulars are of prime importance. They must be used in profusion. They should show not only the general exterior features of a machine, but should also exhibit the interior working details and even give the details of individual pieces. Every machine, every variation of a machine and every part of every machine should be given an individual number, which should appear on the illustrations. These numbers can also be used as references in the descriptive matter and provide an excellent means of conveying information from the southern customer to the northern builder.

This method of designating machines and parts has been worked out by a few of our industries in great detail, notably in shoe-machinery building. Thus the principles of applying such a system in catalogs and circulars are fully established. The method possesses no experimental features and can be easily adopted by every machinery builder who is reaching out for foreign trade.

Supporting and explaining the many illustrations, there must be detailed text, describing every minute feature of the construction, operation and workmanship of the machine. It is impossible to say too much. When an order must travel 3,000 or 4,000 miles before it can be accepted and filled, the one who makes it out wants certainty.

No cross-references or marginal notes or footnotes are permissible in any business literature intended for South America. Better repeat a thing a dozen times than cross-reference once. If this seems like a burdensome requirement, just remember that, if you fail to understand an order received from South America, four months must elapse before you can receive a reply to your letter of inquiry, straighten out the order and make shipment. Four months is a long delay, may easily lead to dissatisfaction and finally result in no business.

In addition to numbering every machine and every variation of a machine, each one of the assembled units should be provided with its own code word. For instance, if a given size of lathe can be furnished with a cone drive, single-pulley drive or motor drive, each one of these three combinations should not only have its own reference number, but also have its individual code word. Do not ask your prospective South American customer to combine code words in order to specify a machine with particular attachments. Do all this work yourself and arrange your code in the simplest manner possible. In addition to coding machines and assembled units, it is also wise to code some of the principal parts that may have to be ordered for replacement. This feature will mean a large amount of detail work in preparing your business literature—but it is a kind of preparation that pays.

The order blank is practically unknown as a bit of business literature sent by builders to prospective customers in the United States, but a blank of this kind should always be included with every piece of descriptive matter sent to South America. It should be carefully planned and divided into columns or sections, each one calling for specific information in regard to the machine or appliance that is wanted. In general, the headings should be these: Serial number; code word; description; number wanted; net and gross weight, in both English and metric units; general dimensions, in both English and metric units. The serial number, code word and description form a triple check upon the customer's requirements. Catalogs and circulars should also specify net prices. Never quote a list and string of discounts. They are confusing at home and doubly so abroad.

The matter of obtaining a satisfactory translation from English into Spanish or Portuguese may look like a serious difficulty to North American manufacturers. This need not be the case. First, prepare everything in the simplest, clearest, most straightforward English that can be written, taking care to avoid unusual expressions or colloquial and shop names for machine parts, operations and the like. (In passing, it is worth while to point out that it is a pity that there are no standards in technical English for the names of common machine parts and shop operations.) When the original matter has been carefully prepared in this fashion, it is not difficult to obtain a satisfactory translation from some native South American. Three things that cannot go wrong are the illustrations, the serial numbers and the code words. These three form the backbone of the means of identification in a customer's order. One of their good points is that they do not have to be translated.

As a rule, business literature sent from European countries fulfills all the foregoing requirements. However, the quality of the mechanical production of the English and German catalogs and circulars is not nearly so good as that which prevails in the United States. The illustrations are cheaper in kind, the paper is inferior in quality, and the general appearance is unattractive. But all the essential information is there, and that feature is far more important than the one of appearance only. There have been cases where a South American buyer turned to his catalog from England to help in interpreting one from Cleveland, Ohio.

Shop Equipment News

Hobbing Thread Miller

The illustrations show a thread miller manufactured by the Taft-Peirce Manufacturing Co., Woonsocket, R. I. This firm has acquired the manufacturing and selling rights in the United States for this machine, which was originally developed by J. Archdale & Co., Ltd., Birmingham, England.

The machine uses, when milling either internal or external threads, a cutter the threads of which have no lead. This cutter is of practically the same width as the length of thread to be cut, and one complete revolution, with a slight over-travel to insure a perfectly finished thread, completes the machining operation. It will thus be seen that the machine is well adapted for rapid production. It is designed for threads of relatively short length, and the work produced shows a high degree of accuracy.

The part to be machined is held in a self-centering chuck designed to meet its special requirements. The handwheel at the rear of the machine, when tightened, draws back the mechanism on which the work is mounted, thus holding it securely. The work is rotated by a five-step cone pulley placed on a jackshaft at the rear of the machine through bevel and worm gearing. The cone pulley is driven from a countershaft, thus giving the machine five feed changes.

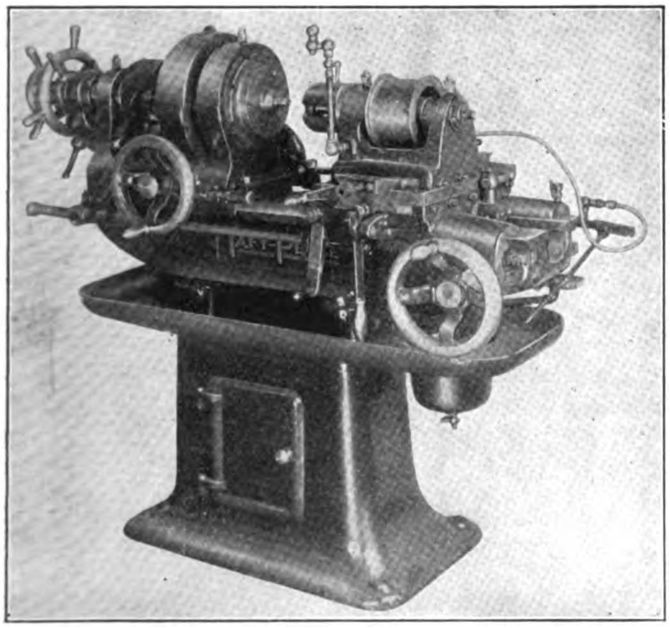


FIG. 1. HOBBING THREAD MILLER

Capacity, internal or external threads, maximum, 4½ in. in diameter, 1½ in. long; minimum, 1 in. in diameter, 1 in. long; length of bed, 3 ft. 10 in.; longitudinal traverse of cutter, 12 in.; transverse traverse of cutter, 6 in.; diameter and width of cutter pulley, 5⅝x5¾ in.; size of bearings in work head, front, 6⅞x4 in. long; size of bearings in work head, rear, 2⅛x2⅓ in. long; distance between countershaft bearings, 15 in.; floor space occupied, 5 ft. 11⅛ in. by 3 ft.; approximate weight, 1,000 lb.

The pitch of the thread being cut is determined by a short detachable guide screw keyed on the tail end of the work spindle. The guide screw engages a nut—also detachable—that is carried by the bracket mounted on the headstock. As the work is rotated, the spindle moves longitudinally forward in its bearings by means of the guide, screw and nut, and in this manner the lead is obtained on the thread being milled.

The cutter spindle is also driven from an overhead countershaft that provides three changes of spindle speed.

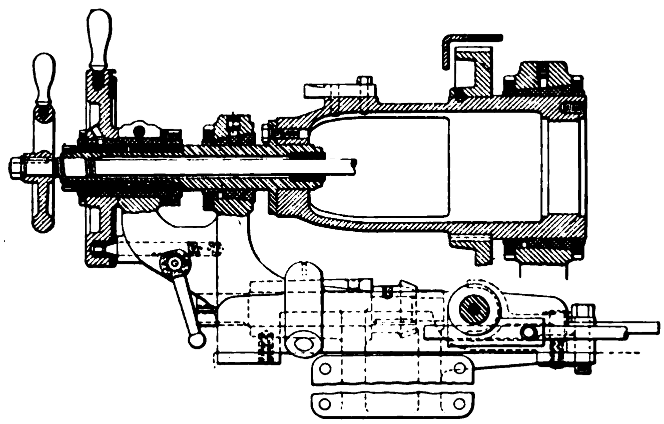

FIG. 2. DETAILS OF WORK-HEAD MECHANISM

The cutter headstock is mounted on a compound slide. The headstock is adjusted transversely by a screw, and a dead stop is provided. After the cutter has been once set for any particular work, it needs no further adjustment until some other class of work is to be threaded. An additional transverse slide is provided under the cutter headstock, which is moved by a lever, bringing the cutter into its working position, after which it latches automatically.

The latch is automatically released by a cam after the thread has been milled on the work, and at the same instant the cutter is withdrawn and the feed motion stopped. As a safeguard, before any thread can be milled it is necessary to draw the work spindle back a distance equal to the pitch of the thread. This is done by the larger handwheel at the end of the machine. However, before this can be performed, a locking pin must be withdrawn by the lever shown under the handwheel. It operates by means of a pinion meshing in rack teeth cut on the pin.

After the handwheel has drawn the work spindle back the correct distance, a spring forces back the locking pin into a tapered hole in the handwheel. The work is then placed in the holding chuck. The cutter slide and cutter are returned to their correct working position by the lever shown in a vertical position under the cutter head. This position is equal to the depth of the thread to be machined.

Another lever, which is alongside of the first one, then drops into a slot in the slide and frame, and the head is locked securely for the milling operation. The machine is now ready for the thread-milling operation. In Fig. 2 are shown details of the work-head mechanism.

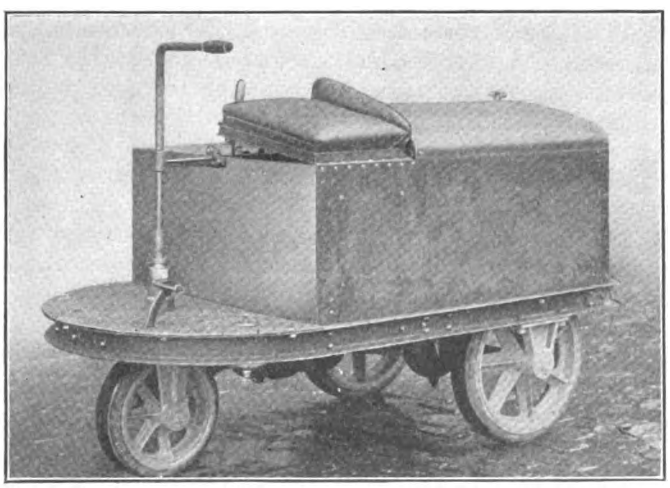
Electric Shop Tractor

In designing the electric shop truck shown in the form of a tractor, the aim is to avoid tying the motor up for long idle periods while the body is being loaded or unloaded. In the tractor form the power unit can be utilized with a minimum of idle time, inasmuch as it can be readily detached from the load-carrying units and put on other work while the loading or unloading of trailers goes on.

The frame of the truck is made of channel iron, riveted and welded. Every moving part has a ball or roller bearing. Power is supplied to the Westinghouse motor by a 250 ampere-hour capacity battery located directly over the rear wheels, thus providing the necessary weight for traction without any surplus or dead-load being carried. The battery space has been designed to accommodate any standard tray, permitting the installation of any battery selected. The motor is of the heavy-duty type, ball bearing throughout, and possesses a 200 per cent. overload capacity. All moving parts are accessible without the use of tools.

The controller gives three speeds forward and two reverse. It is completely exposed for inspection by raising the hinged seat to the left of the controller handle. The handle is automatically locked when the driver leaves his seat.

Power is transmitted direct from the motor to the rear axle through a worm gear. The load on the rear axle is carried mainly on two outward roller bearings. The two rear wheels and the steering wheel are fitted with solid rubber tires. The front wheel is supported by a steel fork, mounted on cup and cone ball bearings, and is turned by a hand lever directly attached.



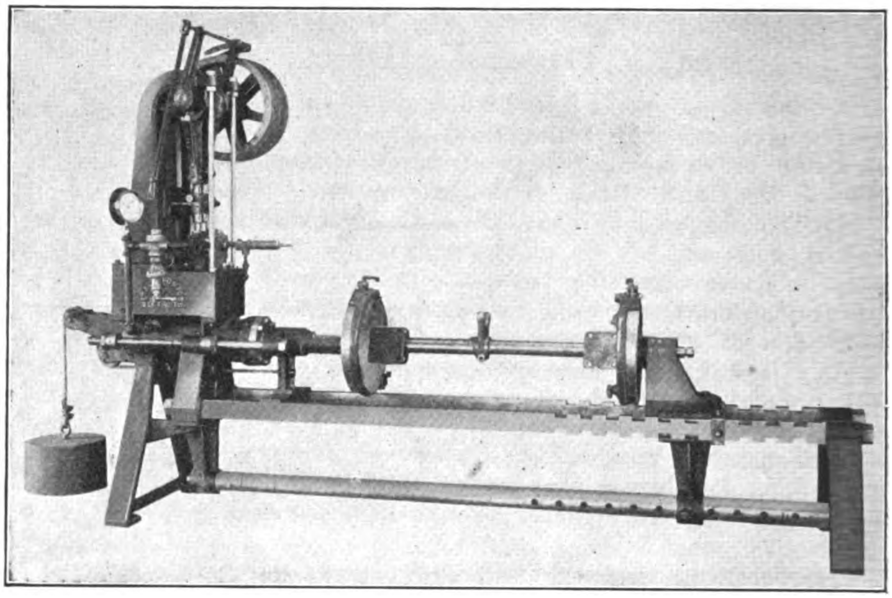
ELECTRIC SHOP TRACTOR

Length over body, 71 in.; width over body, 39 in.; floor to top of driver's seat, 38 in.; floor to top of platform, 19½ in.; turning radius of outside wheels, 46 in.; turning radius of machine, 57 in.

The truck is made by the Mercury Manufacturing Co., Chicago, Ill.

Hydraulic Assembling Press

The press illustrated is shown forcing a brake drum onto an automobile rear axle, but it is adaptable to various pressing and assembling jobs. An especial feature is its quick action, and it is very useful where accuracy and speed are essential. The actual time on the work shown was less than 3 min. from floor to floor.



SELF-CONTAINED HYDRAULIC ASSEMBLING PRESS

Capacity, 20 tons; stroke, 18 in.; ram diameter, 5 in.; speed of ram forward, 5 ft. per min.; pump, Metalwood duplex special hydraulic bronze; speed, 200 r.p.m.; diameter of plungers, 1¼ in.; height of ram center from floor, 34 in.; equipped with 1-in. Metalwood single-lever quick-operating valve and also ¾-in. relief valve; maximum work length of this size, 7 ft.; minimum work length, 3 ft.; floor space, 34 in. by 13 ft. 6 in.; weight, 5,400 lb.

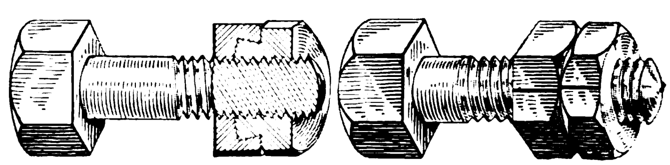
While specific figures are given for a certain size, this machine can be made with a length of bed to suit working conditions. A specially designed safety valve makes the machine foolproof with regard to overpressure, so that if the operator neglects to stop the pumps, no harm is done at any time. A counterweight returns the ram to starting position as soon as the pressure is released.

This machine is made by the Metalwood Manufacturing Co., Detroit, Mich.

Safety Locknut

The illustrations show one of the latest arrivals in the field of safety locknuts. It will be observed that a double nut is provided, one of which constitutes the lock.

The two nuts are placed on the bolt together; but when the securing nut has reached the desired point, the upper locking-nut can be further revolved to a limited degree.



SAFETY LOCKNUT

This is accomplished by providing the lower face of the locknut with a lip which slips into a circumferential recess on the upper part of the first nut, the joint being of the dovetail type. There is a distinguishing mark on the two sections to indicate when the thread on each side is in alignment, and the nut can then be removed as a whole.

By screwing down the top nut a little more, however, a crossthread is obtained, which contracts the lip of the upper nut and thereby produces a circumferential grip, rendering the whole impossible of removal.

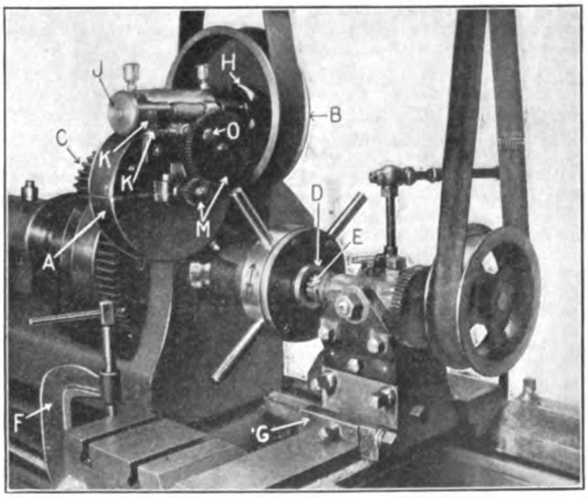
The two nuts are permanently connected and may be rotated separately with a spanner, but cannot be pulled out of engagement with one another. In course of manufacture the lower nut is first drilled and then recessed on the upper face for about half its depth and with the walls of the recess sloping inward. The upper nut is turned with a parallel-sided spigot on its under surface and is drilled with a taper hole. The two parts are then held together by hydraulic pressure while a drift is pressed through them. Thus the spigot is swollen out until it fills tightly the cavity in the under nut. The combined nut is then tapped through with a continuous thread, and in this condition a gage line, half on each nut, is stamped on one of the six flat faces.

The locknut is known as the "Vislok" and is the product of Vislok, Ltd., 3 St. Bride's House, Salisbury Square, London, E. C., England.

Thread-Milling Attachment

The thread-milling apparatus shown is adapted for use on a regular engine lathe. In the case *A* is a bronze worm gear driven by pulley *B*. On the worm-gear shaft there is a pinion gear *C* that engages with the large gear on the cone of the lathe, giving the spindle a backward rotation, as indicated by the arrow.

The piece *D* to be threaded is held in the chuck by a collapsible collet. The cutter *E* is carried in to the full



THREAD-MILLING ATTACHMENT

length of the thread to be cut, being located by moving the carriage up against the stop *F*. The cutter is then brought in to the full depth of the thread by placing the cross-slide against the stop *G*. Next, the clutch *H* is thrown in by pulling the handle *J* to the front, thus allowing the stops *K* and *K* to engage. This starts the spindle rotating.

After the spindle has made about $1\frac{1}{10}$ revolutions, which are governed by the gear ratio *M*, the stop *K* is automatically thrown out by the knock-off pin *O*, and the milling of the thread is complete.

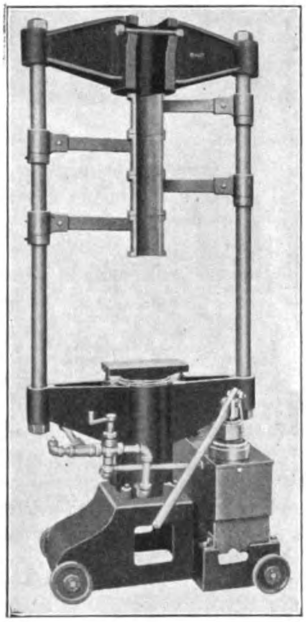
The lathe is geared up as regularly for thread cutting. The cutter is made not as a hob, with spiral grooves, but with straight grooves. The action of the carriage gives the proper pitch of the thread. The apparatus as illustrated is adapted for cutting an 8-pitch Whitworth standard thread in the ogive of a 70-mm. shrapnel shell.

The attachment is a recent product of the New England Butt Co., Providence, R. I.

Hydraulic Arbor Press

The wide range of the arbor press shown is expected to make it well adapted for general machine-shop use.

The movement of the ram is unusually rapid, eight strokes of the pump handle raising the ram 6 in. When heavy pressure is reached, the large piston of the double-differential pump is automatically knocked out and heavy pressure up to 30 tons is produced by the small piston of the pump, which moves the ram at the rate of 1 in. for seven strokes of the pump handle. The V-gap in the crosshead allows shafts and axles to extend up any distance. The ram is provided with two coil springs that return it quickly into the cylinder when the release valve is opened. The press is made of any capacity up to 75 tons and of any desired width between strain rods or distance between top of ram and crosshead. It can be made portable or stationary and can be equipped with power when so desired. The stroke of the ram is 10 in. The machine is the latest addition to the line made by the Lourie Manufacturing Co., Springfield, Ill.



HYDRAULIC ARBOR PRESS
Capacity, 30 tons; width between strain bars, 30 in.

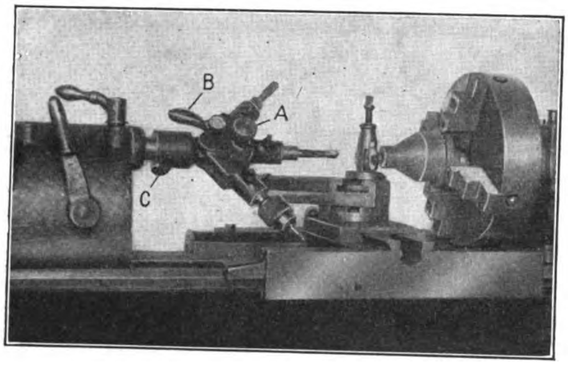
Lathe Turret Head

The lathe turret shown was designed to meet the requirements of toolrooms and machine shops where all kinds of manufacturing are done and where a screw machine is not at hand.

The turret can be put in working position just as quickly as an ordinary lathe center or chuck. It can be turned to any angle without endangering the operator, because the tools are all in one line and do not stick up. The clamping handle is entirely exposed and free. The smallest size is the toolroom bench-lathe size, which is as light as a standard drill chuck, weighing only a little over $1\frac{1}{2}$ lb.

The adoption of three tools in the turret head was based on the experience of the builder in finding that the great bulk of the usual run of work can be made on three settings.

The turret swings only to cover the three or four settings of the tools. To change the tool position, all that is necessary is to pull the knurled knob *A*, as soon as the tool is in position, the plunger will automatically locate the tool in proper line. The clamping handle is shown at



LATHE TURRET HEAD

B, and *C* is the clamp screw to hold the turret on the tail spindle. By using a taper plug, one tool will serve for a number of lathes.

The turret head is a recent product of Charles Eisler, 43 Dodd St., Bloomfield, N. J.

Crane Controller

The Cutler-Hammer Manufacturing Co., Milwaukee, Wis. has recently developed a rope-operated crane controller designed especially for intermittent speed-regulating duty. The control is by means of a rope passing over a sheave at the right of the controller. The rope is run over the sheave from the floor.

I-Beam Trolley

A detachable form of I-beam trolley, designed for use on tracks not having open ends, is a late product of the Chisholm & Moore Manufacturing Co., Cleveland, Ohio. The construction is such that a hinged arrangement permits quick application or removal of the trolley.

Allied Machinery Co. Absorbed

An important step in the machine-tool activities of the American International Corporation was effected in the absorption of the Allied Machinery Co. of America.

The Allied Machinery Co. was formed some four years ago for the purpose of assisting the manufacturers of machine tools in this country to place their goods in foreign markets. The company has been engaged in selling machine tools in Europe, and it is understood that the American International Corporation is formulating plans to expand its machine-tool business and rapidly develop its selling organization.

The company has at present offices and showrooms in Paris, Petrograd, Zurich and Turin. Its branches in Austria and Hungary are closed for the present, on account of inability to ship goods. It will be recalled that Charles E. Carpenter, who is at present in Europe, has been general manager of the Allied Machinery Co. for the past few years.

NEW PUBLICATIONS

PRACTICAL PERSPECTIVE—By Frank Richards and Fred H. Colvin. Fifty-eight 4⅜x6⅞-in. pages; 64 illustrations; cloth bound. Norman W. Henley Publishing Co., New York City. Price, 50c.

This is the fourth edition of a little book that shows how isometric perspective can be used by practical men in every-day work. Nothing confuses many men more than the regular three-view drawings, and they are, at times, very confusing to even experienced mechanics. But an isometric sketch shows the blacksmith exactly what you want to have forged and is equally useful to the pattern maker. Tool draftsmen are using this style of drawing to some extent, and it has many advantages for the work. It will be found useful in many places and is well worth the little time necessary to become proficient in it.

FIVE HUNDRED PLAIN ANSWERS TO DIRECT QUESTIONS ON STEAM, HOT WATER, VAPOR AND VACUUM HEATING. By Alfred G. King. Two hundred and fourteen 6x9-in. pages; 127 illustrations; cloth bound. Published by the Norman W. Henley Publishing Co., New York City. Price, $1.50.

While this book is intended for apprentices and steam fitters, the treatment of the subject matter is so clear and complete that it should prove valuable to anyone interested in the various systems of heating. Heat-generating apparatus seems somewhat slighted, the greater part of the book being devoted to the other parts of the heating systems. The first chapter deals briefly with chimneys, fuels, heating boilers and with their trimmings and settings. This section has not the clearness and completeness which seem to be present elsewhere. For example, we are told that boilers are rated by their horsepower, but the next answer defines horsepower as work required to raise 33,000 lb. 1 ft. per min. The value of the book would seemingly have been increased if a better description of heating boilers had been included. But this sort of information may not be needed by steam fitters. At any rate, the rest of the book is excellent. The elementary theory and the practical construction of heating systems are described. Simple rules are given for determining the sizes of valves, piping and radiators. The advantages claimed and the apparatus required for the systems mentioned in the title are all adequately considered. Few photographs are used, but many line, section and perspective drawings clearly supplement the answers to the questions.

ENGINEERING THERMODYNAMICS—By J. A. Moyer and J. P. Calderwood. Two hundred and three 5¾x9 in. pages; 70 illustrations; indexed; cloth bound. John Wiley & Sons, New York City. Price, $2.

In the introductory chapter the general scope of thermodynamics is outlined, and the important engineering units are defined. The simplest imaginable example of heat engine is taken as that which has for its working substance a long rod of brass, which is heated and cooled and arranged to operate as the pawl of a ratchet wheel. Some actual form of heat engine used as an example in the introductory chapter would prove of greater value in interesting the student in the subject matter.

The laws of perfect gases, including the derivation of formulas for the various thermal lines, are clearly treated in Chapters II and III.

The application of the laws of gases to gas cycles is incompletely discussed in Chapter IV, which has the misleading title, "Cycles of Heat Engines." In this chapter are considered only the Carnot and the regeneration air-engine cycles. No mention is made here or in any other part of the book of the various internal-combustion engine cycles, including the Lenoir, the Otto, the Brayton and the Diesel. In a textbook on "Engineering Thermodynamics" some space should be devoted to the analysis of the possible and practical heat-engine cycles using gas.

One chapter is devoted to the properties of steam and to the use of steam tables. This chapter is very clear, but somewhat incomplete.

The chapter on the properties of steam is followed by one on "Practical Applications of Thermodynamics to Thermal Machinery." This title is somewhat vague. The subject matter of this chapter includes the fundamentals of air and vapor refrigerating machines as well as compressed-air machinery. This chapter is inserted between the chapters on the properties of steam and of the steam-engine cycles. A chapter of this type near the end of the book and with a title "Refrigeration and Compressed-Air Machinery," would be more suitable.

Chapter VII is devoted to entropy of perfect gases and of steam, and this is followed by a chapter on the "Practical

Steam Expansions and Cycles." The first part of this chapter is devoted to steam expansions and to the Rankine cycle.

This is followed by the application of the temperature-entropy diagram to the analysis of the steam engine. The authors then work out problems on the efficiencies of various heat engines. All the engines in the problems given operate under dissimilar conditions, making a comparative study of the merits of different types impossible. Some attention is also given in this chapter to Hirn's analysis.

The last chapter is devoted to the subject of flow of fluids through orifices and nozzles. The various chapters include many well-selected and practical problems.

In general, the book is clearly written, but the attempt to make this treatise brief resulted in the omission of important details. A somewhat more careful arrangement of the subject matter and the addition of the modern internal-combustion engine cycles would serve to add to the value of this book.

PERSONALS

E. P. Worden, formerly of Fred M. Prescott Steam Pump Works, Milwaukee, has been appointed chief engineer of Henry R. Worthington, Harrison, N. J.

Robert G. Nye, for the past few years associated with the Buffalo Forge Co., Buffalo, N. Y., in various capacities, has resigned as factory manager to accept a similar position with the Alberger Pump and Condenser Co., Newburgh, N. Y.

W. R. Noxen who has been connected with the Davis-Bournonville Co. since its organization in 1908 has been appointed manager of the Chicago office, succeeding W. S. Schoenthaler, transferred to the general offices in Jersey City.

R. A. Lewis has become general manager of the Lehigh plant of the Bethlehem Steel Co., succeeding W. Frank Roberts who has been elected vice-president of the company. Mr. Lewis was formerly assistant general manager of the Saucona plant.

P. P. Bourne, formerly chief engineer of Blake & Knowles Steam Pump Works, East Cambridge, Mass., is again associated with the International Steam Pump Co. in connection with special engineering work located at the main office, 115 Broadway, New York.

H. Ulmer has become superintendent of the welding department of the Jersey City shops of the Davis-Bournonville Co., succeeding F. J. Maeurer who has been appointed to take charge of the company's newly established demonstrating and welding plant in Chicago.

A. B. Hazzard, for a number of years general manager of the J. Morton Poole Co., and more recently associated with the Hall Switch and Signal Co., Garwood, N. J., has accepted the position of engineer of equipment with the Amalgamated Machinery Co., with headquarters at 71 Broadway, New York, N. Y.

A. V. Wadsworth for many years foreman in the shops of the National Transit Co., Oil City, Penn., and for the past four years general superintendent of the Buckeye Traction Ditcher Co., Findlay, Ohio, has accepted the position of general manager of the Dayton Pipe Coupling Co., Dayton, Ohio.

OBITUARY

Edward T. Betts, vice-president and treasurer of the Betts Machine Co., Wilmington, Del., died at his home in that city on Feb. 27. Mr. Betts was 60 years of age and of late years took an active interest in civic affairs.

John C. Hooven, one of the founders, and since its organization president, of the Hooven, Owens, Rentschler Company, Hamilton, Ohio, died on Mar. 1 after a brief illness. As the president of this engine-building firm for over 35 years Mr. Hooven became a well-known figure in the engine-building world and as a designer of the Corliss engines of which his company made a specialty he established a reputation for exceptional mechanical ability. Mr. Hooven was a native of Ohio, having been born in Montgomery County in 1843. His early business years were spent in agricultural implement building in association with his father and brother. This led to the establishment of his own business for the manufacture of portable engines and saw mill machinery and in 1880 he was instrumental in the organization of the firm of which he remained president for so many years. Four sons are all associated with the business.

CATALOGS WANTED

L. Rinkel, 3511½ Jefferson Ave., E., Detroit, Mich., would like catalogs from manufacturers of machine tools and machinists' small tools.

Laciny Bros., 2524 N. 25th St., St. Louis, Mo., who are opening a new plant, to be operated as a copper, brass and sheet-iron works, will be in the market for lathes, drill presses, vises, taps, dies, sheet-metal cutters, small tools, measuring instruments, etc., and would like catalogs from manufacturers.

BUSINESS ITEMS

Following out its newly established policy of selling direct in the U. S. the Landis Tool Co., Waynesboro, Penn., announce the following appointments: For New York and Eastern New Jersey, W. G. Neven; New England States, M. G. Dunbar; Pennsylvania, Maryland and Virginia, T. G. Shearer.

The Charles A. Strelinger Co., Detroit, Mich., are breaking ground for the erection of a six-story building at the corners of Larned, Randolph and Bates Streets, to house their business. It will be a warehouse, general office, salesrooms, and machine-tool demonstrating plant and is very close to their present location. Floor space about 100,000 sq.ft. The plant will be ready for occupancy Oct. 1, 1916.

FORTHCOMING MEETINGS

A course of free lectures on military engineering will be given under the auspices of a committee representative of the four national engineering societies, by Captains Robins, Coiner and Ardery, Corps of Engineers, U. S. A. This course will be under the direction of Major-Gen. Leonard Wood and is designed to assist those who desire to enter the engineering battalion which will be formed at Plattsburg next summer. All engineers interested in preparedness will be welcome, but attendance at these lectures does not imply obligation to subsequent camp duty. Through the cordial attitude and coöperation of the United Engineering Society, the auditorium of the Engineering Societies Building has been placed at the disposal of the army officers. These lectures will be given weekly, having begun on Feb. 14, under the following divisions:

March 20, 1916—The selection, laying out and preparation of camps and cantonments; the service of general construction; and the special services, including all public work of an engineering nature which may be required in a territory under military control.

March 27, 1916—The construction, operation and maintenance of railways under military control and the construction and operation of armored trains.

American Society of Mechanical Engineers. Spring meeting, April 11-14, New Orleans, La., Calvin W. Rice, secretary, 29 West 39th St., New York, N. Y.

American Society for Testing Materials. Annual meeting June 27 to July 1, 1916, Hotel Traymore, Atlantic City, N. J. Edgar Warburg, secretary, University of Pennsylvania, Philadelphia, Penn.

American Society of Mechanical Engineers. Monthly meeting first Tuesday. Calvin W. Rice, secretary, 29 West Thirty-ninth St., New York City.

Boston Branch National Metal Trades Association. Monthly meeting on first Wednesday of each month, Young's Hotel. W. W. Poole, secretary, 40 Central St., Boston, Mass.

Providence Association of Mechanical Engineers. Monthly meeting fourth Wednesday each month. J. A. Brooks, secretary, Brown University, Providence, R. I.

New England Foundrymen's Association. Regular meeting second Wednesday of each month. Exchange Club, Boston, Mass. Fred F. Stockwell, 205 Broadway, Cambridgeport, Mass.

Engineers' Society of Western Pennsylvania. Monthly meeting third Tuesday; section meeting, first Tuesday. Elmer K. Hiles, secretary, Oliver Building, Pittsburgh, Penn.

Rochester Society of Technical Draftsmen. Monthly meeting, last Thursday. Secretary, R. H. Barnes, Taylor Instrument Companies, Rochester, N. Y.

Superintendents' and Foremen's Club of Cleveland. Monthly meeting third Saturday. Philip Frankel, secretary, 310 New England Building, Cleveland, Ohio.

Western Society of Engineers, Chicago, Ill. Regular meeting first Wednesday evening of each month, excepting July and August. J. H. Warder, secretary, 1735 Monadnock Block, Chicago, Ill.

Philadelphia Foundrymen's Association. Meetings first Wednesday of each month. Manufacturers' Club, Philadelphia, Penn. Howard Evans, secretary, Pier 45 North, Philadelphia, Penn.

Technical League of America. Regular meeting second Friday of each month. Oscar S. Teale, secretary, 35 Broadway, New York, N. Y.

Prices--Materials and Supplies

IRON AND STEEL

Pig Iron—Quotations were current as follows at the points indicated:

	Mar. 10, 1916	One Month Ago	One Year Ago
No. 2 Southern foundry, Birmingham	$15.00	$15.00	$9.50
No. 2 X Northern foundry, New York	19.75	19.75	14.25
No. 2 Northern foundry, Chicago	18.50	18.50	13.00
Bessemer, Pittsburgh	21.45	21.45	14.55
Basic, Pittsburgh	19.20	18.45	13.45
No. 2 X, Philadelphia	20.00	20.00	14.25
No. 2 Valley	18.50	18.25	13.00
No. 2 Southern, Cincinnati	17.90	17.90	12.40
Basic, Eastern Pennsylvania	19.50	19.50	13.50
Gray forge, Pittsburgh	18.45	18.45	13.45

Steel Shapes—The following base prices in cents per pound are for angles 3 in. by ¼ in. and larger and tees 3 in. and larger from jobbers' warehouse:

	New York				
	Mar. 10, 1916	One Month Ago	One Year Ago	Cleveland	Chicago
Steel angles, base	2.95	2.60	1.85	3.00	2.90
Steel T's, base	2.95	2.65	1.90	3.00	2.90
Machinery steel (bessemer)	2.95	2.60	1.80	3.00	2.90

Steel Sheets—The following are the prices in cents per pound from jobber's warehouse:

	New York				
	Mar. 10, 1916	One Month Ago	One Year Ago	Cleveland	Chicago
No. 28 black	3.50	3.50	2.60	2.95	3.10
No. 26 black	3.40	3.40	2.50	2.85	3.00
Nos. 22 and 24 black	3.35	3.35	2.45	2.80	2.95
Nos. 18 and 20 black	3.30	3.30	2.40	2.75	2.90
No. 16 blue annealed	3.75	3.45	2.30	2.75	3.30
No. 14 blue annealed	3.70	3.35	2.25	3.35	3.20
No. 12 blue annealed	3.65	3.30	2.20	3.30	3.15
No. 28 galvanized	5.65	5.50	4.00	5.25	5.25
No. 26 galvanized	5.35	5.20	3.75	4.95	4.95
No. 24 galvanized	5.20	5.05	3.55	4.80	4.80

Standard Pipe—The following table shows the comparison in discounts, together with the net prices in cents per foot:

	Black		Galvanized	
	Mar. 10, 1916	One Yr. Ago	Mar. 10, 1916	One Yr. Ago
¾- to 2-in. steel butt welded	74%	81%	57½%	72½%
2½- to 6-in. steel lap welded	73%	80%	56½%	72½%
Diameter, In.				
¾	2.99	2.20	5.35	3.50
1	4.42	3.40	7.91	5.20
1¼	5.98	4.60	10.70	7.00
1½	7.15	5.50	12.79	8.40
2	9.62	7.40	17.21	11.15
2½	15.80	12.20	25.45	18.60
3	20.65	16.10	35.57	24.20
4	29.43	22.90	50.87	34.50
5	39.96	29.60	68.82	40.70
6	52.84	38.40	91.08	52.80

Bar Iron—Prices are as follows in cents per pound at the places named:

	Mar. 10, 1916	One Month Ago
Pittsburgh, mill	2.40	2.15
New York	2.60	2.25
Warehouse, New York	2.90	2.55
Warehouse, Cleveland	2.25@2.50	...
Warehouse, Chicago	2.90	...

Cold Drawn Steel Shafting—From warehouse to consumers requiring fair-sized orders the following quotations hold:

New York	List price
Cleveland	List price
Chicago	List price

Swedish (Norway) Iron—This material per 100 lb. sells as follows f.o.b. places named:

New York	$4.50
Cleveland	4.80
Chicago	3.60

In coils an advance of 50c. is usually charged.

METALS

Antimony—Chinese and Japanese brands are quoted as follows in cents per pound for spot delivery, duty paid:

New York...... 44c. Cleveland.... 50c. Chicago.... 44¾c.

Copper Bars from warehouse sell as follows per pound:

New York .... 39.5c. Chicago .... 37.25c.

Miscellaneous Metals—The present New York quotations in cents per pound, with a comparison of a month and year ago, are as follows:

	Mar. 10, 1916	One Month Ago	One Year Ago
Copper, electrolytic (carload lots)	27.25	27.00	14.87½
Tin	55.00	41.25	45.00
Lead	6.75	6.25	3.95
Spelter	19.50	19.50	11.50

Squares					
3	32.50	33.00	33.50	36.00	37.00
Rounds					
3½ to 3 15/16	32.25	32.75	33.25	35.75	36.75
Squares					
3 1/16 to 3 15/16	32.25	32.75	33.25	35.75	36.75
Rounds—Squares					
4 to 4 15/16	33.00	33.50	36.00	36.50	37.50
5 to 6 15/16	36.00	36.50	37.00	34.50	38.50
7	36.50	37.00	37.50	38.00	39.00
Flats	32.50	33.00	33.50	36.00	37.00

Flats not rolled wider than 6 in. or less than ⅛ in. thick.

Hexagon bars 2c. per lb. over corresponding size of round rods.

For cutting to any specified length not shorter than 1 ft. add 1c. per lb.

The scrap allowance is 18c. per lb. delivered at works.

Babbitt Metal—Quotations are as follows in cents per pound from warehouse at the places indicated:

	New York	Cleveland	Chicago
Best grade	55@60	57.00	55@60
Commercial	25@30	22.50	25@30

SHOP ACCESSORIES

Nuts—From warehouses at the places named, the following amount is deducted from list price:

	New York	Cleveland	Chicago
Hot pressed square	$3.00	$3.70	$4.00
Hot pressed hexagon	3.20	3.80	4.20
Cold punched square	3.00	3.50	4.00
Cold punched hexagon	3.75	4.25	5.25

Semifinished nuts sell at the following discount from list:

New York .... 70% Cleveland .... 70 and 10%

Tap Bolts—The discount from list at warehouses is as follows:

New York .... 20% Cleveland 30%

Wrought Washers—From warehouses at the places named the following amount is deducted:

New York....$4.50 Cleveland....$6.25 Chicago......$6.50

At this rate the net prices follow:

Diameter, In.	New York	Cleveland	Chicago
5/8	$9.50	$7.75	$7.50
3/4	7.70	5.95	5.70
7/8	6.90	5.15	4.90
1	6.00	4.25	4.00
1 1/4	5.20	3.65	3.30
1 3/8	4.70	3.15	2.90
1 1/2	4.60	3.05	2.80
1 3/4	4.50	2.95	2.70
2, 2 1/4, 2 1/2, 2 3/4	4.30	2.85	2.50
3, 3 1/4	4.50	2.95	2.70
3 1/2	4.70	3.25	2.70
4, 4 1/4, 4 1/2	5.00	3.25	3.00

For cast-iron washers the base price per 100 lb. is as follows:

New York.... $2.50 Cleveland.... $2.25 Chicago.... $1.90

Carriage Bolts—From warehouses at the places named the following discounts from list hold:

	New York	Cleveland	Chicago
3/8 by 6 in. and smaller	60%	65 and 5%	65 and 10%
Larger and longer	50%	50 and 15%	60 and 5%

Length, In.	New York 1/4	New York 1/2	New York 3/4	Cleveland 1/4	Cleveland 1/2	Cleveland 3/4	Chicago 1/4	Chicago 1/2	Chicago 3/4

3	.52	1.77	4.50	.43	1.50	3.82	.41	1.34	3.42
3 1/2	.56	1.91	4.75	.47	1.62	4.05	.44	1.35	3.61

Bolt Ends—Fair-sized orders of bolt ends with hot-pressed nuts from warehouses sell at the following discounts from list:

New York		50%
Cleveland	small sizes	50%
Chicago	large sizes	20%
		60 and 10%

Turnbuckles—From warehouses at the places named the following prices prevail:

	New York	Cleveland	Chicago
Smaller than 1 1/4-in. diam.	40%	50 and 10%	...
1 1/4- up to 2-in. diam.	30%	40%	...
Size			
1/2	$0.27	$0.21	$0.28
3/4	.38	.29	.32
1	.53	.40	.44
1 1/2	1.05	.90	.83
2	1.86	1.59	1.75

These prices are for buckles having right and left stub ends with turnings between the heads measuring 5 1/2 in.

Rivets—The following are the base quotations from warehouse for fair quantities:

	New York	Cleveland	Chicago
Steel 7/16 and smaller	65%	60%	60—10%
Tinned	65%	60%	60—10%*

*An addition of 3.5c. per lb. is usually charged.

For button heads 3/4, 7/8, 1 in. diam. by 2 in. to 5 in. sell as follows per 100 lb.:

New York.... $4.50 Cleveland.... $3.00 Chicago.... $3.25

Cone heads, same sizes:

New York.... $4.60 Cleveland.... $3.00 Chicago.... $3.35

	Extra per 100 Lb.
1 1/4 to 1 3/4 in. long, all diameters	$0.25
5/8 in. diameter	0.15
1/2 in. diameter	0.50
1 in. long and shorter	0.50
Longer than 5 in.	0.25
Less than kegs	0.50
Countersunk heads	0.50

Coach or Lag Screws—For fair-sized orders from warehouses at the places named the following discounts hold:

New York	65%
Cleveland	60, 10 and 5%
Chicago	70 and 10%

Machine Bolts—For fair-sized orders from warehouses at the places named the following discounts hold:

	New York	Cleveland	Chicago
3/8 by 4 in. and smaller	60%	65 and 10%	70%
Larger and longer up to 1 in. by 30 in.	50%	50 and 20%	60 and 10%

Length, In.	New York 1/4	New York 1/2	New York 1	Cleveland 1/4	Cleveland 1/2	Cleveland 1	Chicago 1/4	Chicago 5/8	Chicago 1
2	$0.71	$1.93	$8.00	$0.56	$1.54	$6.40	$0.54	$1.29	$5.76
2 1/2	.74	2.06	8.45	.58	1.65	6.76	.56	1.48	6.08
3	.78	2.19	8.90	.61	1.75	7.12	.58	1.57	6.40
3 1/2	.81	2.32	9.35	.64	1.86	7.48	.60	1.67	6.73

Copper Rivets from warehouse sell at the following rate:

New York	25% from list
Cleveland	List price
Chicago	10% from list

Nails—Wire nails f.o.b. Pittsburgh sell at $2.40; galvanized, 1 in. and longer, $4.40, and shorter, $4.90. These prices are to regular customers and delivery is made at the mill's convenience. From warehouse wire and cut nails sell as follows:

New York.... $2.90 Cleveland.... $2.85 Chicago.... $2.60

MISCELLANEOUS

Welding Material (Swedish)—Prices are as follows in cents per pound f.o.b. New York:

Welding Wire

3/8, 11/32, 5/16, 1/4, 7/32, 3/16	8.50
No. 8, 5/32 and No. 10	9.25
1/8	10.00
No. 12	11.00
3/32, No. 14 and 1/16	12.00
No. 18	14.00
No. 20	16.00

Special Welding Steel

1/8	33.00
5/32	30.00
3/16	28.00

Cast-Iron Welding Rods

1/4 by 19 in. long	22.00
3/16 by 12 in. long	26.00
3/8 by 19 in. long	20.00
1/2 by 21 in. long	20.00

Vanadium Wire in Coils or Sticks

1/16	15.50
3/32	15.00
1/8	14.00
5/32	12.00
3/16 and larger	11.00

Seamless Drawn Tubing—The base price per pound from warehouse is as follows:

The contract has been awarded for the construction of a cooling and distributing plant at East 117th St. and Kinsman Rd., Cleveland, Ohio, for the Tellings-Belle Vernon Co. Estimated cost, $15,000.

The Western Reserve Rubber Co. plans to construct a plant in East Akron, Ohio.

The contract has been awarded for the construction of a 3-story, 32x75-ft. factory at Norwood, Ohio, for the Cincinnati Rubber Manufacturing Co. Estimated cost, $25,000. Noted Feb. 17.

Swift & Co., Union Stock Yards, Chicago, Ill., has awarded the contract for the construction of a 3-story, 56x108-ft. packing plant at Toledo, Ohio.

The Indiana Public Elevator Co. has awarded the contract for the construction of a grain elevator at Indianapolis, Ind. Estimated cost, $500,000.

The contract for the construction of a factory at Tipton, Ind., for the McIntosh Broom Co. has been awarded.

The Wabash Cabinet Co. will build additions to its plant at Wabash, Ind.

The Michigan Carton Co., manufacturer of cartons and containers, will build a 1-story, 109x120-ft. factory at Battle Creek, Mich.

The Manistee Manufacturing Co., manufacturer of furniture, plans to construct an addition to its plant at Manistee, Mich.

The contract has been awarded for the construction of a 1-story, 60x66-ft. factory at Clearing, Ill., for the Clearing Building Material Co. Estimated cost, $4,000.

WEST OF THE MISSISSIPPI

The Clinton Sugar Refining Co. plans to build an addition to its plant at Clinton, Iowa.

The Oskaloosa Vitrified Brick Co. will issue $50,000 bonds for enlarging and improving its plant at Oskaloosa, Iowa.

Plans being prepared by C. H. Patsche, Arch., for a 1-story addition to the plant of Fairmount Packing Co., Fairmount, Minn.

Contract for 3-story plant for the Lowell Bleacheries, 3907 Laclede Ave., St. Louis, Mo., has been awarded. Noted Feb. 24.

The Clanton Lumber Co., Shreveport, La., will build a box factory at Hamburg, Ark.

The Dixie Broom Works, recently incorporated, contemplates building a factory at Hope, Ark. L. W. Rogers is interested.

The Quachita Power Co., Little Rock, Ark., contemplates building a cotton duck mill.

The Ben D. Schaad Machinery Co., Little Rock, Ark., manufacturer of plate glass, gravel roofing, vestibules and elevators will remodel its building at 301 East Markham St., Little Rock.

S. Saxe, Boston, Mass., contemplates constructing a tannery at Denison, Tex. Estimated cost, $150,000.

L. T. Lewis, Fletcher, Okla., will reconstruct its cotton gin at Floydada, Tex.

The Cheek-Neal Coffee Co., Houston, Tex., contemplates building an addition to its plant. Estimated cost, $100,000.

F. M. Newton, Jacksonville, Tex., will build a broom factory.

The Texas Cotton Mills, McKinney, Tex., will enlarge its main structure and dye house. Park A. Dallas Co., Atlanta, Ga., Engr.

Edward Dawson has purchased the cotton gin of Hubbell, Slack & Co., Mission, Tex., and will enlarge same.

The North Loop Gin Co. will build a cotton gin at San Antonio, Tex. Conrad Pape is interested.

The Independent Gin Co., Sinton, Tex., will build a cotton gin at Sinton. J. A. Bartlett, Pleasanton, is interested.

The Solms Farmers' Gin Association has been organized with capital of $12,000 and will build a cotton gin at Solms, Tex.

CANADA

The St. Maurice Paper Co. has awarded the contract for the construction of a factory at Cap Magdeleine, Que. Noted Mar. 9.

The Northumberland Paper and Electric Co. plans to rebuild its plant at Campbellford, Ont., which was recently destroyed by fire. Noted Mar. 2.

Plans are being prepared for the construction of woolen mills at Lindsay, Ont., for Horne Bros., Windsor St., Lindsay. Alexander Borne is Mgr.

The Martin Corrugated Paper Box Co., will build a plant at 353 Pape Ave., Toronto, Ont., to replace the one recently destroyed by fire. Estimated cost, $16,000.

The McLagan Furniture Manufacturing Co., 93 Trinity St., Stratford, Ont., will construct an addition to its plant at Stratford.

Work will soon be started on the construction of a plant at Calgary, Alta., for the J. C. Boyle Packing Co. Estimated cost, $1,000,000.

The Vancouver Creosoting Co. will build a plant at North Vancouver, B. C. Estimated cost, $100,000. J. C. Storey, Engr.

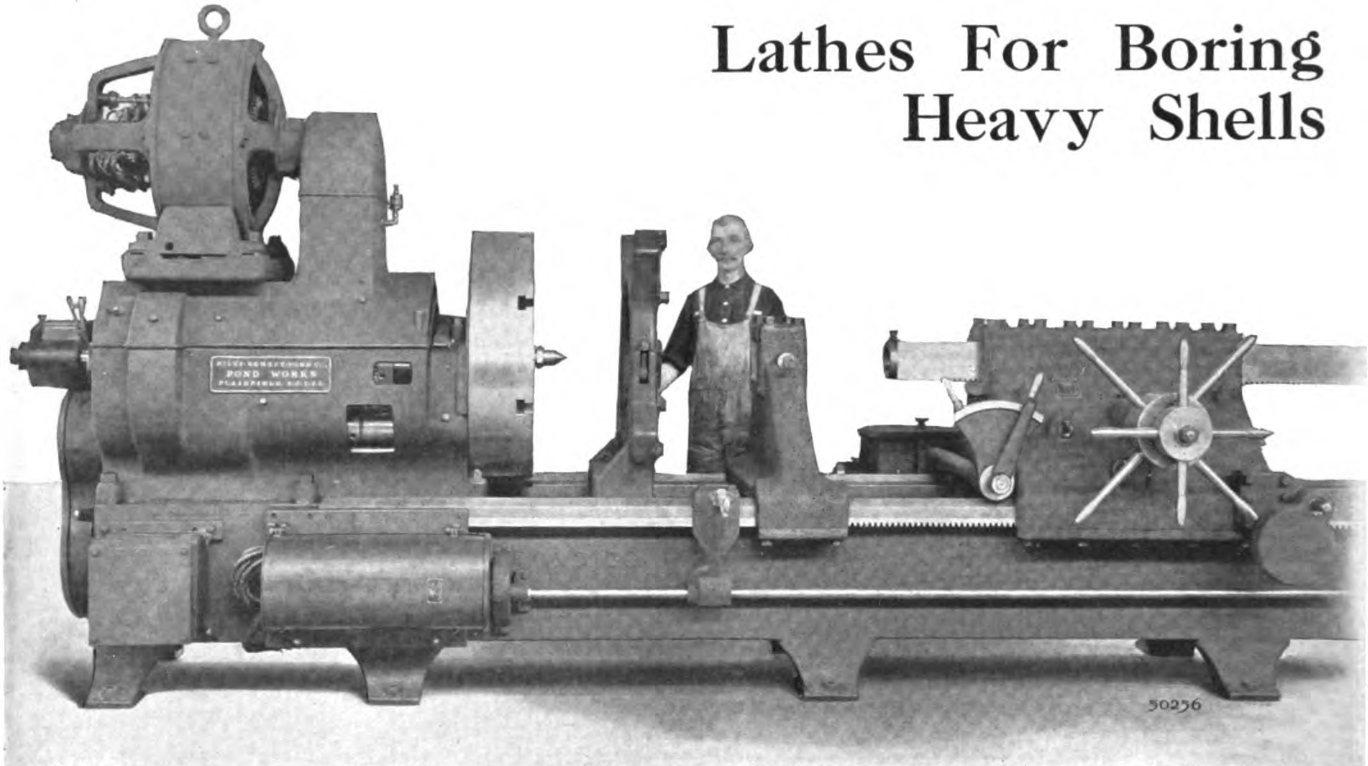
For Short Delivery

Lathes For Boring Heavy Shells



36" Heavy Lathe with boring tailstock.

All Steel Gears

Lathes are equipped throughout with steel gears and are driven by 20-hp. motors. Rear end of spindle is provided with a special thrust bearing of heavy construction to take the end thrust due to boring large holes.

Boring Tailstock

The boring ram is forged steel 6 in. square, and has a very long bearing in the tailstock. The ram feed is driven from the feed shaft, at the rear of the bed, through worm and worm wheel giving a smooth motion for boring. By means of two levers, four feeds can be obtained without changing any gears. These levers are attached to the tailstock and hence are always in a convenient position.

Supports for Work and Boring Ram

A steady rest is provided to support the shell or other work. There is also furnished a special rest to support the end of the boring ram. This rest moves along the bed with the ram as it feeds.

Specifications, Delivery, Prices, etc., Promptly Furnished on Request.

If I Knew You and You Knew Me*

IF I knew you and you knew me,
'Tis seldom we would disagree;
But never having yet clasped hands,
Both often fail to understand
That each intends to do what's right,
And treat each other "honor bright."
How little to complain there'd be
If I knew you and you knew me.

Whene'er we ship you by mistake,
Or in your bill some error make,
From irritation you'd be free
If I knew you and you knew me.
Or when the checks don't come on time,
And customers send us nary a line,
We'd wait without anxiety,
If I knew you and you knew me.

Or when some goods you "fire back,"
Or make a "kick" on this or that,
We'd take it in good part, you see,
If I knew you and you knew me.
With customers two thousand strong
Occasionally things go wrong—
Sometimes our fault, sometimes theirs—
Forbearance would decrease all cares;
Kind friend, how pleasant things would be
If I knew you and you knew me.

Then let no doubting thoughts abide
Of firm good faith on either side;
Confidence to each other give,
Living ourselves, let others live;
But any time you come this way,
That you will call we hope and pray;
Then face to face we each shall see
And I'll know you and you'll know me.

Making Wire Automobile Wheels with Demountable Rims

By Ethan Viall

SYNOPSIS—The wire automobile wheels described in this article are of a special type and differ considerably from others of the same class. The process of making these wheels is described from start to finish, though only major operations are illustrated.

One big difficulty in the way of using wire-spoked wheels has been the tendency of the spokes to crystallize and break after a certain amount of use. Those who have even ridden a bicycle for any length of time will recall the spokes that had to be replaced occasionally, even though no accident was the cause. Another difficulty where wire wheels have been used on automobiles has been the collecting of dirt and mud on the inside of the rim, caused by the wide, flat rim and the size and position of the spokes and nipples. Of course, this collecting of mud is true to some extent with the wooden-spoked wheels, but to a far less extent on account of the "ridge" on the rim in which the spokes are set, which is comparatively narrow and affords less lodging surface.

Demountable rims have been common for use with wooden wheels, but with wire wheels it has been the general practice to carry an extra wheel instead, or else depend on changing tires as punctures developed. With the type of wire wheel described in this article the tendency of the spokes to crystallize has been minimized. The inside of the rim closely resembles that of a wooden wheel, with consequent lessened dirt lodgment, and the rim is demountable and interchangeable, making it unnecessary to buy and carry an entire extra wheel for quick repairs on the road.

This type of wheel is made by the Spranger Rim and Wheel Co., Detroit, Mich., and a glance at Fig. 1 will show the close resemblance of the rim section to that of a wooden wheel. The rim consists of two principal parts: One is the channel in which the spokes are held; and the other is the rim proper, which holds the tire. It is this double construction that gives practical freedom from spoke troubles. The channel is heavy and tightly laced to the hub by the spokes. The shape of the channel and the method of lacing are such that the springy, vibratory movement of the spokes while the wheel is running under stress is largely eliminated. This is also greatly assisted by the fact that the rim itself takes up most of the tire

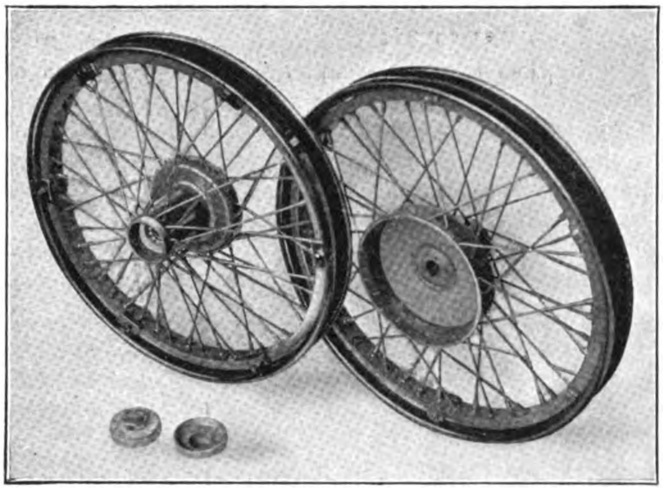

FIG. 1. WIRE AUTOMOBILE WHEELS WITH DEMOUNTABLE RIMS

movement, which owing to the method of attaching, does not affect the channel to any extent.

At present the rims are not made by this company, but are purchased already shaped and welded from one of the big steel companies. They have to be sized and otherwise finished, however. The channels are made from the straight stock, which is first cut to length, shaped in regular circle rolls and the ends fitted and welded. The welding is done in the type of butt welder shown in Fig. 2. This machine was made by the F. L. Jacobs Co.,

Detroit. The two work-clamping jaws are operated by means of the levers *A*, which act eccentrically on the tops of the jaw bars. On being released the jaws are raised by means of weights *B* on the rear ends of the bars. Ample adjusting arrangements are provided for various sizes of work.

The right-hand movable slide is operated by means of a hydraulic cylinder with a quick-return release, which is operated by the lever *C*. This arrangement makes it easy for the operator to force the channel ends together as much as needed. A scale *D* and a pointer *E* on the jaw slide show him how much movement to give, to produce the right diameter of rim. In the particular example shown, standard 2-in. channels are being welded, the time taken being about 30 sec. each, at an estimated cost of ½c. each. This will be recognized as a fine record.

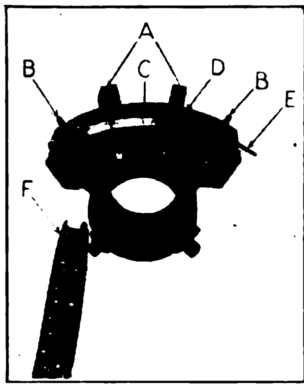

FIG. 7. DETAILS OF SPOKE-HOLE DIE

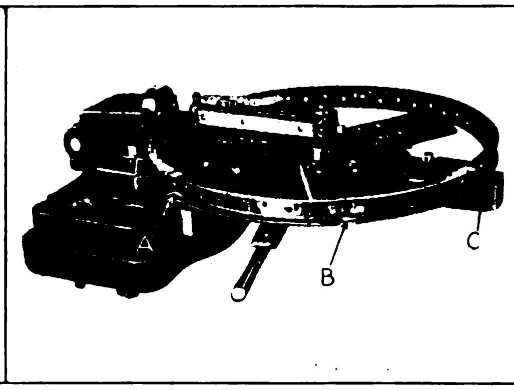

FIG. 8. PUNCH AND INDEXING FIXTURE FOR LUG SPACES

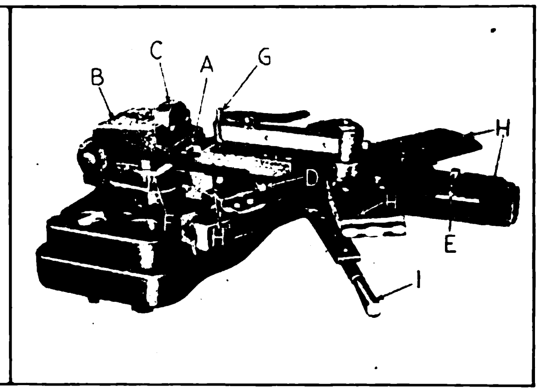

FIG. 9. DETAILS OF PUNCH AND INDEXING FIXTURE

Neither the rims as received nor the welded channels are either round or of exact size, so they must be worked in a special stretching machine to remedy their faults. The stretching machine used, shown in Fig. 3, is made by the Charles Grotnes Machine Works, Chicago. It is a back-geared powerful machine, and the rim and channels are both sized on it. They are placed over the expanding head *A*, the jaws of which work out and in. As the jaws move, the operator turns the work so that it is kneaded to size and perfectly rounded. The movement of the jaws is comparatively slow, and in some cases the work has to be stretched so as to increase it ¼ in. or more. Test gages for different diameters of channels and rims are shown at *B*. A closer view of the expanding head, with its reciprocating jaws, is shown in Fig. 4. These jaws are operated by crank and toggle movements.

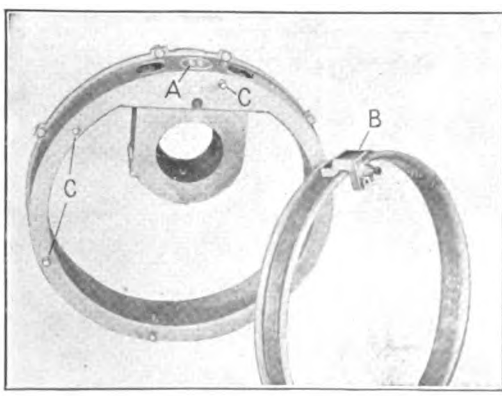

FIG. 10. DIE AND FIXTURE FOR LUG RIVET HOLES IN RIM

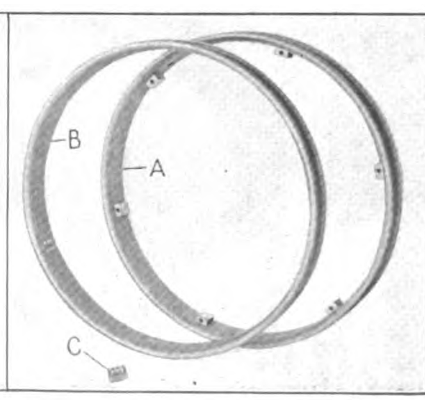

FIG. 11. RIMS WITH AND WITHOUT LUGS

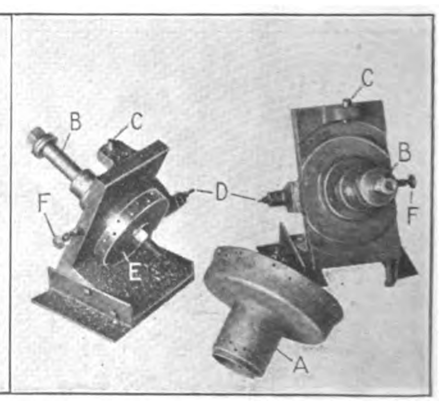

FIG. 12. HUB SPOKE HOLE DRILLING FIXTURES

After being sized and made perfectly round in the stretching machine, the channels are chucked on a special faceplate, as shown in Fig. 5, and the outside edges of the channel are trued and rounded, which makes the channels true, outside and in.

The holes for the spoke nipples are punched in the channels in a horn press, with an ordinary punch and the die shown in Fig. 6. This same die is shown more in detail in Fig. 7. The channel to be punched is placed under the stripping guides *A* and against the pins *B*. The holes are punched through at *C*. The spacing is done by means of the pin *D*. This pin is spring-backed, so that it is pressed down while the first hole is punched. The punched hole is then moved along until the pin will enter it, which gives the correct distance for the next hole, and so on. Slight adjustment for this spacing pin is provided by mounting it in a slotted carrier. An adjusting screw *E* is used to get the exact distance needed. It will be seen from the punched channel at *F* that the holes are staggered. This result is obtained by punching one row of holes that are in line and then turning the channel around and punching the other row.

An Indexing Punch Fixture

Places in the sides of the channels for the rim lugs to enter are punched out in the indexing fixture, shown in Fig. 8. The places punched out are shown at *A, B* and *C*. Six places are punched out of each channel. This fixture, with the channel removed, is shown in Fig. 9. As the places are punched from inside the channel proper, the punch *A* is an extension one carried in a hinged block *B*. A bumper is carried in the press ram, which hits the piece *C* and forces the punch downward. As the ram rises, the hinged block and punch are forced upward by a spring. An arm is provided on the fixture for each place to be punched. The channel is placed over these arms and is located so that the punched places will be in correct relation to the valve and spoke holes, by means of pins *D* and *E*, which enter the spoke holes previously punched. Stripper hooks *F* prevent the channel from being carried upward by the punch.

The work is indexed for the six positions by means of the latch at *G* and bushed holes *H* in the different arms. The entire indexing mechanism and channel holder are carried on a slide operated by lever *I*. By using this lever the fixture is run back from the punch for the insertion or removal of the work. When in working position, the slide is locked by a latch device.

There are six lugs placed on the inside of each rim. They are held to the rim by six rivets each. The rivet holes in the rims are punched out in a horn press, using the fixture shown in Fig. 10. The die proper is shown at *A*. The valve hole is previously punched in the rim, and this hole is used as a locating point for the placing of the rivet holes. A special clamp *B* is slipped over the rim, and a pin is pushed down through a hole in it into the valve hole in the rim. The setscrew is then tightened, the pin removed and the rim placed over the die frame. There are six pins *C* in the frame, and a notch in the rim clamp fits over these pins in turn, as the rim is moved around to the different punching positions.

A rim with a set of lugs in place is shown at *A*, Fig. 11. One without the lugs is shown at *B*, and a lug with rivets in place is shown at *C*. The lugs are riveted to the rim in a multiblow riveting machine.

Spoke holes in the hubs are drilled in the type of fixture shown in Fig. 12. One of the hubs is shown at *A*. This is placed over the center pin *B* and held in place by washers and a nut. The drill bushing is shown at *C*. As a hole is drilled, the work is indexed for the next by means of the spring-pin *D* and the spotted disk *E*. As the holes are staggered, the fixture is provided with a shift pin at *F*, by which both the work and the indexing disk are shifted over for the second line of holes. Different fixtures are used for the various sizes of hubs and also for opposite ends of the same hub.

Photostatic Reproduction

By Samuel Crane Williams

The reproduction of blueprints, pen and pencil sketches, maps, excerpts from books, contracts and specifications was more or less difficult up to a year or two ago, but with the introduction of the photostat, or commercial camera, the process has become exceedingly easy and, for the kind of work accomplished, comparatively cheap. Although yet in its infancy, its adoption by the Government and by industrial corporations that are also large users of the blueprinting process has led the author to believe that the photostat has a field of its own which the blueprint cannot touch. Consequently, the cost data given herewith, derived from the experience of a concern that makes on an average of 190 to 200 copies per day by this process, may be of interest.

Before going into the cost of production, a word as to the method of making copies might be of general interest. The photostat works similarly to an enlarging camera. The object to be copied (enlarged or reduced) is placed upon a horizontal board with a glass top. Two mercury-vapor tubes parallel to the length of the board and on each side illuminate the object strongly. The rays from these lamps are reflected from the object through a right-angle prism and photographic lens, the image striking a sheet of sensitized paper. After having been properly exposed, this sheet of paper is cut from the roll and dropped automatically into a tray of developing solution. It is next drawn out of this tray and placed in a fixing bath of hypo. If the print is satisfactory, it is then washed for 15 or 20 min. and hung up to dry; or if needed urgently, it may be dried between blotters and then ironed out with an electric iron.

The finished photograph will have its blacks and whites reversed; that is, it will be a negative the same as a film or plate. If it is desired to have the blacks and whites the same as in the original, a copy of this negative—a positive—must be made. If several copies of the same original are to be made, it is more economical to make one negative and the rest positives, as the negatives require more developer, owing to the greater amount of chemicals to be removed. If the object to be photographed is small enough, one-half the lens may be closed off and the image taken on a half sheet. If the object is too large to go on the board at one time, it may be taken in sections and the sections pasted together when dry. This pasting and matching take considerable time, a skillful boy being able to trim and match a four-section sheet, requiring three matches, in about 15 min.

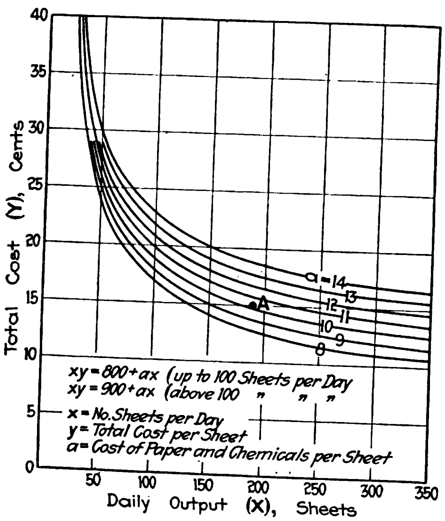
A large amount of our work is two-section work on drawings, and the reproduction of specifications. We get

three sheets of these, slightly reduced, upon a full-sized sheet 18x13 in. With a first-class operator and two expert boy trimmers we are able at maximum capacity to turn out 350 full-sized sheets in an 8-hr. day, but this rate cannot be kept up. A good average output from this size of machine would be about 300 full-sized sheets a day and could be kept up indefinitely.

Preparing Cost Data

In preparing these cost data the subject was attacked from two different angles—as a business investment, pure and simple, requiring the soliciting of work, and also as an adjunct to another business, in which case the work is unsolicited. The first condition does not interest the average user and will not be considered here.

In either case the total cost per sheet multiplied by the number of sheets in a given period is equal to the total overhead charges for the same period plus the cost per



COST OF PHOTOSTATIC REPRODUCTION

sheet for chemicals and paper multiplied by the number of sheets. Thus if we let

y = Total cost per sheet;
x = Average number of sheets per day for a month's work;
a = Cost per sheet for chemicals and paper;
K = Overhead charges per day;

then

$$xy = K + ax.$$

In this equation x and y are variables, while a and K are constants, the value of the former depending upon the cost of chemical and paper, and the value of the latter depending upon the size of the machine used and the number of operators.

In arriving at a value for a the following notation is used, with the costs in cents:

Let

b = Cost of paper per sheet;
c = Cost of chemicals per sheet;
d = Cost of sodium carbonate per pound;
e = Cost of sodium sulphite per pound;
f = Cost of hypo per pound;
g = Cost of citric acid per pound;
h = Cost of powdered alum per pound;
i = Cost of hydroquinone per pound;
j = Cost of photol per pound;
k = Cost of potassium bromide per pound.

By test we have found that 6 per cent. of every roll of paper is thrown out for wrong exposure, weak chemicals, joints in the roll, etc., so that in figuring the cost of paper per sheet this loss is taken into account. Although each finished sheet is 18 in. long, there is 1 in. of paper that is unexposed each time, so that we consider the actual length of each sheet as 19 in. The length of each roll is 350 ft., and the cost per sheet works down to

$$b = \frac{(cost\ per\ roll) \times 19 \times 100}{350 \times 12 \times 94}$$

The figure 94 per cent. should be determined by experiment in any case, as an inexperienced operator can waste a great deal of paper. With paper costing $16.50 per roll the price per sheet, using this formula, would be

$$b = \frac{1{,}650 \times 19 \times 100}{350 \times 12 \times 94} = 7.95c.$$

On the same test that determined the amount of paper wasted per roll we found that six mixings of developer and fixing bath were necessary per roll of paper. This is equivalent to 35 full-sized sheets for each mixing of developer and fixing bath. The formula which we use in making up these chemical solutions gives us the following:

$$c = \frac{96d + 80e + 256f + 8g + 8h + 16i + 2j + k}{256 \times 35}$$

The prices of chemicals have increased considerably since the war, owing to the fact that the most important ones are produced in Germany only and hence are very hard to obtain. The huge demand occasioned by the rapid growth of the motion-picture industry has also caused the price to go up. At the time of preparation of this article the various chemicals are selling at as high a rate as they will probably reach, because manufacturers in this country are beginning to produce them. The prices paid in New York in December, 1915, were as follows:

Chemical	Price per Lb.
Sodium carbonate, d	$0.08
Sodium sulphite, e	.10
Hypo, f	.025
Citric acid, g	.75
Powdered alum, h	.10
Hydroquinone, i	7.75
Photol, j	18.00
Potassium bromide, k	5.00

Substituting these prices in cents in our formula, we get $c = 2.16$c.

With a value of $b = 7.95$c. and $c = 2.16$c., a would equal $7.95 + 2.16 = 10.11$c. In plotting the curves, a is given for 8, 9, 10, 11, 12, 13 and 14c., which will take care of all likely fluctuations in price of paper and chemicals.

If we assume that there are 300 working days a year, the value of K can be taken as 900 and can be reduced to 800 when the average output is less than 100 sheets per day, as then the services of the boy can be dispensed with.

A graphical representation of these costs is given. During the month of December our outfit made an average of 190 sheets per day, with chemicals and paper costing 10.11c. per sheet, which from the curve gives a total cost of 15c. per sheet.

Carbonizing Small-Shop Steels

BY JOHN H. VAN DEVENTER

SYNOPSIS—Carbonizing is the first step in casehardening. Unless this part of the work is done with a knowledge of the principles involved, the final result will be uncertain. This article gives an explanation of the action of carbonizing processes as applied to both low- and high-carbon steels.

Out in the woods of North Carolina, ten miles from the nearest populated point, a gang of men were converting pine trees into rough lumber. For this purpose they used axes and a portable sawmill outfit run by a side-crank engine such as is commonly found in these migrating lumber camps. One day the boiler, which was rather inclined to bad attacks or spasms, delivered an unusually large gob of water through its discharge pipe to the long-suffering engine cylinder just at the time that the saw was biting its way through a pugnacious pine knot. The combination of circumstances was too much for the crosshead pin of the engine.

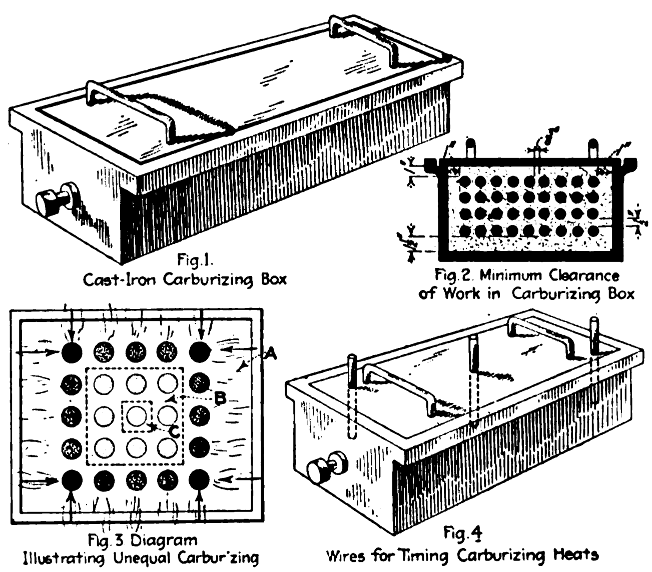
"I don't see what made the darn thing break," said the lanky North Carolinian who acted not only as boss of the outfit, but also as master mechanic. Indeed the fracture, to one who was not experienced in such matters, would appear to be a good one. Still, it was evident that something must have been wrong with the pin, for by all expectations the cylinder head should have gone before this part of the apparatus gave away.

To get at the real reason for this mishap, which meant the loss of many dollars and a shutdown of many days to this lumber camp, let us go back to the factory in which this crosshead pin was made and see how the work was done. If the lanky lumber-camp boss could go along with us and also see what caused the accident, I am sure that he would be more particular in the future in buying an engine and possibly willing to pay enough to avoid the junk that is frequently offered.

In the shop that built this engine the aim was not so much to give service as it was, to put it crudely, to find suckers. The idea was to produce an engine at the lowest possible cost, sell it at a price that would be an inducement much greater than quality and not worry too much about what happened to it after it was in use. One of the safeguards of this policy was the knowledge of many ways by which a skillful correspondent can make defects of construction appear as errors in operation.

To make the descriptive matter as imposing as possible, such items as charcoal-iron castings, hammered babbitt bearings and casehardened pins were described at length, although as a matter of actual fact the nearest that any charcoal got to the iron was in the fire used in drying the skin of the mold, and the only hammering that the bearings received was that due to the pounding of the rod after the engine was in service. As for the casehardened pins, the blacksmith took them under his wing after they were fully machined, heated them up in his forge, sprinkled a little cyanide of potassium over their surfaces, turned them around in the fire once or twice, to get the same effect as is obtained by basting chickens, and then plunged them into a cold brine solution. This procedure did make the outer skins of these pins very hard, but it left the inner core extremely coarse-grained and weak. The pin could not be touched with a file and might appear to be a very long-wearing product, but was brittle and weak. If it had really been wise on the subject of carbonizing and casehardening, this firm could have avoided this feature and also reduced the cost of carbonizing the crosshead pin—getting a high-grade result for less money.

Casehardening divides itself into two parts—carbonizing and quenching. A great many people think that the quenching must be done at the same heat as that at which the piece is carbonized. This idea is entirely wrong, and these two processes can be regarded as separate operations; in fact, in this article I will stick to the carbonizing part of it as closely as possible and save the quenching for another time.



FIGS. 1 TO 4. CARBONIZING BOXES AND DETAILS ILLUSTRATING THEIR USE

There are four different reasons for casehardening, and they must be considered in connection with the way of doing it. The first is to secure a hard surface—maximum hardness to resist wear without shock. Again, a piece may be casehardened for the purpose of securing stiffness, thus reducing the likelihood of the stretching of light sections while at the same time allowing the use of cheap machinery-steel stock. A third purpose is to secure colors on certain classes of work. The fourth, which is possibly the least understood in most shops, is that of securing a hard cutting edge, not only on low-carbon steels, but also on tool steels.

These different purposes are secured by the proper selection of the carbonizing material in which the articles are packed and of the bath in which they are quenched.

The general practice of carbonizing is as follows: The articles are placed in cast-iron boxes surrounded by materials that will give up carbon when heated. These boxes and their contents are next heated through, beyond the critical point of the steel involved (see page 447) and are allowed to soak at this temperature for a length

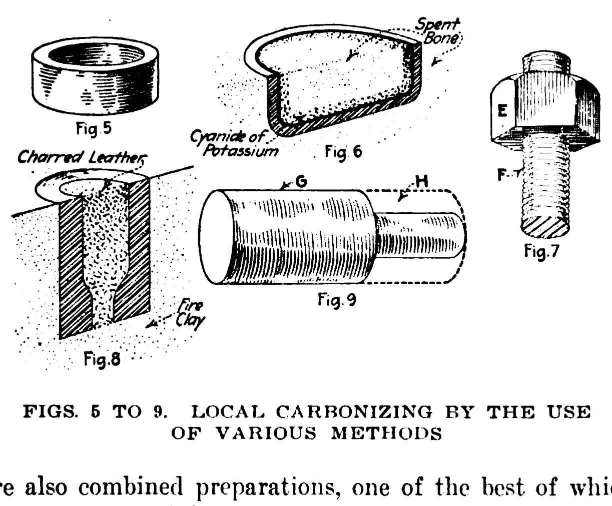
of time depending on the depth of case wished. A convenient box for this purpose is shown in Fig. 1.

There are certain precautions to be taken in packing a box of this kind. In the tug-of-war to absorb whatever free carbon is released by the heated carbonizing material, cast iron has a much stronger pull than has steel. As a result, if the pieces are placed too near the cast-iron walls of the containing box, these walls will get the benefit of the carbon to the detriment of the pieces. Fig. 2 shows a cross-section through a casehardening box and gives the minimum clearances for the articles with relation to each other and to the walls and bottom of the box.

The casehardening box must not be too large, especially for light work that is run on a short heat. The reason for this is shown in the diagram in Fig. 3. When a box of this kind is put into a furnace, it heats from the outside toward the center, taking from one-half hour to an hour and a half to heat through uniformly, depending upon the liveliness of the fire. If the contents of such a box are dumped after a short heat, the pieces on the outside rows will have been at the carbonizing heat much longer than those nearer the center of the box, the result being a much greater gain in carbon in these outer pieces, as illustrated by the sectional shading in Fig. 3.

The temperature to be used for carbonizing depends on the amount of carbon already in the steel to be treated. This temperature must be above the critical point of the steel; and if you know its carbon contents, you can obtain this point from the table on page 447. Low-carbon machinery steel containing from 15 to 20 points carbon is commonly used for this purpose, and such steels must be heated to between 1,650 and 1,750 deg. F. The more carbon that there is in the steel to start with the slower it will be in taking on additional carbon and the lower is the temperature required. In ordinary casehardening, the outer surface of steel has its carbon increased from 15 or 20 points to 80 or 85 points. Tool steels may be carbonized as high as 250 points, but this amount is a maximum and is seldom, if ever, required.

The materials used for carbonizing are many. Among the most common are wood and bone charcoal, ground or crushed bone, charred leather, horns and hoofs. There



FIGS. 5 TO 9. LOCAL CARBONIZING BY THE USE OF VARIOUS METHODS

are also combined preparations, one of the best of which is a mixture of barium carbonate, 40 per cent., and charcoal, 60 per cent. This mixture gives a rate of penetration which is from 10 to 20 per cent. faster than that of charcoal, bone or leather. Fig. 10 shows the penetration of this mixture on ordinary low-carbon machinery-steel stock over a range of 2 to 12 hr.

Each of these different packing materials has a different effect upon the work in which it is heated. Charcoal by itself will give a rather light case. Mixed with raw bone it will carbonize more rapidly, and still more so if mixed with burnt bone. Raw bone and burnt bone, as may be inferred, are both quicker carbonizers than charcoal, but raw bone must never be used where the breakage of

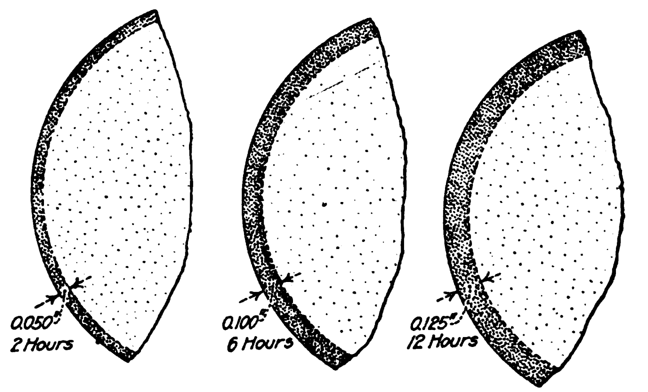


FIG. 10. ORDINARY CASE PENETRATION IN LOW-CARBON STEEL FOR VARIOUS HEATS

hardened edges is to be avoided, as it contains phosphorus and tends to make the piece brittle. Charred leather mixed with charcoal is a still faster material, and horns and hoofs exceed even this in speed; but these two compounds are restricted by their cost to use with high-grade articles, usually of tool or high-carbon steel, that are to be hardened locally—that is, "pack-hardened." Cyanide of potassium and prussiate of potash are also included in the list of carbonizing materials; but outside of carbonizing by dipping into melted baths of these materials, which I will describe later, their use is largely confined to local hardening of small surfaces, such as holes in dies and the like.

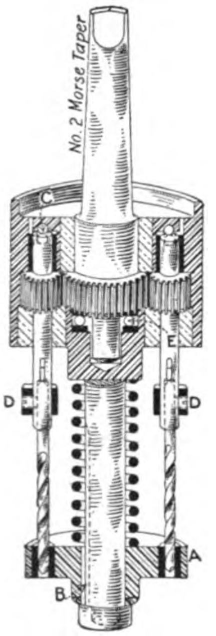
One of the advantages of hardening by carbonizing is the fact that you can arrange to leave part of the work soft and thus retain the toughness and strength of the original material. Figs. 5 to 9 show ways of doing this. The inside of the cup in Fig. 5 is locally hardened, as illustrated in Fig. 6, "spent" or used bone being packed around the surfaces that are to be left soft, while cyanide of potassium is put around those which are desired hard. The threads of the nut in Fig. 7 are kept soft by carbonizing the nut while upon a stud. The profile gage, Fig. 8, is made of high-carbon steel and is hardened on the inside by packing with charred leather, but kept soft on the outside by surrounding it with fireclay. The rivet stud shown in Fig. 9 is carbonized while of its full diameter and then turned down to the size of the rivet end, thus cutting away the carbonized surface. Pieces of this kind are of course not quenched and hardened in the carbonizing heat, but are left in the box to cool, just as in box annealing, being reheated and quenched as a second operation. In fact, this is a good scheme to use for the majority of carbonizing work of small and moderate size. Sometimes it is wished to harden a thin piece of sheet steel halfway through, retaining the soft portion as a backing for strength. Material is on the market with which one side of the steel can be treated; or copper-plating one side of it will answer the same purpose and prevent that side becoming carbonized.

Neat Multiple Drill Head

By P. Baldus

A good construction of a multiple drill head is shown in the accompanying illustration. The design is of the four-spindle type.

The drill-head body is turned from a bar of 3-in. diameter cold-rolled steel and carries the jig plate *A*, which is held in line with the four spindles by the key *B*, which permits it to slide up and down the central stem of the head without getting out of line. The compression spring which surrounds the central stem bears on a shoulder at the top and on the jig plate *A* at the bottom; its function is to return the jig plate to its extreme downward position. A collar on the end of the stem prevents the jig plate being pushed off the end. When twist drills with right hand twist are used the spindle of the drill press must be reversed. A bar, not shown, projects at right angles from the body and prevents it from turning with the work. Where the holes are spaced far enough from the center it is quite feasible, with a powerful drive, to make these heads with a larger number of spindles. The drill thrust is taken up by the ball bearings *C*. The drills are held by the headless setscrew *D* and driven by a slot in the spindle. The thrust of the driver is taken up by the ball bearing *E*. This head has been in use for a year and is giving good results.



NEAT MULTIPLE DRILL HEAD

Old Universal Hand Shaper

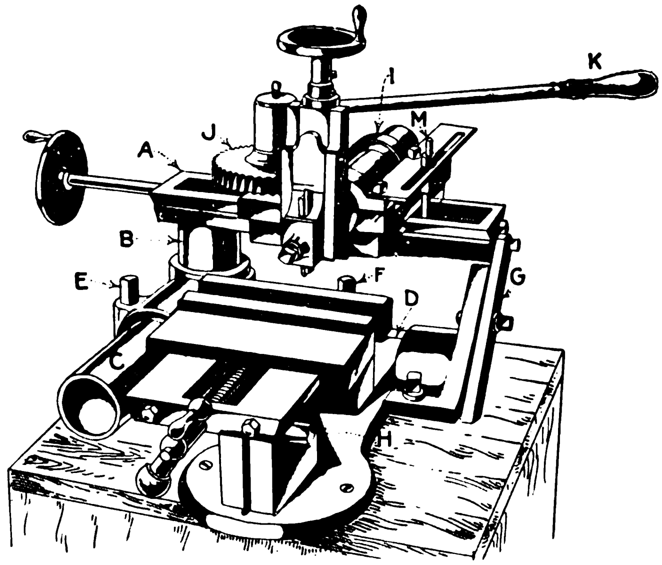
By C. O. Hyde

The hand shaper shown has been in use for a good many years and is now in the shop of the Spranger Rim and Wheel Co., Detroit, Mich. There is no nameplate on it to indicate the maker, but the simple ingenuity of the design is worthy of comment. There is practically no position or angle of stroke that cannot be obtained with it. Originally it was used in the making of steel stamps.

The basis of the various position adjustments is a series of round arms. The ram carriage is placed on a crossrail that is supported by a round arm *B*, set into a circular clamp in the end of the arm *C*. The clamping bolt is at the back and cannot be seen from the front, though its position will be readily understood. The arm *C* runs through a clamp in the end of the arm *D* and is locked by means of the bolt *E*. The arm *D* is run through a clamp on the back of the machine and is locked by the bolt *F*.

The brace *G* can be used to support the crossrail in the various positions, except when it is swung around on the arm *B*. The vise, too, is carried on a round support and may be swung around in a circle and locked in the different positions by the bolt *H*. The clapper block and vertical tool slide are carried on the end of a round arm *I*, which may be adjusted similarly to the other arms.

The ram is actuated by a gear *J* and a rack on the side of the ram slide, the hand-operating lever being shown at *K*. The crossrail feed is worked by the hand-



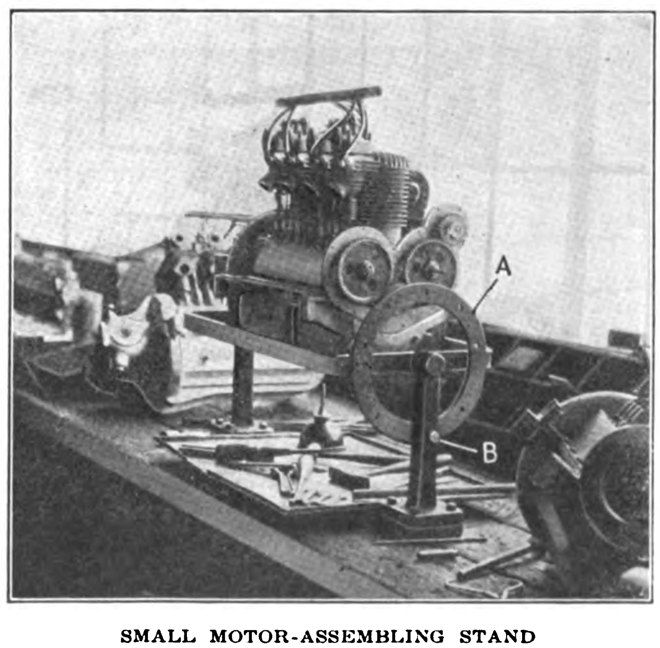
AN OLD UNIVERSAL HAND SHAPER

wheel *L*, or by the adjustable trip *M*, which operates an automatic feed in either direction. The whole machine is well made and in good condition, considering its long use.

Small Motor-Assembling Stand

By V. E. Mason

The bench stand shown is used in assembling Henderson motorcycle motors and is very simple and convenient. The upright brackets are made of cast iron, but the remainder is of heavy strap iron. Crosspieces hold the motor in place, so that it may be tilted in either direction, permitting easy access to all parts. It is held in different positions by the holes drilled in the circular end piece *A*, into which the pin *B* is inserted.



SMALL MOTOR-ASSEMBLING STAND

Drilling and Milling Work for Press Details

By Robert Mawson

SYNOPSIS—Owing to the fact that the number of these printing presses manufactured is comparatively small, many of the jigs used are designed to accommodate a number of different detail parts. The jigs are made with pin-headed binding screws so that the parts may be quickly placed in and removed from the tool.

The two-sheet rotary printing press made by the United Printing Machinery Co., Woonsocket, R. I., was illustrated and described on page 58. Some of the jigs and fixtures used in its manufacture were shown on pages 56, 138, 232, 318 and 408. In this article four other details used on the same press are taken as the subject, the tools, jigs and fixtures used for their machining being described.

By the application of pin-headed binding screws the necessity of using a wrench in the insertion and removal of work is obviated, while the rapidity with which the jigs can be operated is correspondingly increased.

For locating surfaces V-blocks are used where a circular contour obtains on the piece and stop pins are used in the case of flat surfaces.

The production of the jigs and fixture shown, in the drilling, milling and reaming operations, has met commercial requirements and the accuracy of the work indicates high-grade small-tool construction. The four parts machined are representative machine-shop products.

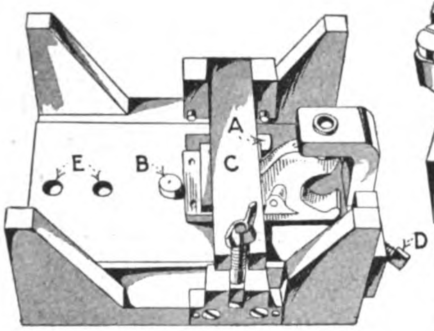


FIG. 2

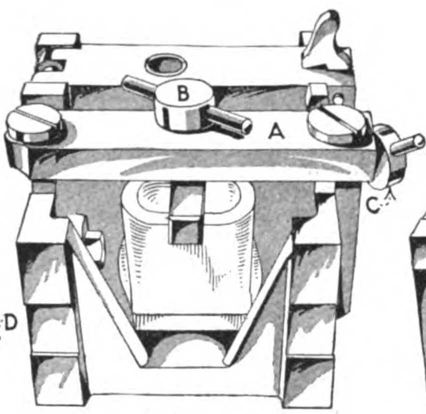

FIG. 4

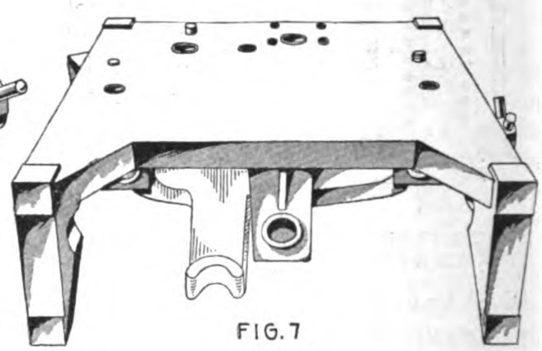

FIG. 7

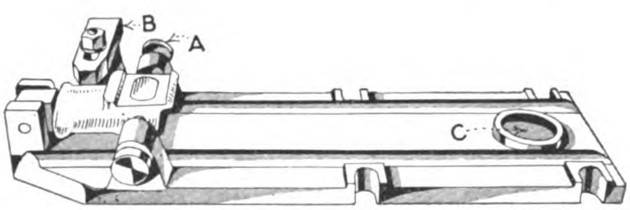

FIG. 5

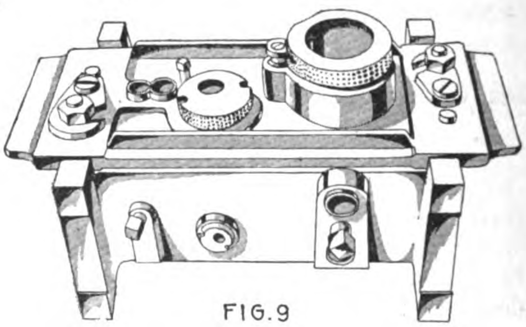

FIG. 9

JIGS AND FIXTURES USED IN MANUFACTURING A PRESS, WITH WORK SHOWN IN POSITION

FIGS. 2 AND 2-A

Operation—Drilling holes in jogger-blade support, Fig. 1. The rough casting is located by the steel plate A, pin B and the V-block in the cover C. The block in the cover and pressure on screw D hold the casting securely. This jig is used for several different parts. By changing the pin B into the holes E it is utilized as a locating surface.

Holes Machined—Four No. 19 drilled and one $\frac{11}{32}$-in. drilled. The latter hole is tapped with $\frac{3}{8}$-in. U.S.S. threads with the casting removed in a later operation.

FIGS. 4 AND 4-A

Operation — Drilling and reaming form-roller socket bracket, Fig. 3. The rough casting is placed in the jig and the cover A swung back. A clamp operated by the pin-headed screw B locates the part in one direction. The pin-headed screw C pushes the casting back against an adjustable screw, thus locating it in the other direction.

Holes Machined—One $\frac{1}{2}$-in. spot drilled and reamed, one $1\frac{31}{32}$-in. drilled and reamed $\frac{7}{8}$ in.

FIGS. 5 AND 5-A

Operation—Milling slot in form-roller socket bracket, Fig. 3. The casting is located on a $2\frac{7}{8}$-in. pin that fits into a reamed hole. Screw A and strap B hold the piece securely. The fixture is located on a plug in the miller table that fits into the hole C.

Surfaces Machined—Slot and sides, using a 3-in. end mill operating at 55 r.p.m. with a feed of 0.02 in. per revolution.

FIGS. 7 AND 7-A

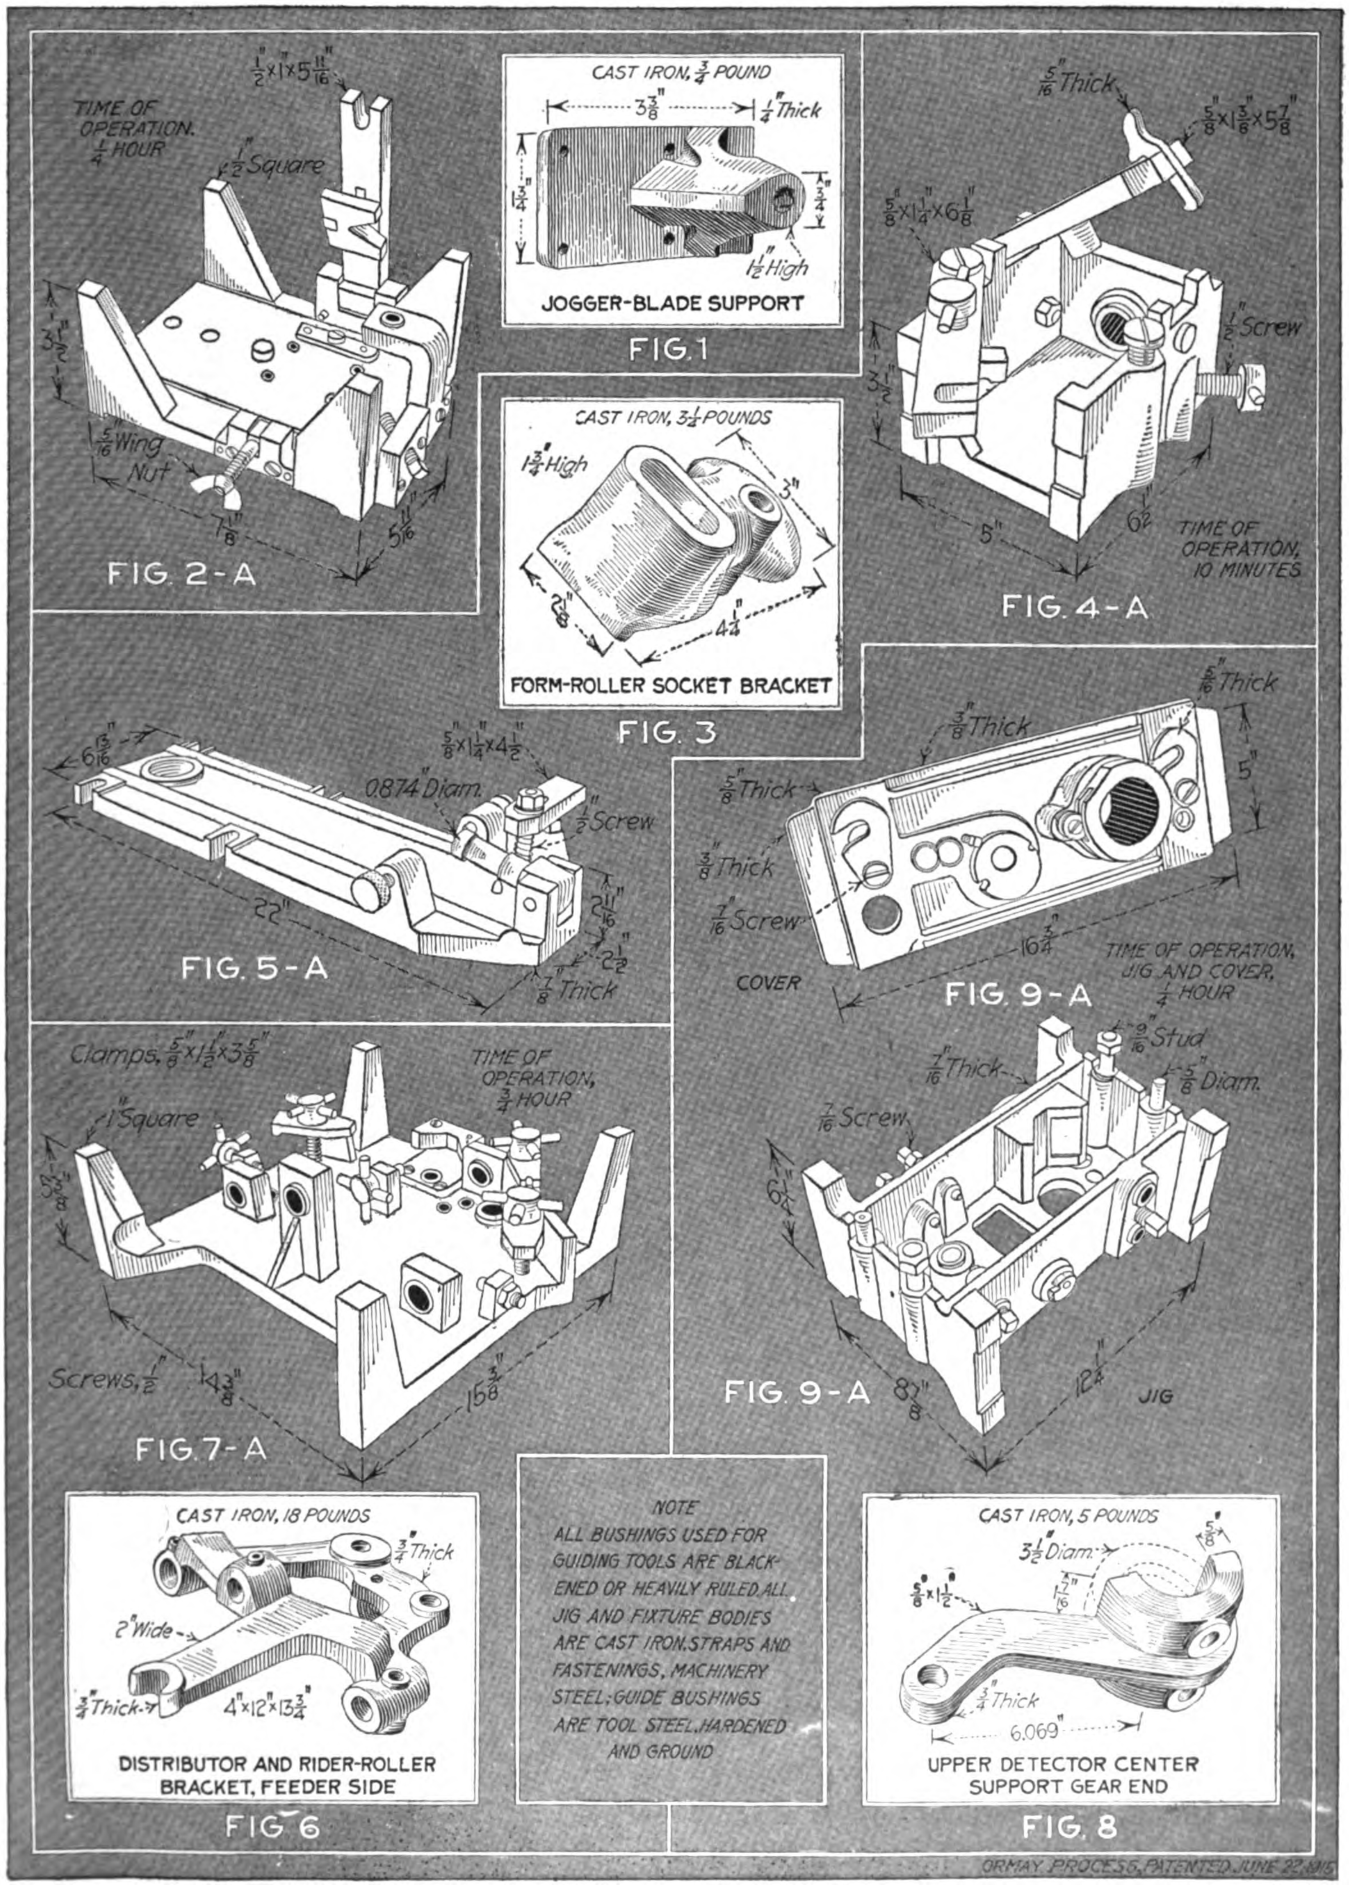
Operations—Drilling and reaming holes in distributor and rider roller bracket, Fig. 6. The milled casting is located against a V-block and an adjustable screw, being forced against them with pin-headed screws. Three straps are then tightened onto the piece to hold it securely. The jig is swung over, resting on four legs when drilling.

Holes Machined—Three $\frac{7}{8}$-in. spot drilled and reamed, two $\frac{1}{2}$-in. spot drilled and reamed, two $\frac{33}{64}$-in. drilled, one $\frac{5}{16}$-in. drilled. The $\frac{5}{16}$-in. hole is later tapped with $\frac{3}{8}$-in. U.S.S. threads with the piece removed from the jig.

FIGS. 9 AND 9-A

Operations—Drilling and reaming upper detector center support, Fig. 8. The casting is made with a tie-bar, as shown by the dotted lines. It is located in the jig by a V-block and adjustable screws being forced against them with setscrews. The cover is then dropped over the jig, located by dowels and held in place with swinging clamps.

Holes Machined—One $1\frac{63}{64}$-in. drilled and reamed 2 in., one $\frac{39}{64}$-in. drilled and reamed $\frac{5}{8}$ in., and two $\frac{1}{2}$-in. spot drilled and reamed. The other bushings shown in the jig are used in machining other details.



DETAILS OF JIGS AND FIXTURE USED IN PRESS MANUFACTURE

A Recessing Tool

By E. V. Allen

The Henderson Motorcycle Co., Detroit, Mich., uses on its machines a mechanical filter with a brass body that has a hole in it that must be bored and recessed, or chambered, a short distance from the outside. The holding jig and recessing tool are shown in working position in Fig. 1. The casting is clamped in the jig, and then the

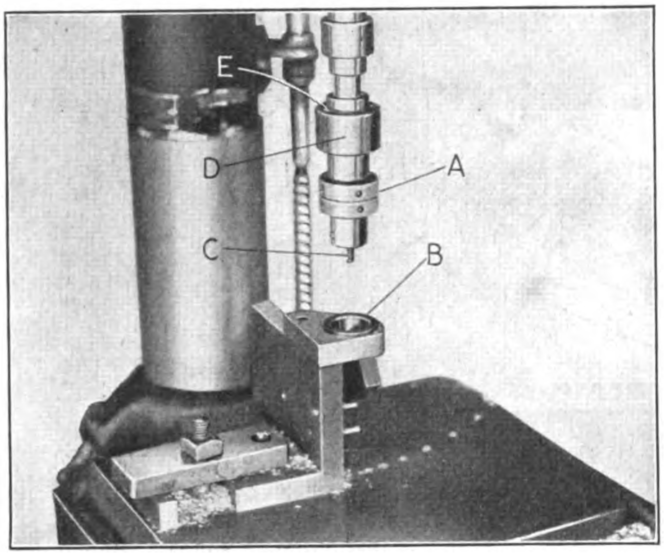


FIG. 1. RECESSING TOOL IN A DRILLING MACHINE

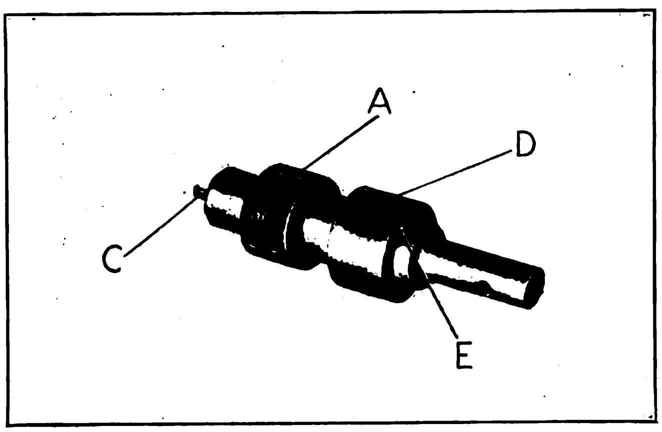

FIG. 2. THE RECESSING TOOL ALONE

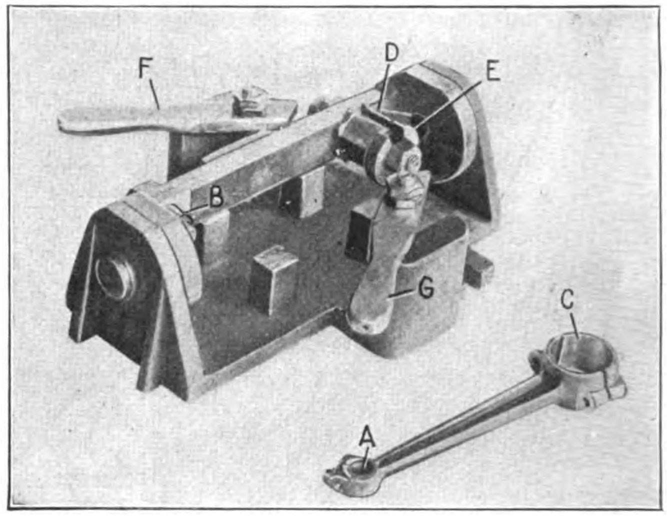
tool is run down until the adjustable collar stop *A* is in contact with the top of the bushing *B*. The hooked recessing cutter *C* is fed to the work by lifting the sleeve *D*, which forces the pin *E* inward and, through it, the end of the cutter outward.

The tool is shown out of the machine in Fig. 2, with the parts given the same letters. This view will give a good idea of the way the tool is made, as everything is shown except the pivoting of the cutter shank, which can easily be imagined.

Cap-Splitting Fixture

The Caille Perfection Motor Co., Detroit, Mich., makes a small portable boat motor for making any common rowboat into a motor boat. The number of these motors produced is of course not to be compared with the quantities produced by most of the automobile factories. For this reason the tools and jigs must be designed with a view to interchangeable production without too much expenditure.

The fixture used for splitting connecting-rod caps, here shown, is a good example. The connecting-rod is first bored and faced, then placed in the fixture with the hole



A CAP-SPLITTING FIXTURE

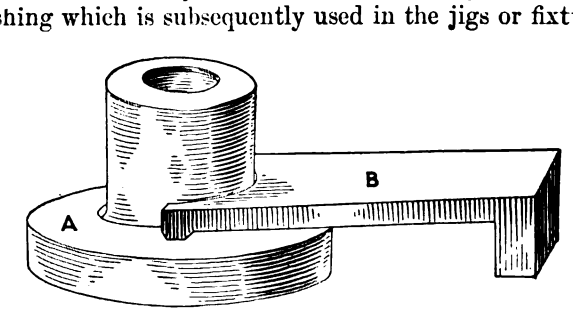
A over the pin *B* and with the hole *C* over the pin *D*. The slotted washer *E* makes the locking on of the connecting-rod an easy matter. One side of the cap is then cut through with a milling saw, the holding cradle being held down in position by the lever *F*. The cradle is next swung over on its trunnions and locked down by the lever *G*. This brings the other side of the cap upward, where the same saw can be used to split it off the connecting-rod.

A Simple Method of Locating Buttons for Tool Work

By J. H. Bondreau

The following method is good for jig and fixture work and should be of service in the tool room:

The buttons *A* are of tool steel—hardened and ground all over. Generally the holes are the body size of the bushing which is subsequently used in the jigs or fixtures.



LOCATING BUTTONS FOR JIG WORK

With the aid of the strap *B* the button can be located at any desired point and securely held while drilling and reaming the hole.

The buttons are especially handy when the size of the hole permits the use of interchangeable bushings for drilling and reaming small holes, as it can be done with the buttons clamped securely in position.

Manufacturing British 18-Pounder High-Explosive Shells--VI*

By E. A. Suverkrop

SYNOPSIS—In the final government inspection the shells are subjected to a very rigid examination. In it all the gages that have previously been used in the examination of the shells are again made use of. Besides gaging, the interior of the shell is examined to see that the surface is smooth and that the varnish entirely covers it. Then follow painting, packing and shipping.

Having passed the final inspection the shells are trucked to the painting department, which is in a separate building, shown in the illustration, Fig. 65, and also, in part, in Fig. 66, which gives a view of the boxing and shipping departments. Located in this same building and shown at A, Fig. 65, is a bank of cutting-off machines for cutting the bar stock into machining blanks for the 18-pounder high-explosive shells. Storage room is also provided here for the shell boxes and benches and for other facilities for packing and shipping the shells when they are finished. A spur line of track from the railway enters the building at one end.

The painting machines are very similar to those used in the shops of the Canadian Allis-Chalmers Co., with the exception that they are driven by friction cones mounted on shafts instead of being belt driven from small individual motors. The arrangement of the friction-driven painting machine is shown in Fig. 67. A single motor and a system of shafts and friction cones drive the six painting machines in this department. At A is a shaft that is driven from a small motor. At B are the friction cones, and at C, on the end of the vertical shaft from the friction cones B, is the painting machine, or turntable. A small vertical flange is provided on the upper surface of the turntable, to retain the shell and prevent it from being thrown off. The priming coat is white and is made up from the following ingredients in the proportions given:

Dry zinc oxide, free from lead, 9¾ lb.; boiled linseed oil, free from lead, 1¼ pints; terebene, free from lead, 1¼ pints; spirits of turpentine, 1½ pints. It is of the utmost importance that the ingredients employed in the manufacture of paints for high-explosives shells be entirely free from lead. The reason for this was given in the series of articles on the 4.5 high-explosive shell; but as that series may not be readily accessible, it is as well to reiterate the explanation here. Lyddite, with which these shells are loaded, is one of the explosives into the manufacture of which picric acid enters. Picric acid in combination with certain other elements, one of which is lead, forms what are called unstable compounds; that is, should the picric acid in the lyddite come in contact with lead in the paint, the resultant compound, picrate of lead, would be subject to spantaneous explosion.

The actual work of painting is done by boys in the following manner: Referring to Fig. 67, a boy takes a shell D from the truck tray and places it on the turntable C of the painting machine. The paint is applied with an ordinary flat brush E about 2 in. wide, which is dipped into the paint and traversed up and down over the body of the shell, which rotates with the turntable. Care is exercised to keep the paint from getting on the copper band and also to keep the film of paint from being too thick, as the painted shells must later pass through a ring gage.

As the boys finish the painting, others take the shells carefully and stand them on their noses on the bench F (shown at D, Fig. 65). When in this position, shown at G, Fig. 67, the bottom of the shell base is painted with the priming coat. Again the shells are carefully lifted, so as to remove as little of the paint as possible, and stood nose down, as shown at H, in the hot cupboard. The position of this cupboard is shown at E, Fig. 65. It is of wood, and at the bottom is a steam-heating coil. Above this are several sheet-steel shelves perforated so that the heat from the coil at the bottom can circulate freely through the whole cupboard. Each compartment will accommodate an entire series. The shells are stood in the cupboard as close as they will go without touching. They remain there till they are dry, which under normal conditions takes about an hour. The cupboards are provided with doors on both sides, so that the boys who put on the second coat of paint can take the shells direct from their own side.

The finish-painting department F, Fig. 65 shown also in Fig. 68, where the second coat is applied, is laid out in exactly the same manner and has the same equipment

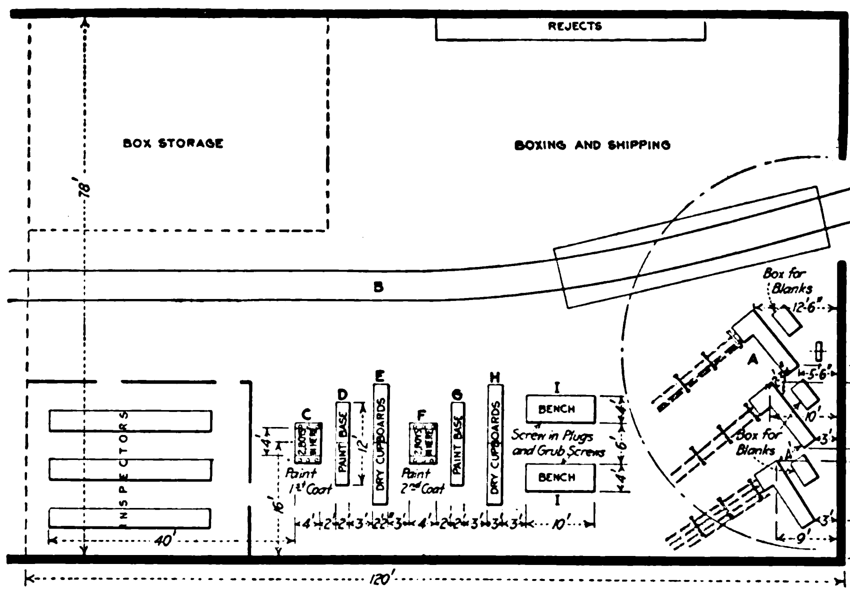


FIG. 65. NORTH END OF PAINTING AND SHIPPING DEPARTMENT

*Previous installments appeared on pages 1, 45, 145, 221 and 353.

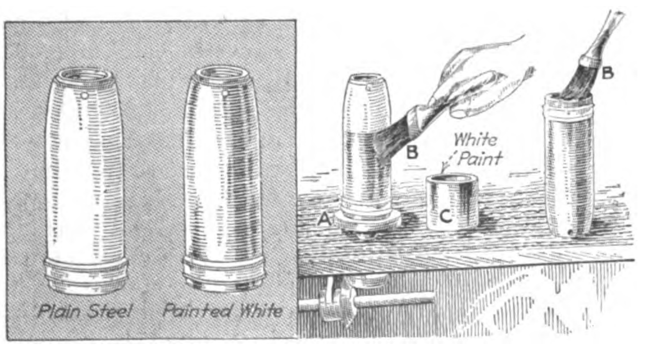
FIG. 66. BOXING AND SHIPPING DEPARTMENT FOR HIGH-EXPLOSIVE SHELLS

as the one shown at *C*, Figs. 65 and 67, for the first coat. The paint used for the second coat on the 18-pounder high-explosive shell is yellow. It consists of dry Oxford yellow stone ocher, 8½ lb.; boiled linseed oil, free from lead, 1¼ pints; terebene, free from lead, 2½ pints; spirits of surpentine, 1½ pints. It is applied in exactly the same way as the first coat, with this exception: The first-coated shells are taken by a boy, who places them on the turntable of the painting machine, as shown at *A*, Fig. 68. He then takes the gage *B*, which is made of steel; and hooking the end *C* over the top of the shell, he scribes two parallel lines an inch apart around the body of the shell, as shown at *D*. These lines are made by two pencils *E*, which go through holes in the long member of the gage *B*. After the yellow paint has been applied to the parts of the shell above and below the lines *D*, a band of green paint is applied between them. This green band of paint signifies that this is the 18-pounder *high-explosive* shell and not the 18-pounder *shrapnel*.

At *F* in Fig. 68 is shown a finished shell painted yellow, with the distinguishing green band *G* about the center of its length. At *H* are shown a number of finished-painted shells and at *I* the drying cupboard into which they will subsequently go. The bases of the shells are also painted with the second coat, which is applied in exactly the same manner as was the priming coat to this part of the shells.

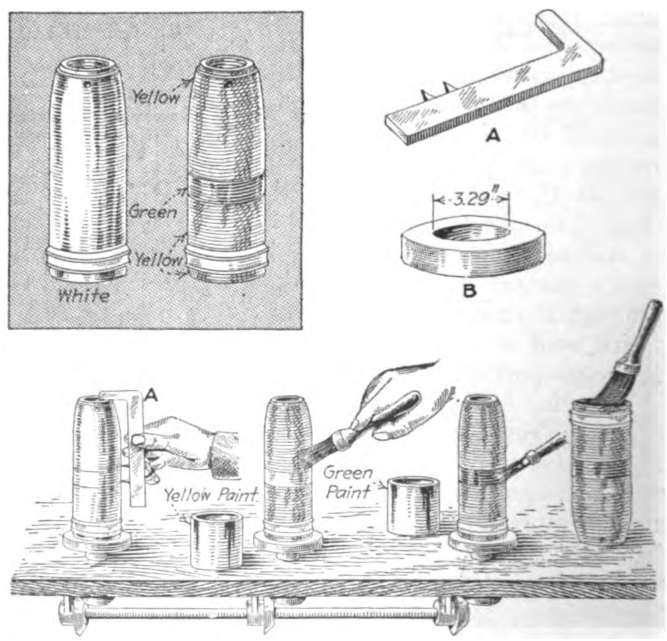
Six boys on first-coat painting will average 15 series in 10 hr.—that is, 2,750 shells in 10 hr., or approximately 46 shells per boy per hour. A record run was made by the 6 boys, and they succeeded in painting 247 shells (approximately a series) in 10 min., which would be equal to 247 shells per boy per hour.

On the second-coat painting, owing to the extra work necessary because of the green band, 8 boys are employed, and on this work the 8 boys will average the same as the 6 on the priming coat—15 series in 10 hr. A record



OPERATION 38: PAINTING THE PRIMING COAT

Machines Used—Motor-driven turntables A.
Tools and Accessories—Benches and drying cupboards; flat paint brush B; paint pot of white paint C.
Gages—None.
Production—Six boys, 15 series (2,750 shells) in 10 hr.
References—See Figs. 65 and 67.



OPERATION 39: FINISHING COAT AND GREEN BAND

Machines Used—The same as in operation 38.
Tools and Accessories—The same as in operation 38, except that the paint for the body is yellow and for the band green. A narrow brush is used for the band.
Gages—Gage A for position of the green band; ring gage B over painted body.
Production—Eight boys, 15 series (2,750 shells) in 10 hr.
References—See Figs. 65, 68 and 69.

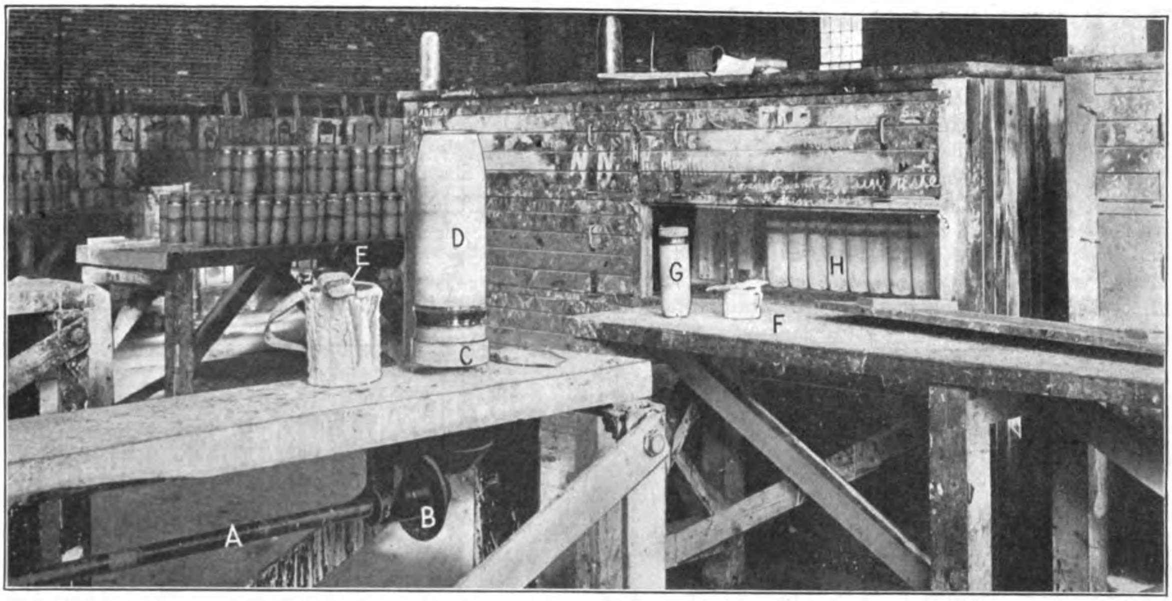


FIG. 67. PAINTING DEPARTMENT IN WHICH THE PRIMING COAT IS APPLIED

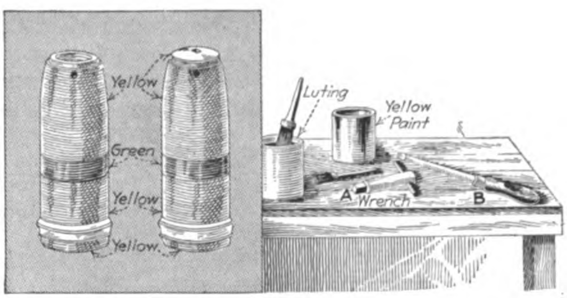
run was also made by the 8 boys on the second coat; they painted a series in 17 min., or about 105 shells per hour per boy. The drawing, Fig. 69, shows the official location of the green band on the shell body.

After the second coat is thoroughly dry, the shells are taken to the bench, *A*, Fig. 70, to have the plugs *B* and fixing screws *C* inserted. Formerly the caps, or plugs as they are also called, were made of brass; but with copper and zinc at their present prices (approximately 22c. per pound) this metal is too expensive. The object of the plug is merely to act as a stopper to retain the explosive and protect the nose and fuse-hole thread from injury. When the shell arrives at its destination, the artilleryman unscrews the plug and throws it away; he then screws the fuse in its place in the nose of the shell. Plugs are now made of cast iron; and to prevent their rusting, they are plated with zinc, copper or nickel. Two shapes of plugs are in common use; these are shown in Figs. 70 and 71, the one at *A*, Fig. 71, being the same as those shown at *B*, in Fig. 70. The one at *B*, Fig. 71, is fitted with a wooden gaine *C*. This wooden gaine fits a cylindrical recess in the lyddite explosive charge, which later accommodates the steel gaine that is screwed into the adapter in the fuse.

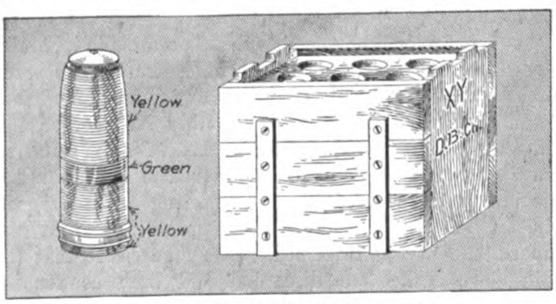
Before leaving the subject of wooden gaines, it will be well to recount some of the troubles experienced by the manufacturers of cast-iron plugs into which wooden gaines are to be fitted. These cast-iron plugs are bored, concentric with the thread on the outside, for the reception of the large end of the wooden gaine. The hole in the plug is about 1¼ in. in diameter, 1 in. deep. The large part of the gaine is required to be a snug push-fit in this hole. When the gaine is pushed to the bottom of the hole, a $\frac{3}{16}$-in. hole *D*, Fig. 71, is drilled through the plug and gaine at right angles to their axes and about ⅝ in. from the face of the plug. Into this hole a steel pin is driven, to prevent the gaine from being accidentally pulled out. The pin is made shorter than the diameter of the plug, so that, when driven into the hole, both of its ends are below the bottom of the thread on the outside of the plug. Obviously, if they were not, the plug could not be screwed into the fuse hole.

The wooden gaines are usually made of beechwood. After being turned on a back-knife lathe, they are given



OPERATION 40: LUTE AND SCREW IN PLUGS AND FIXING SCREWS AND PAINT THE PLUG

Machines Used—None.
Tools and Accessories—Square-end wrench A; screwdriver B; luting and yellow paint; paint brush; luting brush.
Gages—None.
Production—See operation 41, as this is a part of that operation.
References—See Figs. 70 and 71.



OPERATION 41: PACK AND SHIP

Machines Used—None.
Tools and Accessories—Cases holding six shells each; screwdriver.
Gages—None.
Production—Twenty men can screw in plugs and fixing screws, paint tops of plugs, put in cases 3,220 shells and screw down the case lids ready for shipping. This work is under the supervision of a man from the Canadian Inspection Co.
References—See Figs. 66, 70 and 71.

a coat of shellac varnish, as required by the specifications. Unfortunately, a great number of the manufacturers of wooden gaines did not appreciate that there is considerable difference between making wooden gaines and turning wooden tenpins for children. They did not realize that the wood for gaines should be well seasoned and absolutely dry; that after turning, it should not merely be given a coat of varnish, but should be thoroughly impregnated with some substance that would make it absolutely impervious to moisture. Wood that is not protected in this manner will shrink or swell with every change in the atmosphere, but the hole in the cast-iron plug into which the gaine is fitted does not alter. The experience of one manufacturer of cast-iron plugs may be of interest.

The weather, just before the reception of the wooden gaines, had been very wet for several days. When the inspectors went over the gaines with a standard plug, it was found that only a small percentage were small enough to enter the hole in the plug and that there were none too small to pass inspection. The plugs that failed to go into the hole in the standard plug and were therefore too large were put into a bag under the bench at the close of the day. Beneath this same bench, but against the wall, was a steam coil that was kept hot all night, so that the shop would be warm for the boys in the morning.

The next morning one of the inspectors accidentally picked up one of the rejected gaines from the bag of discards below the bench, tried it in a plug and found that it was a good fit. He then tried another and another, and all of them either fitted or were too small for the standard plug. He then tackled the inspector who had discarded the plugs and accused him of rejecting perfectly good plugs. The fuss assumed such proportions that the superintendent was informed. One man swore that the gaines which he had discarded had been condemned because they were "a mile" too big. He said the other inspector had mixed the bags so as to get him "in bad." The other one was just as positive that he had not mixed the bags, but had accidentally discovered that the first inspector did not know enough to push a perfectly fitting gaine in the hole in the standard plug. And to prove his words, this inspector took one of the gaines from the bag, pushed it into the standard, and handed it to the superintendent.

On the bench near them was a small pool of soda water, where one of the machine hands had been filling a squirt can. The superintendent drew the gaine out of the plug and, without being observed by the inspectors, stood it large end down in the pool of soda water. While it stood there for a couple of minutes, he talked to them about their differences. When the gaine had had time to soak in some of the water, he picked it up, wiped it with his hand and asked the man who had previously pushed it into the plug to do so again. But it had swelled so much in the two minutes it had been in the water that it would not go in. I have in my possession one of these gaines. It was far too large to go into the plug when I first got it, but is now $\frac{3}{32}$ in. smaller than the hole in the plug. Half a minute in water at any time will swell it so that it is too large to enter the hole in the plug.

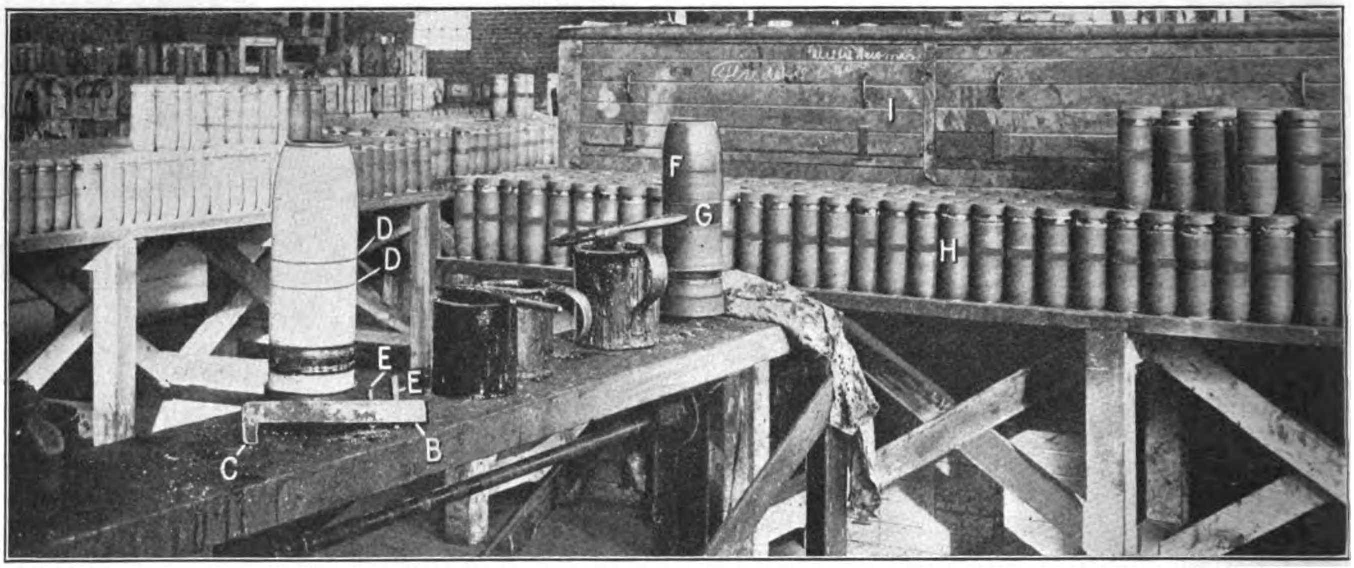


FIG. 68. THE SECOND-COAT PAINTING DEPARTMENT FOR APPLYING IDENTIFYING FINISH

The small grub screws in the nose of the shell are called fixing screws. They are $\frac{1}{4}$ in. in diameter, and their function is to hold the plug from turning and to prevent its being lost. After the plug is removed and the fuse screwed into the nose of the shell, the fixing screw is tightened down on it. It may be necessary to have a fixing screw for the plug, although even that is doubtful; but it is difficult to imagine the necessity for a fixing screw for the fuse. The fuse screws into the nose with a right-hand thread, the rifling of the barrel is right hand, and all the forces at and after the moment of discharge would tend to screw the fuse tighter into its seat in the nose of the shell.

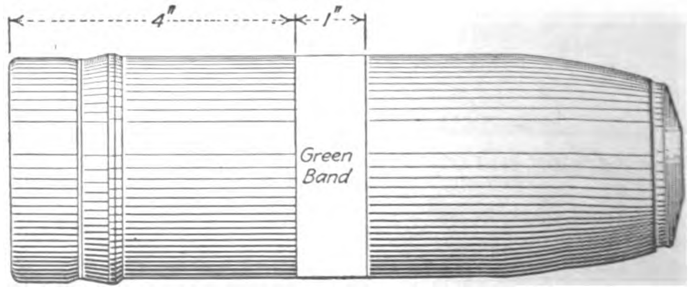

FIG. 69. LOCATION OF GREEN BAND

The plugs are screwed in with the wrench *D*, Fig. 70, which fits a square hole in them. The grub screws are put in with a screwdriver. There is a leather washer *E*, Fig. 71, between the nose of the shell and the flange of the plug. Both the fixing screws and the plugs are luted with the Government luting compound.

The luting consists of 80 parts of whiting and 21 parts of oil, both by weight, kept fluid by heating. The materials must be of the finest quality. The oil is 20 parts vaseline and 1 part castor oil, well mixed before it it added to the whiting. The vaseline is to be a genuine mineral-oil residue, without any foreign mixture. It should have a flash point not below 400 deg. F., a melting point not below 86 deg. F. and be free from solid mineral matter. The castor oil must be genuine. The whiting is to be of the quality known as "Town Whiting" and is to be free from moisture.

The luting must be thoroughly mixed, plastic and free from lumps. If on examination of a sample of 10 per cent. of the invoice, it is found that the sample does not comply with the specification, all the material invoices will be rejected without further examination. The luting may be inspected during the manufacture by, and after delivery will be subjected to test and to the final approval of, the chief inspector, Royal Arsenal, Woolwich, or an officer deputed by him.

With the plugs luted and screwed home and the fixing screws set up tight, the shells are ready to pack. A good idea of what the shell boxes are like can be had by referring to Fig. 70. At *E* is shown a box already packed and closed for shipping. It will be noticed that the letters VJ appear on the front near the lid. This is the series symbol; that is to say, six shells of series VJ are in the box. Below this symbol is D. B. Co., signifying the manufacturer—the Dominion Bridge Co.

The upper box has the shells in it, but the cover for it is at *F*. The two daubs of black paint on the face of this box show that it has been used twice before and that two series symbols have been painted out. In the bottom of each box is a board similar to that shown at *G*, except that the board for the bottom of the box has holes in it of sufficient size to accommodate the bases of the shells. The holes in *G* are coned to fit the noses of the shells. At *H* are shown the heavy steel straps on the boxes. As six shells are packed in each box, it takes 41 boxes to accommodate a series of 250 shells, leaving four shells over, which have to be taken care of in subsequent series. After the boxes are filled with shells, one of the Canadian Inspection Co.'s men superintends the screwing down of the lids.

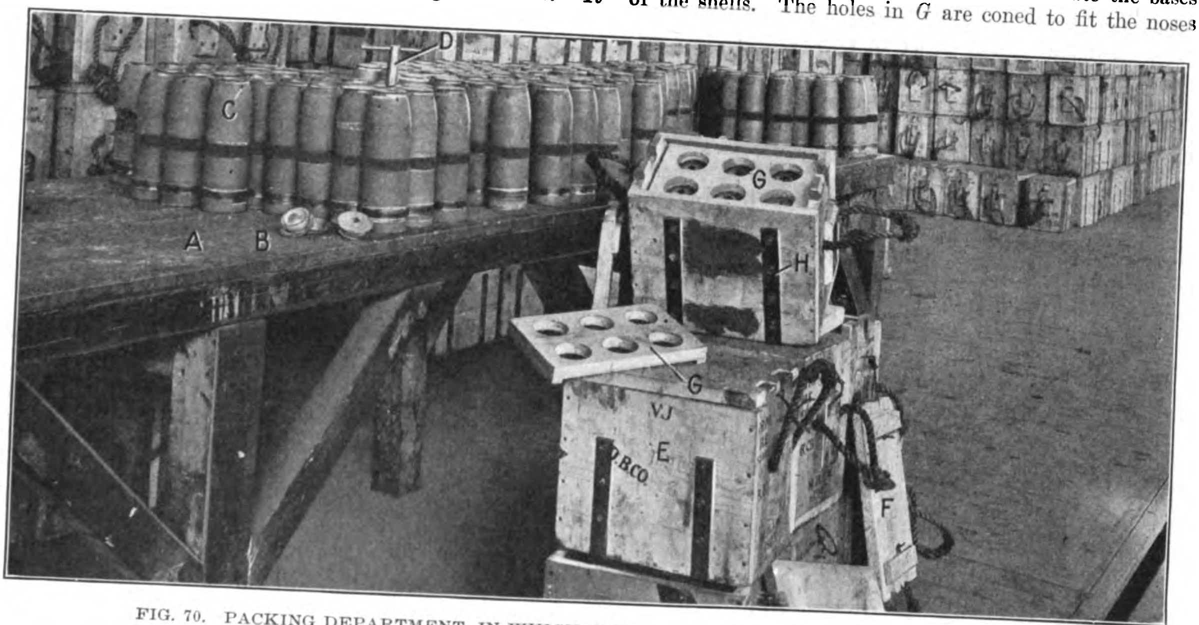

FIG. 70. PACKING DEPARTMENT, IN WHICH PLUGS AND GRUB SCREWS ARE ASSEMBLED

Each shell box lid is held down by four screws. The work of preparing the shells for packing (by screwing in the plugs and fixing screws, painting the tops of the plugs, putting the shells in the boxes and screwing down the lids) is done by a gang of men, the number varying with the amount of work going through the shop at the time. A statement of actual performance will, however, aid the reader in forming an idea of the time necessary to do the work. On an occasion when 20 men were engaged on the work, 3,220 shells were packed ready for shipping in 5 hr., equal to 32 shells per hour per man.

When the lids are screwed down, the boxes are loaded in cars. This work is also done under the supervision of one of the Canadian Inspection Co.'s men. The ordinary box-car holds 540 boxes, each containing six 18-pounder shells.

In conclusion I would like to say a few words regarding two elements which have been of vital importance to the smooth working of shell production in this shop.

There is splendid team work on the parts of the officials and the employees of the company, and real coöperation

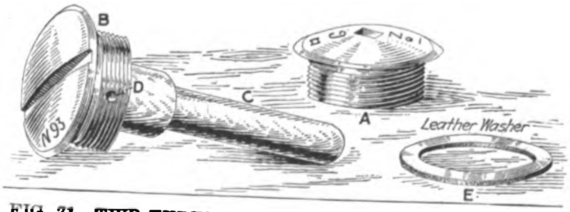

FIG. 71. TWO TYPES OF PLUGS AND A WOODEN GAINE

One is also favorably impressed by the absence of friction between the works representatives and the Government inspectors.

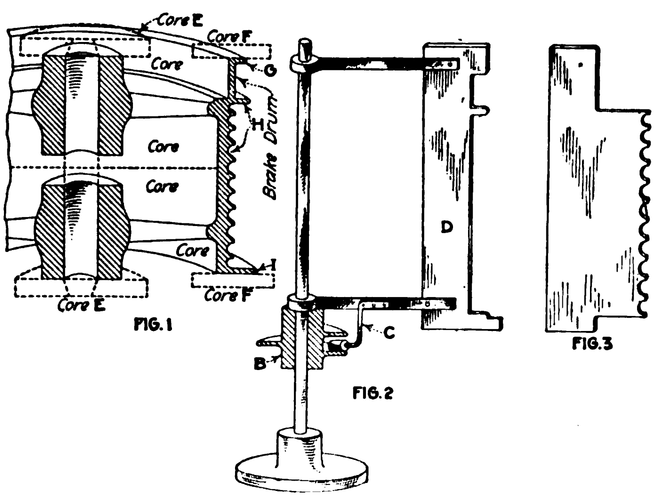
Loam Sand Mold for Winding Drum with Grooves

By Alfred W. Cookson

An interesting problem that will perhaps present difficulties to the average foreman will be found in molding a winding drum for a hoisting machine, with grooves to retain the rope in proper position.

A sectional view of such a casting is shown in Fig. 1. The rope grooves are in the form of a screw thread on the surface of the drum. The center stake is set in the usual way, but care must be taken to set it solid and true. In place of the collar ordinarily employed to support the sweep arm a casting *B*, Fig. 2, is used, and a roller and the arm *C* are provided. The casting *B* is a hub of suitable diameter and length, with a projection in the form of a screw thread, cast on the outer surface at right angles to the center line.

This projection must be of the same pitch as the required pitch of the grooves on the drum. The casting



METHOD OF MOLDING A WINDING DRUM

shown is bolted to the center stake in its proper position at the beginning of the job, and the projections must form a path for the roller for one complete revolution plus about 20 deg. A stop must be provided at each end, to keep the roller from running off the end of the screw thread, or cam, but still letting it go far enough to overlap the starting point of the sweep and make a smooth job.

Considering the mold as built up in the usual way and ready to sweep up, the sweep shown at *D* in Fig. 2 is attached, and all parts are swept, except the diameter where the grooves are to be.

The sweep, shown in Fig. 3, is then attached in such position that the first groove on the sweep will be at the point where the rope end will fasten to the drum, and the roller at one or other of the stops on the cam.

Observe that Fig. 1 shows the bottom diameter of the brake drum larger than the rope drum. This is the usual practice; but if a casting must be made with this part smaller than the brake drum, an additional sweep will be required to finish this part after the grooves have been finished and the second sweep removed.

One complete revolution of the groove sweep will finish up the complete screw thread on the drum mold, but care must be used both in making and setting this sweep, or the grooves will not match.

The arms and shaft bosses are made in cores, and a sweep will have to be provided to set them. A core box for one-half of one arm is all that will be necessary, this being made with a joint between the arms—six cores to the circle for a six-arm drum and eight cores for an eight-arm drum.

The cores must be made of the proper depth to be placed one above the other and make the hubs the correct length. A core *E*, Fig. 1, must be provided to support the upper and lower ends of the hub core. If the hub projects outside the rim of the drum, it will be necessary to set a ring core *F*, Fig. 1, under the flange, both top and bottom. If the flanges *G*, *H* and *I*, Fig. 1, are high enough to make it unsafe to form them on the sweep, patterns can be made and placed in the mold; but it must be remembered that they draw in and that the joints will have to be cut to allow for this.

Safety in the Pattern Shop

By J. J. Eyre

In these days, when "Safety First" is the watchword heard everywhere, it behooves the wise pattern maker or machine woodworker to look over his department.

Are the circular saws kept sharp, or are they allowed to be used until it requires a man's strength to push a board through and at the same time hold it down on the table? Does the saw gage clear, or does it bind the work against the back of the saw in pushing the saw across? I have seen serious accidents, which could have been avoided, result from the neglect of these two things.

Are the new safety (?) cylinder heads on the planer properly cleaned in the knife seat when the knives are changed? I have seen the heads of several of the screws broken off and the cap and knife thrown against the planer bed (which fortunately saved the workman), because the seat was not clean when the knife was tightened in place. Hardwood chips were packed between the joints, forcing the knife up and breaking the screws.

Realizing the danger of workmen slipping while pushing a piece of work over the machine, I recommended the placing of rubber mats 1/4 in. thick by 2x4 ft. at all planers and saws in the department.

I also had safety cylinder heads put on all the planers. They were a decided improvement over the old square heads, but I found that they were not foolproof. One day my machine man, while putting new knives in the planer, was called away, and before leaving neglected to tighten the bolts on one of the blades. A workman started the machine, and immediately that 24-in. blade entered upon a rapid journey—in sections. Fortunately, no one was hurt. I might have been justified in discharging the machine man; but he was a conscientious workman, and I felt that we had both learned the need of being more careful.

One of my boys, who had the knack of acquiring things, came in one morning with several "Safety First" and "Watch Your Step" stickers. I do not know what he intended to do with them, but I persuaded him to change the wording to "Watch Your Paws" and shellacked the stickers on the saws in a prominent place.

Some Recent Developments in Tool-Steel Testing--II*

By Edward G. Herbert†

SYNOPSIS—The experiments and results of Captain Denis, of the French artillery, are discussed. Curves are shown giving important relationships between cutting speed, metal removed, hardness and toughness, and temperature. Tests on stellite are also described.

The other investigator whose work bears directly on the subject of tool durability is Capt. M. Denis, of the French artillery. Captain Denis carried out his experiments at the Puteaux arsenal, where a tool-steel testing machine is installed. He has described his work in a remarkable article contributed to the *Revue de Metallurgie* of January, 1914. It is possible to give here only a brief résumé of this work.

The task Captain Denis set himself was to establish exact relations between the testing-machine conditions and those of the workshop, so that it should be possible after making a speed curve on the tesing machine to predict with certainty the behavior of a given tool steel under any combination of workshop conditions—cut, speed, etc.—when cutting any class of material, hard or soft steel, cast iron, bronze, etc. It should also be possible to say with certainty what speed would give the longest life to the tool, what speed would give the greatest output per hour and how many cubic centimeters of metal the tool would remove under any particular set of working conditions before becoming so blunt as to require sharpening. This task Captain Denis claims to have accomplished after his extended analyses and comprehensive series of tests.

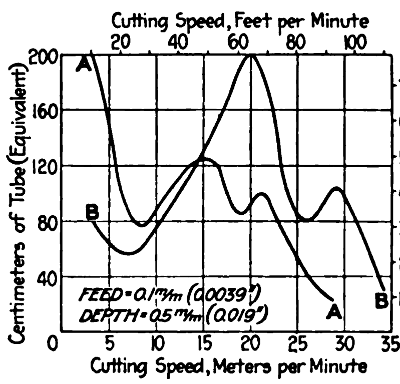


FIG. 7. LATHE TESTS
A = carbon steel; B = H. S. steel

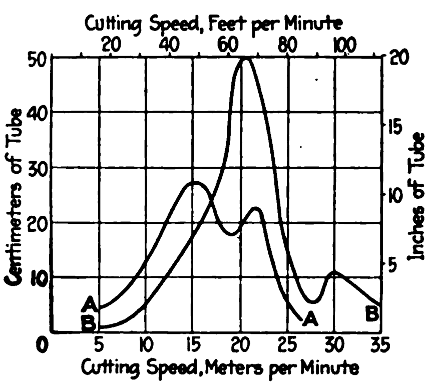

FIG. 8. TESTING MACHINE TESTS
A = carbon steel; B = H. S. steel

Of the actual procedure adopted in carrying out the experiments we have rather scanty particulars. The tests were made on a single-pulley lathe having 8 speeds and 30 feeds. The cutting was done dry and was apparently continued until the tool failed. The durability of the tool was measured by the amount of work done and not by the duration in time. In this respect the tests correspond with those made by Professor Poliakoff and those on the testing machine, but differ from the well-known tests made by Mr. Taylor and other experimenters, who have measured the durability of their tools in time and not in output of work.

It is important to keep this difference in view when making comparisons, since the results of the two methods of measuring durability are very different, though mutually convertible by calculation. Thus, two tools that failed after doing exactly equal amounts of work—the one at 30 ft. and the other at 60 ft. per min.—would, according to Captain Denis' method, be accounted equal in durability, since their output was the same.

According to the time-durability method the former would be accounted twice as durable as the latter, since the work, being done at half the speed, would naturally take twice as long. The adoption of either method is merely a matter of convenience, though in actual practice it is perhaps not always realized that a speed which wears out the tool quickly is more economical than a slower speed which gives the tool a longer life, but accomplishes only the same amount of work between each grinding. From this point of view the measurement of durability by output rather than by time has much in its favor.

The first step in Captain Denis' investigation was to make speed-durability curves from the same tool, first in the lathe, then in the testing machine. The lathe tests were made on a bar of steel of 156,000 lb. per sq.in. tensile strength, very homogeneous and heat-treated by quenching in water at 825 deg. and tempering. The feed was 0.1 mm. per revolution and the depth of cut 0.5 mm., giving a chip area approximately equal to that of the standard cut on the testing machine. A square-nose tool was used, having a cutting angle of 75 deg. and a clearance of 6 deg. The cutting was done dry.

The speed durability curves produced on the lathe are given in Fig. 7, in which *A* is the curve of a carbon steel and *B* that of a high-speed steel. The same steels were then tested on the testing machine under standard conditions. The machine was one of the original type (it has since been brought up to date), and water was used.

The resulting curves are given in Fig. 8. A comparison of the two sets of curves shows a remarkable similarity and important difference. The lathe tests show a decline in durability as the speed was raised from 3 to 7.5 m. per min., this feature being entirely absent from the testing-machine results.

Particular interest attaches to this falling durability at very low speeds, because it corresponds with results that the present writer obtained when investigating the variations of hardness and toughness of hardened tool steel at varying temperatures, the investigation being made by breaking specimens of steel supported on knife-edges in an oil bath. The experiments were described in the *American Machinist* ("Influence of Heat on Hardened Tool Steel"), Vol. 37, page 47, and two of the resulting

*Previous installment appeared on page 419.
†Director, Edward G. Herbert, Ltd., Manchester, Eng.

curves are reproduced in Figs. 9 and 10. In each case there was a decline in the calculated durability (hardness and toughness) between the temperatures of 20 and 70 deg. Every attempt to confirm this fall in durability at low cutting temperatures by cutting tests on the testing machine has failed, but the cutting test on the lathe shows it quite clearly.

To return to Captain Denis' experiments. Having made speed-durability curves from the same steel on the testing machine and on the lathe, the material and the area of cut being practically the same, and having found that the form of curve produced was almost identical, his next step was to make a series of lathe tests on a different material with a much heavier cut. The material chosen was an ordinary mild steel of 42 kg. (60,000 lb. per sq.in.) tensile strength, and the cut was 0.5x5 mm. bronze. Some of the resulting curves are given in Figs. 11 to 15. All these curves were made from lathe tests using a feed of 0.5 mm. and a depth of cut of 5 mm. In each case the points of maximum and minimum durability were compared with the corresponding points on the testing-machine curve. Fig. 8 and a diagram of correspondence were constructed as before, from which it was possible to find the lathe speed corresponding to any testing-machine speed for each of the 12 materials tested on the lathe. This diagram of correspondence is given in Fig. 16 and is intended to be used under practical conditions as follows:

Suppose it is required to find what speed will give maximum durability to a given tool when cutting gun metal of Brinell hardness 170. The tool, or a sample of the same steel similarly hardened, is tested on the tool-

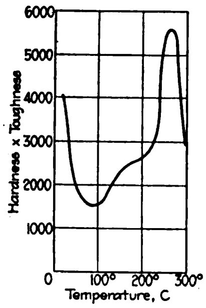

FIG. 9. BREAKING TESTS—CAR. STEEL

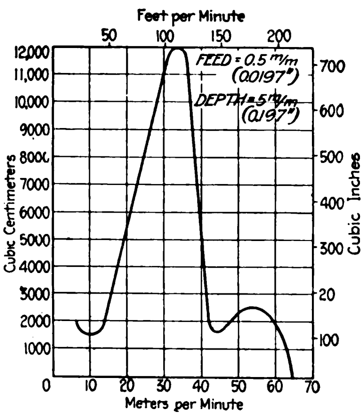

FIG. 14. LATHE TESTS ON CAST IRON

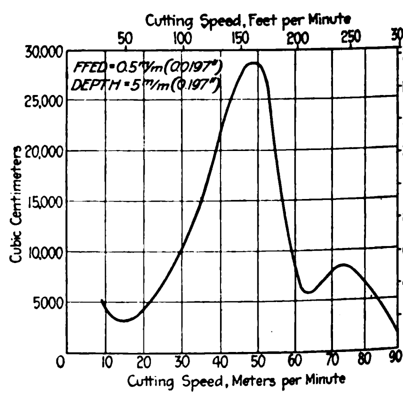

FIG. 15. LATHE TESTS ON BRONZE

(about 1/50 feed and $\frac{3}{16}$ in. depth of cut). The speed-durability curve produced is given in Fig. 11.

It is similar in form to that produced on the testing machine (Fig. 8), but the corresponding peaks and hollows occur at considerably higher speeds. Thus the first maximum occurs at 26 m. on the lathe and at 20 m. on the testing machine. By comparing the points of maximum and minimum durability on the two curves he was able to construct a diagram of correspondence, or double scale of speeds, from which he could read off the lathe speeds corresponding to any testing-machine speed.

The same process was gone through with lathe tests on steel bars of various compositions (the tensile strengths being 60, 70, 85, 105 and 115 kg. per sq.mm.), a nickel steel, various qualities of cast iron and three kinds of steel testing machine, and the speed that produces maximum durability is observed. This speed, say 22 m. per min., is found on the scale at the bottom of the diagram. A vertical line is drawn from this point, cutting the diagonal line for gun metal at point A. A horizontal line is drawn through A, cutting the vertical scale at 38. Then 38 m. per min. is the speed that will give this particular tool its maximum durability when cutting gun metal with a feed of 0.5 mm. and depth of cut 5 mm. Thus the diagram serves to connect the standard cutting conditions of the testing machine with the standard cutting conditions adopted for the lathe tests (feed 0.5 mm., depth 5 mm.), and it only remains to find a connection between these standard lathe conditions and any set of cutting conditions.

This problem was already solved by the "cube law of cutting speed." According to this law, "For constant durability the cutting speed varies inversely as the cube root of the product of feed by area of cut"

$$\left(V_2 = V_1 \sqrt[3]{\frac{f'a'}{f_2 a_2}}\right)$$

This law was discovered and published by me in 1909 and appeared in the *American Machinist* ("Relation of Cutting Speed, Feed, Depth of Cut"), Vol. 32, Part I, page 1063. Several investigators claim to have subsequently arrived at it independently, and it has been verified and

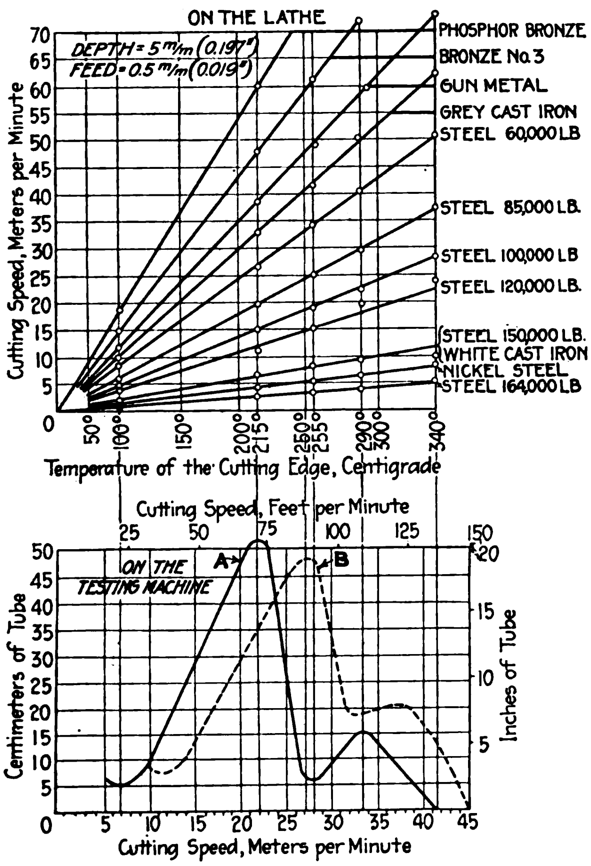

FIG. 16. DIAGRAM OF CORRESPONDENCE

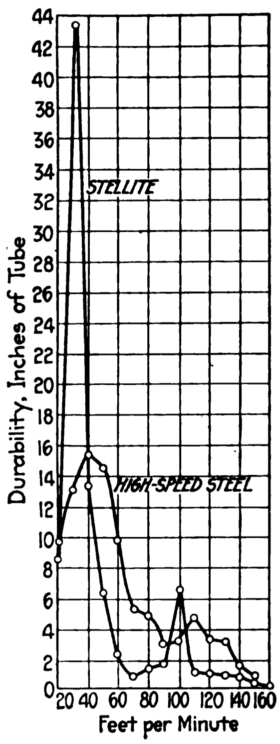

FIG. 17. MACHINE TESTS

fully established by the results of many carefully conducted experiments carried out by eminent experts from Fred Taylor onward.

Captain Denis has used the cube law as the final link between the testing machine and the diverse cutting conditions of the workshop, and in order to facilitate its application he has embodied it in an ingenious slide rule that is now manufactured by Messrs. Huré, of Paris. By the use of this instrument it is a simple matter to find the correct cutting speed for any feed and depth of cut, when once the correct speed for the standard cut has been found by the process described.

This résumé does not by any means exhaust Captain Denis' article. He has worked out an elaborate set of tables and diagrams for finding from a preliminary test on the testing machine, not only the volume of any class of material that a given tool will remove under any combination of cutting conditions and the length of time it will continue cutting before it requires grinding, but also the most economical speed to employ, having regard to the calculated time durability of the tool and the time occupied in sharpening it. Of these elaborations it must suffice to say here that they are based on reasoning which is as logical as it is ingenious and that the results arrived at appear to be in accordance with one's experience of tools in practice. The article will repay careful study in the original (it is of course written in French), but it appears to be open to criticism under two heads:

First, as to the experimental basis of the whole investigation: Captain Denis would have inspired greater confidence in the remarkable results set forth, if he had vouchsafed a more detailed account of the manner in which the tests were carried out. For instance, the number of critical speeds indicated in his numerous speed-durability curves is more than 30. A critical speed is one at which a definite peak or hollow occurs in the curve, and obviously, tests must have been made at these 30 speeds and probably a great many more; but there is nothing to indicate how these speeds were obtained on a single-pulley lathe having 8 speeds. Of course, they could easily be obtained by using bars of different diameters, or the lathe may have been driven by a variable-speed motor; but no information is given on this point.

Again, the curves in Figs. 11 to 15 and many others not here reproduced are all of an extraordinarily uniform character. Experiments on the testing machine have shown that a given tool does not usually produce the same shape of curve when tested on such different materials as semihard steel and brass, yet Captain Denis shows a long series of curves produced on the lathe on materials ranging from semihard steel to cast iron, mild steel and brass; and all these curves are almost exactly similar in shape to the curve produced on the special steel tube in the testing machine. The questions present themselves: How many observations were made for each of these curves? Did the results all lie on the curve; and if not, what degree of divergence was experienced? The value of the results depends absolutely on the correctness of the experimental methods employed, but of these we are given no account.

Another criticism relates to the utility of the elaborate diagrams and tables for calculating the correct cutting speed for any particular work. The importance of a knowledge of correct cutting speeds is beyond question. The process by which Captain Denis proposes to find it is, first, to make a speed curve of the tool steel on the testing machine (this involves making tests at 10 or 15 different speeds); second, to observe which of these speeds gives the best durability and to find by means of the diagram of correspondence, Fig. 16, the corresponding speed for a lathe tool cutting dry with 0.5 mm. feed and 5 mm. depth of cut on the kind of material that is to be machined; third, by means of the special slide rule or the cube formula to find the corresponding speed for the traverse and cut that it is proposed to use.

The workman will then set his lathe to the nearest speed available and go ahead. He will be working under

ideal conditions, if his tool is tempered exactly like the specimen used for the speed curve, if his tool angles are the same as those used by Captain Denis in his lathe tests, if he is cutting dry (as Captain Denis did) and if the material he is cutting is exactly similar to that used by Captain Denis. If there is a variation in any one of these factors, his speed will be wrong and he will have to reduce or increase it according to the behavior of his tool. In short, he will have to set his speed at last by observing how his tool stands up to the work in hand, as he would have done if no preliminary tests had been made.

This criticism does not imply that Captain Denis' work is of no value. On the contrary, his work is of great practical value; but it may be questioned whether he has not mistaken the true function of the testing machine, or at least laid undue stress on a function that it can hardly perform, owing to the great number of variable factors involved in fixing the correct speed of a given tool on a given job.

The chief utility of the testing machine is in comparing the cutting qualities of various steels, or of the same steel subjected to various hardening processes. We may, for instance, require two tool steels—one for the rapid removal of stock with heavy cuts and the highest possible cutting speed and the other for form tools that must keep their edge for a long time under comparatively light cuts at moderate speeds. A comparison of a series of speed curves will show that one steel, hardened in a particular way, has a very high, and a wide range of, durability under "blue-chip" or "red-hot chip" conditions. This steel will be chosen for heavy roughing work. Another steel, differently hardened, produces a speed curve showing exceptional durability under low-temperature cutting conditions. This is the steel for a forming and finishing tool.

In making such investigations Captain Denis' work will be most useful, since it enables us, working backward from any representative workshop cut and speed, to find the corresponding testing-machine speed and to select a steel that gives a high, and a wide range of, durability in that part of its speed curve.

Tests on Stellite Cutting Tools

A recent example of the use of the testing machine may be of interest—the testing of stellite. Particular interest attaches to this material, because it contains no iron; and it might be anticipated that its speed curve would show some characteristic feature peculiar to itself and that some of the features common to all kinds of tool steel would be absent from the stellite curve.

Fig. 17 reproduces a curve taken from a stellite tool and one from a very good quality of high-speed steel. Contrary to expectation, the general form of the curve is the same in each case. In particular the rise in durability as the speed increases from 20 ft. per min. is seen to be common to stellite and to steel. The outstanding feature of the stellite curve is the extraordinarily high durability at the rather low speed of 30 ft. per min. No steel that has been tested up to the present time has approached this durability at the same or any other speed. At only one other point does the stellite rise above the steel—at 100 ft. At the red-hot chip speeds—130 ft. and upward—its durability is nil. Stellite is used in practice at speeds much higher than 130 ft.; but as previously explained, the cutting conditions on the testing machine are such as to generate a very high temperature at moderate speeds. What inference is to be drawn from this result? Stellite would appear to be unsuitable for heavy roughing work and not especially suitable for any very high-heat cutting, though capable of standing up as well as, or better than, a steel tool under some blue-chip conditions of cutting. It might be expected to show extreme durability, far surpassing that of a good high-speed steel, under conditions that produce only a moderate amount of heat (a light cut at high speeds with coolant, or a moderate cut at fairly slow speeds). When cutting cold, it is not especially durable.

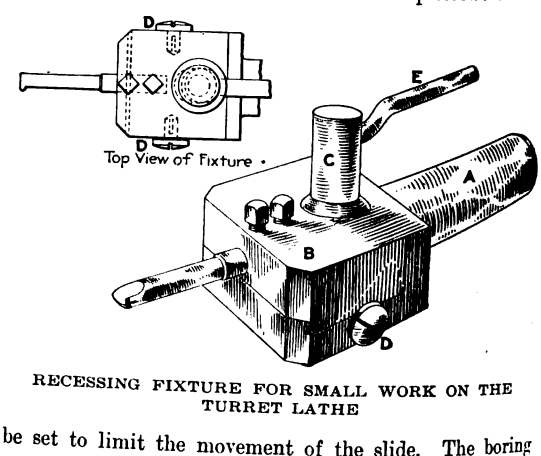
It is not altogether easy to say how far these conclusions agree with the published descriptions of stellite tests. Some of the statements appear to be contradictory and others somewhat indefinite, though there is a fairly general agreement that stellite is very durable when used with light cuts at high speeds.

In my own experience stellite has been used chiefly in turning cast-iron pulleys 16x3¼ in., with a traverse $^1/_{40}$ in. and a cut about ⅛ in. deep. The work was done at 68 ft. per min. At this speed a good high-speed steel tool required grinding three times for each pulley, whereas the stellite tool turned six pulleys without grinding, showing an advantage of 18 to 1 in favor of the stellite. At the next lower lathe speed—40 ft.—both tools stood up a long time, with a decided advantage in favor of the stellite. The next higher lathe speed was 104 ft., which was too high for both stellite and steel.

Recessing Fixture for the Turret Lathe

By Charles W. Oviatt

The illustration shows a turret-lathe fixture for recessing small work. The shank *A* is made to fit the turret. The slide *B* travels crosswise, operated by an eccentric on the lever stud *C*. The stop-screws *D* can



RECESSING FIXTURE FOR SMALL WORK ON THE TURRET LATHE

be set to limit the movement of the slide. The boring or recessing tool, of any shape with a round shank, is held in the slide by two screws.

By setting the slide against one stop-screw the tool will enter the hole in the work without touching. Then by operating the lever *E* and bringing the slide *B* over to the other stop-screw, which is set as required, the recess is cut by moving the turret slide forward the length of the recess to be machined.

Opportunity for Machine Tools in Holland

By Ludwig W. Schmidt

SYNOPSIS—Although machine tool manufacture in Holland has developed in recent years the market still remains a foreign one. Direct result of the war has made itself felt with every prospect that the demand for machine tools will continue after hostilities cease. Suggestions are given for American manufacturers.

During the last year the exports of American machine tools to Holland have risen from an average of about $80,000 a year to nearly $200,000. This increase has been regarded as a sign that Holland was supplying Germany with American machine tools; but this claim can scarcely be upheld, seeing that in normal years Germany used to send to Holland machine tools of a value of about $800,000. This comparison shows that, even if America has been able to send nearly three times as many machine tools as in former years, the country must still be considerably behind its usual requirements.

All indications point to the fact that Holland will soon have to begin to buy again in larger quantities, as she is able to take care of a certain percentage of the required machine tools and the present equipment is said to be deteriorating rapidly. Industry has been unusually busy and consequently needs more machines than under normal circumstances. Holland has been cut off for some time from her ordinary supplies of practically all classes of industrial goods. England, Germany, Belgium and France used to take care of a very large part of the industrial needs of the country, but none of them is able to do so now to any great extent. Consequently, Hollandish manufacturers have been compelled to attend to these necessities themselves. This situation has put increased pressure on all classes of industrial enterprise, which has been still further increased, owing to the fact that Holland has to provide for her colonies as well. Those also were accustomed to buy largely outside of Holland.

Prosperity in Dutch industry is not evenly distributed; while some branches have been fairly busy, others have suffered. As far as can be seen, it seems that most of the machine shops, especially the larger ones, have been doing well and most likely will do so during the remainder of the war. The Government, anxious to be prepared for all eventualities, has given larger orders to the few firms in the country able to make armaments, and the state of preparedness that has been necessary during the last 18 months has been reflected in many ways in the business of the machine-building industry.

It is therefore not surprising that Dutch buyers of machine tools are turning to the United States for supplies; and since the foundation of the Oversea Trust, shipments have been more easily arranged. All goods can be consigned to that body, by which they are forwarded to the respective owners under a guarantee that they are not sent to Germany.

Holland has a number of machine-tool manufacturers, of whom some have made a considerable name for themselves, mainly in the building of certain of the newer types of machines. With these they have begun effectively to combat American, English and German competition in their own market. They have even been able to carry the war into the home of their former aggressors by exporting to the neighboring markets. Today one finds Dutch machine tools in France, Germany, England, Belgium and in the Northern European countries. At the same time they have found a very considerable market at home, where the increasing needs of the machine-building industry opened a good field. Dutch machinery builders have shown themselves generally very active during the last few years. The success of one of the leading motor cars in London, for instance, has created a good sale for such motor cars in that market.

The biggest users of machine tools in Holland are the large engineering works in and round Rotterdam, of which some are excellently equipped, having in several cases a considerable number of American machine tools. Many of those plants are said to have been exceptionally busy during the last months. The shipbuilding industry is using heavy types of machine tools in which the American industry cannot compete so easily as the English and the German, the two latter having cheap means of transport—an essential for the supply of that class of machines. A well-known Scotch firm is doing a great deal of business in such lines, and of course the Rhenish-Westphalian machine builders have worked that market thoroughly.

Foreign Machine Tools in Holland

Generally speaking, it is astonishing how large the foreign participation is in the machine-tool supply to Holland. Passing through the larger plants, one frequently sees machine equipments of quite a modern style being made up out of German, English, American, French, Belgian and home-made machines of all descriptions. The newer machines, as a rule, are German, American or Dutch. Many plants have recently made a cleaning up and have renewed a large part of their equipment. But there are still firms of standing which are working with a rather mixed assortment of different types and different ages. This condition, however, may change rapidly after the war. It is said that the Dutch manufacturer is well able to see the value of the newer and speedier machines, but that his conservative and saving disposition will not allow him to replace an old and trusted lathe while it is still able to do work. So business is slow, and success comes only to him who waits.

This characteristic will work during normal times to the disadvantage of the American manufacturer and to the advantage of the neighbor supplier. The English and German manufacturers find it easy to work Holland. The market is not large, and it is easily visited either from England or Germany. A machine can be supplied nearly at once when desired, and there is not much difficulty with regard to repairs. Spare parts can be obtained easily and without large cost. All these things favor the

home manufacturer or his near-by competitor. On the other hand, the American machine is not always on hand when needed; and even if it can be sold from stock either by an English or a continental agent, the sale is not always as pleasing for the buyer as when he receives a brand-new machine from the shop.

Those difficulties in the way of American sales are increased at present, owing to the war. Dutch manufacturers and buyers of machine tools apparently have a good deal of complaint to make about American makers. The first claim is that they cannot get attention quick enough. This is not the fault of the American manufacturer, but of the interruption of the ordinary postal service, which affects, as well, telegraphic communication. Prices or price offers are frequently changed, or offers are made under the condition that they can be changed if the situation alters. As this contingency arises nearly every week, business is seriously affected. American manufacturers do not want to give the credit the manufacturers are accustomed to. Finally, machines, if ordered, do not arrive in time. This is quite a long list of complaints, and it could be extended from letters received by American exporters.

These disadvantages acting against the American machine-tool manufacturer and his business in Holland are considerably counterbalanced by the fact that the Dutch machine user is very much in need of machines and consequently is inclined to be less critical and less ready to stand on his rights. In fact, it appears that the American-Holland machine business could be considerably larger, if only the American makers were able to fill orders. As it is, business is freakish, falling off in one month and increasing rapidly in another, as has been the case already during the first year of the war. The reason for this is most likely that shipments collect in New York or other places and that it takes some time before arrangements for their release are made.

The immediate future of the business seems to depend largely upon the economic conditions in Holland. If they remain as they are, demands from that country ought to increase again during the coming months; but it seems that the Dutch industry is feeling very much the influence of the war in the form of financial pressure. Difficulties have increased of late, owing to trouble in obtaining raw materials from outside Europe in consequence of the English blockade of Germany.

What will be the condition of the business in machine tools in Holland after the war is not very easy to predict. Of course, the German manufacturers will return to the market when the war is over, as the relations between the two countries have remained quite satisfactory. Nevertheless, it is expected that American machine tools will be sold in a larger percentage to Holland after the war than before. Besides that, the importance of Rotterdam as a trading port between Europe and the United States may increase considerably, which would affect as well its shipbuilding and engineering industries.

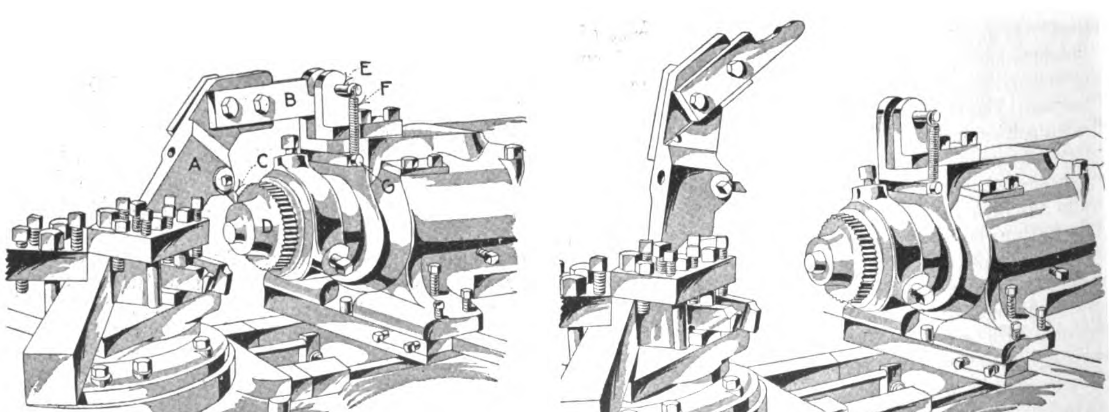
At the moment it might pay well to keep in touch with affairs in Holland. English, as a rule, is well understood there, so that American catalogs can be used with advantage. German is also spoken generally in that country; but it is doubtful whether the use of German lists would be an advantage just now, owing to the fact that the country seems to be somewhat split in the distribution of sympathies for the belligerent nations. It would be a great advantage, if offers could be made accompanied by price quotations. Owing to the rather slow and frequently interrupted postal service, it is further advisable to answer letters immediately.

Turning Profile on Pulley in Turret Lathe

A pulley-turning method is here shown that can be applied to numerous other similar jobs. The device is used in the shop of the Disco Electric Starter Co., Detroit, Mich., for turning and crowning a small pulley that is cast integral with a gear of larger diameter.

The gear is placed over a plug on the nose of the lathe spindle and is held in position by a split washer and a draw-in rod. The arm *A*, Fig. 1, is carried in a hinged bracket on the turret. A master form *B* is bolted to the end of the arm, to guide the cutting tool *C* as it is fed over the pulley *D*. The master form is cut into the upper side of the steel piece just opposite the pulley crown. This master form is pressed up against the hardened-steel pin *E* by a pin that is forced upward by a spring *F* and a lever *G*.

The shape and placing of the various parts will be better understood by referring to Fig. 2, where the arm is shown thrown back out of position.



FIGS. 1 AND 2. FIXTURE FOR TURNING AND CROWNING PULLEY ON THE TURRET LATHE

Special Shell and Fuse Drilling and Tapping Machines--II*

SYNOPSIS—This article shows a somewhat unusual use of 10 drilling heads on a turret in two planes, as well as a three-spindle tapper and a light drilling lathe, both of which have interesting features.

Fig. 16 shows a semiautomatic 10-spindle drilling, reaming, bottoming, counterboring, grooving and tapping machine for fuse bodies. It completely finishes five holes in the fuse body, which is shown in Fig. 17.

The operations are drilling, reaming and bottoming the bottom detent hole *A*, drilling the top detent hole *B*, drilling, reaming and counterboring the centrifugal bolt hole *C*, drilling and counterboring the needle cap check screw hole *D* and drilling, reaming, bottoming, grooving and tapping the percussion-pellet hole *E*—a total of 14 distinct cuttings for the five holes.

These fuse bodies are of brass forgings, so that they are very tough and hard and require a reduction both in cutting speed and feed per revolution of the drills. Taking common brass as a base, the cutting speed had to be reduced one-half and the feed per revolution two-thirds. Under these conditions an output of 35 to 40 finished bodies can be produced per hour.

The tooling spindles are arranged in two groups—seven on the faceplate *F*, Fig. 18, lying radially around the horizontal axis of the machine, and three on the turret *G*, Fig. 19. The top, rear and bottom spindles on the faceplate are in couples, 3 in. apart, and identical, as each pair operates on the same holes in the fuse body. The spindles in each of the three pairs nearest to the faceplate, upon which they are mounted, are the inner spindles and correspond to the inner position of the fuse-body holder *H*. The three outer spindles likewise correspond to the outer position of the holder. The front spindle *I* on the faceplate is single and is operated by hand. The three-arm turret *G* is mounted upon a compound saddle; the main saddle *J* is used only to shift the turret *G* to either its inner or outer working positions, the subsaddle *K* being for feeding only. This subsaddle can be fed either by hand or by power.

The fuse body is chucked in the machine by an internal threaded holder *H*, which is integral with the main, or shifting, saddle *J*. The externally threaded end of the fuse body is screwed tight into the holder *H*, Fig. 18, to a depth of four threads. The fuse body is operated on in either its inner or its outer position. The top inner spindle L, Fig. 19, drills the centrifugal bolt-hole *C*, which is reamed and counterbored by the outer spindle *M*, the mate of *L*. The rear inner spindle *N* drills the bottom detent hole *A*, which is reamed and bottomed by *O*, the mate of *N*. The bottom inner spindle *P* drills the needle cap check screw hole *D*, and *Q*, the mate of *P*, counterbores the hole. The front single spindle *I* drills the top detent hole *B*.

The first spindle *R* on the turret drills the percussion-pellet hole *E*; the second spindle *S* reams, bottoms, counterbores and grooves it, and the third spindle *T* does the tapping. The first spindle is provided with a receding steadyrest *U*, to provide means for accurately starting the drill. The second spindle is equipped with a special combination reaming, bottoming, counterboring and grooving tool *U*, the grooving being done after the tool has come to its stop by depressing a small lever *W*. No starting bushing is used, as the tool follows accurately into the previously drilled hole. The third spindle is equipped with a Jarvis reversible tapping chuck *X*.

The drilling of the fuse body, which utilizes the three inner spindles on the faceplate and the first spindle on the turret, is done with a power feed having a quick return and automatic knockout. The power feed can be thrown in or out at any time. While the power feed is in action, the operator drills the small top detent hole *B* by means of the push-drilling spindle *I* at the front of the machine

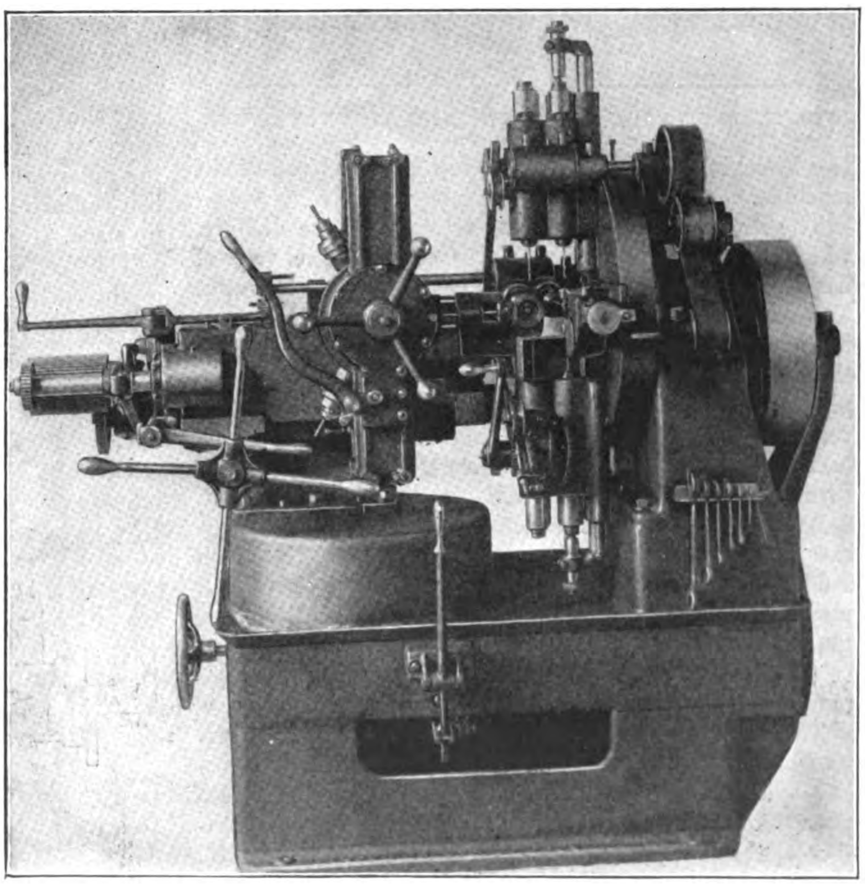


FIG. 16. TEN-SPINDLE DRILLING MACHINE WITH TWO TURRETS

*Previous installment appeared on page 465.

on the faceplate *F*. All the drilling is done while the main, or shifting, saddle *J*, which carries the fuse-body holder *H*, and the turret saddle *Y* are in their inner working positions. All the other cuttings, such as reaming, bottoming, counterboring, grooving and tapping, are done in the outer working position.

The three outer spindles *M, O, Q* on the faceplate *F* have a rack-and-pinion hand-lever feed, also an adjustable screw stop for varying cutting depths. The second and third spindles *S, T*, on the turret *G*, have a rack-and-pinion feed operated by a four-arm spider wheel *Z*. They also each have an independently adjustable feed stop.

The fuse body is chucked in holder *H*, while the turret *G* and the main saddle *J* are in the outer position. By means of a compressed-air tube the operator first frees of chips the internally threaded part of the fuse-body holder *H*, steadyrest *U* on turret *G* and drill-guide bushings *A2*. The fuse body is then screwed firmly to its seat in the holder *H*. The turret *G* is unlocked by a hand lever *A3* and turned by a triple-arm lever *A4* so as to bring the drilling spindle *R* into the line of action; the subsaddle *Y* is also locked to its feeding cam *A5*. The operator advances the main saddle *J*, carrying the holder *H* and subsaddle *Y*, with turret *G*, to the inner working position by a bell-crank lever *A7* and link *A8*, which

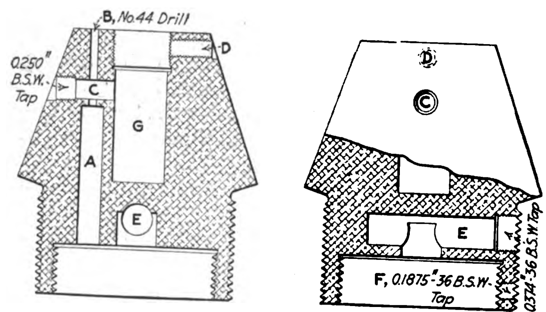

FIG. 17. FUSE BODY FOR BRITISH NO. 100 GRAZE FUSE

is self-locking and located at the top left-hand end of the machine.

The machine is now properly set to start the drilling, which is done by simply pulling outward the vertical hand lever on the front of the bed near the operator. The drilling being automatic, the operator uses his spare time in drilling the top detent hole *B* by hand-feeding the drilling spindle *I*, located at the front on the faceplate *F*. Should a drill break or any other need arise, the operator can instantly stop the power feed by throwing back the starting lever. Means are also provided for returning all the drilling spindles to their starting point.

After the drilling is done, which is fully automatic excepting the starting, the operator returns the main saddle *J* to the outer position. The fuse body is now in position to bring the three spindles *M, O, Q* into action, the feeding being done by a hand lever at the lower front of the faceplate, which acts on the three spindles simultaneously.

The operator then unlocks the turret subsaddle *Y* from its feed cam *A5*, turns the turret *G* so as to bring the second spindle *S* into the line of action and feeds it into the work to its stop. He then cuts the groove and chamfers the hole by depressing the small hand lever *W*, attached to the combination tool *V*, and backs it out of the work. He next turns the turret *G* so as to bring the tapping spindle *T* into line, advances the tap to the work, follows the tap to the stop, allows the tap holder *X* to unclutch itself, then backs up the turret, which causes the tap holder *X* to reverse and back the tap out of the

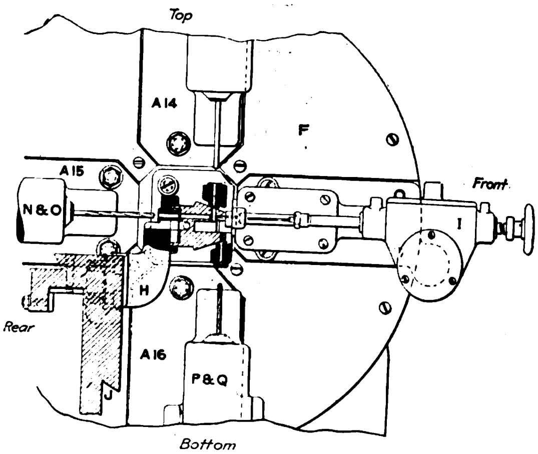

FIG. 18. DETAILS OF THE DRILLING HEAD

hole. The fuse body is now completely drilled and is removed by unscrewing from the holder.

The outer construction of the machine can be plainly seen, but the mechanism that controls the speed of the cutting spindles and the power feed is of interest. The drive is of the single-belt type, the driving pulley being 18 in. in diameter for a 4-in. belt, which revolves upon a stationary shaft and is integral with a pulley at the outer end that drives the feed. A fabroil gear on the inner end drives all the cutting spindles through a pair of spur gears mounted on the outer ends of shafts that carry the two main endless-belt driving pulleys. The cutting spindles are driven by spiral gears, the driving spiral-gear shafts *A9* extending to the rear of the machine and carrying pulleys lining up with the two endless-belt driving pulleys, between which are idle pulleys to give proper belt contact. A belt tightener is also provided for taking up slack.

The rear driving spiral-gear shaft extends to the rear of the turret and makes connection to the turret spindle through bevel and spiral gears, the driver of which is

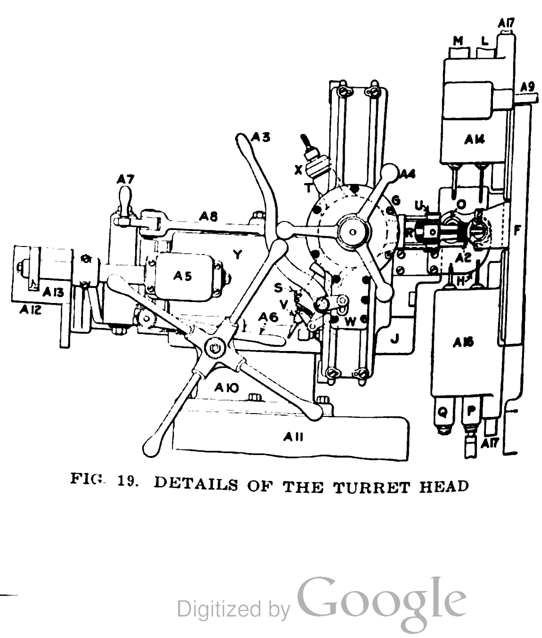

FIG. 19. DETAILS OF THE TURRET HEAD

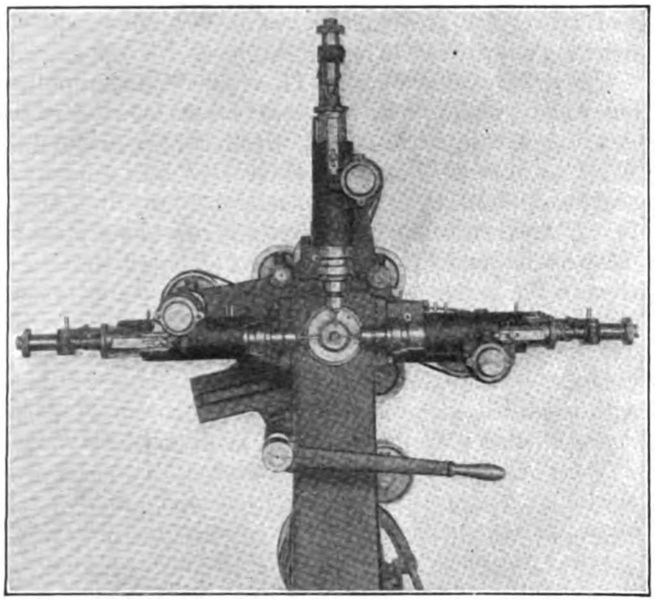

FIG. 20. THREE-SPINDLE TAPPING MACHINE

a slip gear, to allow for the shifting of main saddle J and the feed of subsaddle Y. All cutting spindles are driven at their practical cutting speeds.

The turret G and the saddles J Y are mounted upon a standard $A10$ that is bolted to the dome projection $A11$ at the left of the bed. At the rear of standard $A10$ is mounted the main horizontal shaft, carrying on its left a spur gear that meshes through a long intermediate gear $A12$ with a traveling gear $A13$. This operates the helical-screw cam $A5$, which actuates the feed of the turret subsaddle Y. This cam is provided with a locking mechanism operated by the hand lever $A6$, whereby the turret G can be fed either by hand or by power. Each of the three spindle heads $A14$, $A15$, $A16$, on the faceplate F, is provided with a feed yoke $A17$, and rollers are mounted upon their inner ends. These rolls engage with segment cams that are fastened at about quarterly intervals to a large rim gear lying inside, and concentric with, the faceplate. The front, or hand, push-feed spindle I at the front has no feed connection to this gear.

The large rim gear in the faceplate is actuated by a spur gear mounted on the right-hand end of the main feed shaft located at the rear of standard $A10$. All cutting spindles having power feed are operated by this shaft. Inside of the dome projection $A11$ on the left of the bed is mounted a 20-in. drum cam on a vertical shaft. This cam is actuated by a combined worm gear and roll clutch, and an automatic knockout is arranged so that the cam can make only one revolution at a time. The cam gives, first, a quick advance of the drills, a cutting feed and a quick return.

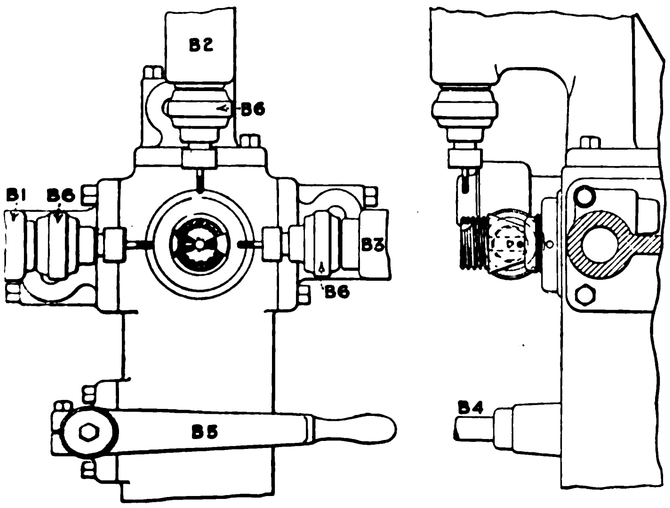

FIG. 21. DETAILS OF THREE-SPINDLE TAPPER

The wormwheel runs free on the camshaft and only operates the cam when the operator throws in the roll clutch in starting the power feed. On the rear of the cam is mounted a vertical slide carrying a roll engaging with the cam. Extending up on this slide is a rack meshing into a gear on the main feed shaft. It can be seen that all drill power feeds are actuated by the drum cam.

The wormwheel meshes into a worm mounted upon a shaft running the entire length of the bed and extending out at each end. The right end carries a pulley belting to the driving pulley mounted integral with the main driving pulley. A handwheel is used on the left end, so that the cam can be run backward in case of drill breakage.

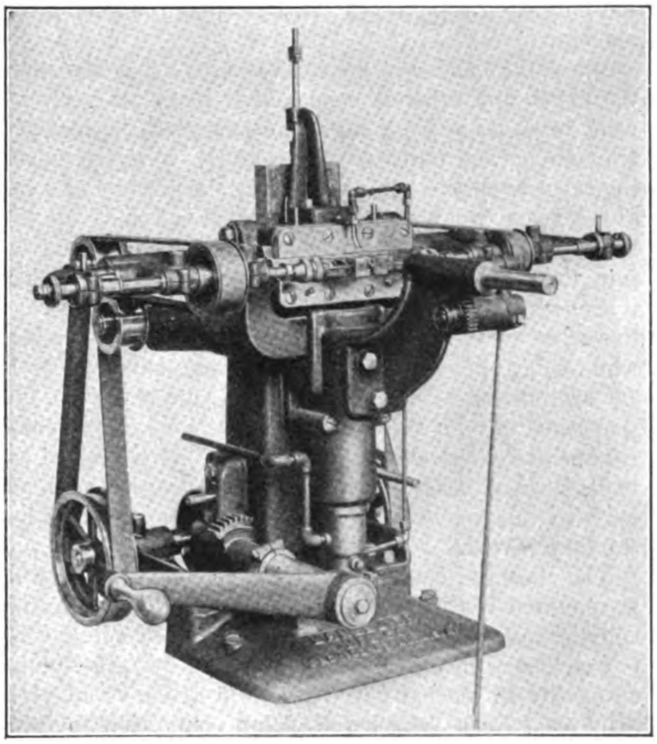

FIG. 22. DRILLING THE CROSS HOLES IN PERCUSSION PELLET

The machine covers a floor space of 3 ft. 9 in. by 6 ft. 1 in. and is 5 ft. 8 in. in height. Its weight is 3,900 lb.

The three-spindle multiple tapping machine, Figs. 20 and 21, simultaneously taps the three holes in the fuse body. The output with a skilled operator is about 6 completely tapped fuse bodies per minute, or 360 per hour. The holes tapped include the needle cap check screw hole D, Fig. 17, which is made by the right-hand spindle; the centrifugal bolt hole C, by the left-hand spindle; and the adapter check screw hole F, by the top spindle. The body is chucked by a pneumatically operated expanding arbor fitting into the graze-pellet hole G. It is located by means of a stationary pin in the chuck that enters the top detent hole B. This arrangement brings all the three holes to be tapped in line with their respective spindles $B1$, $B2$, $B3$. The expanding arbor exerts a drawing-in effect that seats the body firmly. This arbor is fully automatic and requires no attention whatever from the operator.

At the rear of the machine, on the same center as the expanding arbor, is located a cylinder to which the piston rod of the expanding shell of the arbor is attached. The tapered arbor is fixed, the shell being drawn over it to expand it. To the cylinder is attached a piston valve that is operated by a small lever mounted on the rear end of the hand-feed lever shaft *B*4, shown at the front of the machine.

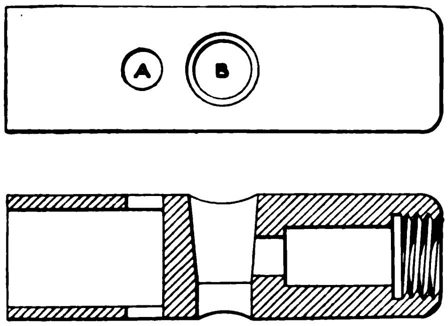

FIG. 23. PERCUSSION PELLET FOR GRAZE FUSE

When the hand-feed lever *B*5 is in the position shown, the expanding arbor is open and is ready to receive the work to be tapped. A slight movement of the feed lever from its normal position will instantly cause the expanding arbor to close. In manipulating the machine the operator takes a fuse body by the threaded end and puts it on the expanding arbor, turns it until the locating pin falls into the previously drilled top detent hole *B* and holds it there until he starts the hand-feed lever *B*5. This causes the arbor to tighten instantly on the work and holds it while being tapped. The three tapping spindles *B*1, *B*2, *B*3 are advanced to follow the taps into the work until they come to their stops. The instant the tapping chucks *B*6 unclutch themselves, the hand-feed lever *B*5 is fed back to its normal position. The expanding arbor, with feed lever in this position, is open, and the tapped fuse body can be removed.

The machine consists of a circular base upon which is mounted a vertical column of U-section, with three spindle heads *B*1, *B*2, *B*3, attached. Each spindle head is provided with a feed yoke, connected by racks, pinions and gears to the hand-feed lever *B*5 at the front of the machine. Each yoke has a clamp connection to its respective spindle. This clamp connection permits the spindles to be set for different tapping positions. The tapping spindles run in nonrevolving sliding sleeves that carry the driven gears, a Jarvis reversible tapping chuck *B*6 being attached to the inner ends. The driving spiral-gear shafts on each tapping head extend to the rear of the machine and carry pulleys over which runs an endless belt, driven by the tight and loose pulley shaft at the rear and bottom of the U-column. Intermediate idle pulleys are provided to give ample belt contact, and a belt-tightener pulley is also used. Each spindle has its separate adjustable feed stop. The machine occupies a floor space of 45 in. by 30 in. and is 59 in. in height. Its net weight is 1,400 lb.

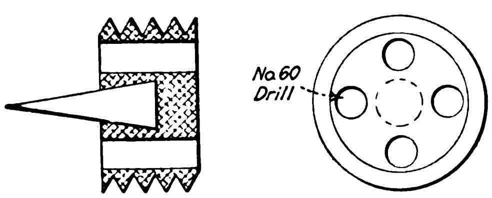

FIG. 24. PERCUSSION NEEDLE PLUG

The drilling machine, Fig. 22, is for drilling simultaneously and from opposite sides a 0.095-in. to 0.105-in. hole *A* through both walls of the rod-brass percussion pellet, Fig. 23, at a single handling. It also drills the combination straight and 10-deg. taper hole *B*, 0.191 in. to 0.185 in. by 0.155 in. to 0.145 in., midway of the same piece and 0.205 in. away from the first hole. These holes are too close to the center distance to be both handled at a single operation from one side only, by a regular multiple drill. The brass pellets, Fig. 23, are 0.320 in. to 0.312 in. in diameter by 1.080 in. long. In actual tests one machine, with unskilled operator, maintained an output of about 5 pieces, drilled with the two holes mentioned, per minute.

The work-holding fixture is a vise built as a part of the machine, so that the operator has merely to insert the blank pellets, drilled end first, between the jaws of the fixture. He then depresses the foot-treadle wheel to send the locking plunger forward against the outer end of the blank and to bring it into proper drilling position. Then he raises the hand lever at his left, to feed both spindles and their tools toward the piece from both sides at the same time. As the spindle-feed lever is elevated, an air valve automatically opens, letting compressed air of about 45 lb. pressure into the pneumatic cylinder at the center of the machine. This air pressure acts against the under side of the cylinder piston, forces it upward and at the same time forces up a U-shaped yoke fastened to the top side of the piston. As this movement takes place, the two inner edges of the yoke, which are tapered, draw in two jig-jaw slides, closing them firmly on the work.

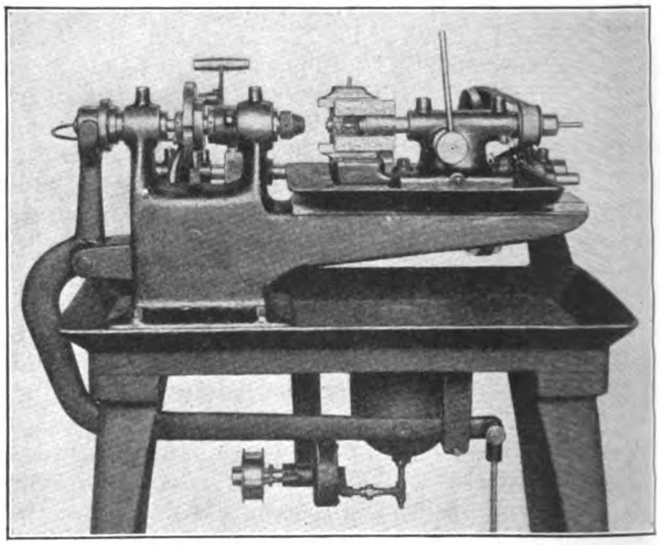

FIG. 25. MACHINE FOR DRILLING PERCUSSION NEEDLE PLUG

After the drilling operation is complete, the feed lever is lowered, the air valve shutting off automatically. At the same time the work-holding jaws spread apart and the drilled pellet is ejected by a spring. The exhaust air from the work-operating cylinder is piped up to blow away any chips, after every piece is ejected. These jaws are thus kept thoroughly cleaned, and all pieces fit snug. The drilling spindles are tapered on their inner ends to fit the sockets of the No. 1, either Jacobs or Skinner chuck for drills up to $\frac{7}{32}$ in. in diameter. Their outer ends run in sleeves with 2-in. endwise adjustment, a...

ing means of easily maintaining the proper depth of taper in the combination hole and also of compensating for the shortening of the straight drill by grinding.

The spindle for the combination straight and tapered drill runs at 2,436 r.p.m. and the spindle for the 0.095 tc 0.105 drill at 3,350 r.p.m. Spindle-driving pulleys are 1¼ in. in diameter by 1⅜-in. face and run on projections of the phosphor-bronze spindle bushings inserted in the spindle frames, thus eliminating all belt tension from the spindles themselves and permitting them to run practically as floating spindles. The bench space occupied is 33 in. by 26 in. by 28 in. high. The weight of the machine is approximately 400 lb.

Light-Drilling and Indexing Lathe

For drilling the four holes in the percussion needle plug, Fig. 24, the drilling lathe, Fig. 25, is used. The output obtained is 4 completely drilled pieces per minute, or 240 per hour. The percussion needle plug is of brass, and the drill a No. 60 0.040-in. stock twist drill with special temper. It is drilled at a speed of 6,000 r.p.m.

The drilling is done by a light sensitive spindle running in a feed sleeve, which is fed by the hand lever, shown at the front of the tailstock. On the chuck end of the sleeve is a sliding steadyrest that travels in a guide. The steadyrest is provided with a drill bushing that supports and accurately starts the drill. In drilling, the steadyrest is fed up until it stops against the piece being drilled, while the drill continues on and performs the drilling.

The spindle pulley runs on a sleeve clamped into the rear end of the tailstock and drives the drilling spindle by means of a keyed collar fastened to the pulley, insuring a sensitiveness that is desirable when drilling very small holes. The drilling spindle is driven by a 1-in. endless canvas belt from a countershaft fastened to the back of the machine. A belt tightener is provided. The headstock is a casting with an extending slide upon which the tailstock can be adjusted to its proper drilling position. The spindle is provided with a four-notch index wheel that is actuated through a ratchet and pawl by a hand lever, so as to bring successively each of the four holes in the percussion needle plug into line with the drilling spindle. The spindle is locked in its drilling position by a lever located at the rear of the indexing wheel.

The tailstock is adjustable crosswise, like a lathe, to accomplish this. The spindle is also provided with a spring chuck that is opened by means of a sliding thimble connection on the left end of the spindle. The thimble is actuated by the long bent lever that passes underneath the table and that is connected to a foot pedal by a link rod. The chuck is closed by a heavy compression spring when the operator removes his foot from the pedal. The work, after being drilled, is automatically ejected by a sudden jet of compressed air, provided by a small special shut-off valve that is opened only during the interval that it takes to move the index wheel. The valve is connected to the spindle by a single brass tube. The floor space required is 3 ft. 1 in. by 2 ft. 7 in., and the machine is 4 ft. 2 in. in height. Its net weight is 500 lb.

The machines herewith described are made by the Langelier Manufacturing Co., Providence, R. I., and indicate the possibilities of shell production in the use of specialized tools as opposed to the adaptation of regular machining equipment.

Two Different Mold Dies for a Radiator Cap

By Gustave A. Remacle

The two mold dies shown herewith are the product of two different shops, and while they both produce a radiator cap of similar form the dies themselves differ in construction and are operated in a different manner. The only noticeable dissimilarity in the product of the dies is that the product of the single die has a double fin at *A* and *B*, Fig. 1, while that of the multiple die has only one fin at *A*.

The parts *A* and *B*, Fig. 2, were turned in the lathe and the outside milled. The hole *B* was bored to the finished size and the plug inserted as shown. This plug was inserted to facilitate milling the grooves. After

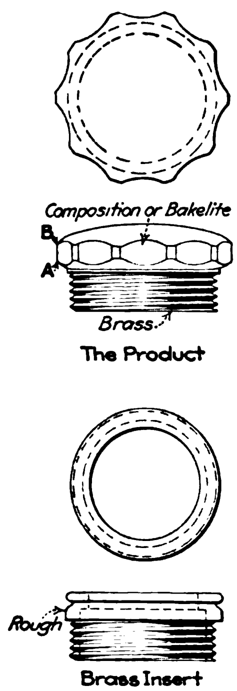

Fig.1

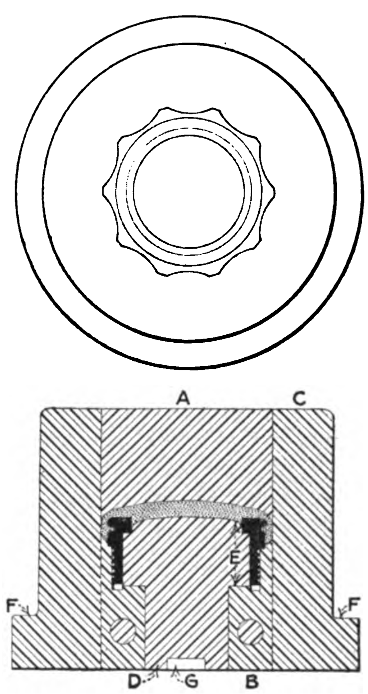

Fig.2

FIGS. 1 AND 2. MOLDING THE RADIATOR CAPS

having been milled to size, the piece was parted in the proper place and the pieces worked separately. The cavity in the force which forms the top of the product was machined to shape. The bottom force was next placed on a plug arbor which had been turned, and ran true in the lathe and was machined internally and on the face to the finish size and shape. When machining the chase or shell *C* as much metal as possible was removed while the piece was in the lathe. One of the forces was then placed over the hole and the form marked off. The hole was then machined to the line in the slotting machine and filed to fit the forces. The plug *D* was finished to size at all points except *E*, which was made the finish size plus the distance desired between the top of the plug and the top force. The chase *C* had $\frac{1}{32}$ in. surplus stock on each face, which was left to allow the piece to be machined so that the bottom would be square to the hole and the proper space would exist between the top force and the plug when the top of the force was flush with the top of the chase. The bottom force was then doweled in position in the chase, the force being set in so that a light cut from the bottom of the chase brought the force flush. With the bottom

force doweled in position, the plug and top force were inserted and the whole placed between centers in the lathe and machined all over to finish size. The chase was then hardened and drawn.

In operating the die the plug was set in place with the brass insert, the powdered compound poured into the die, the top force inserted and the die set under the

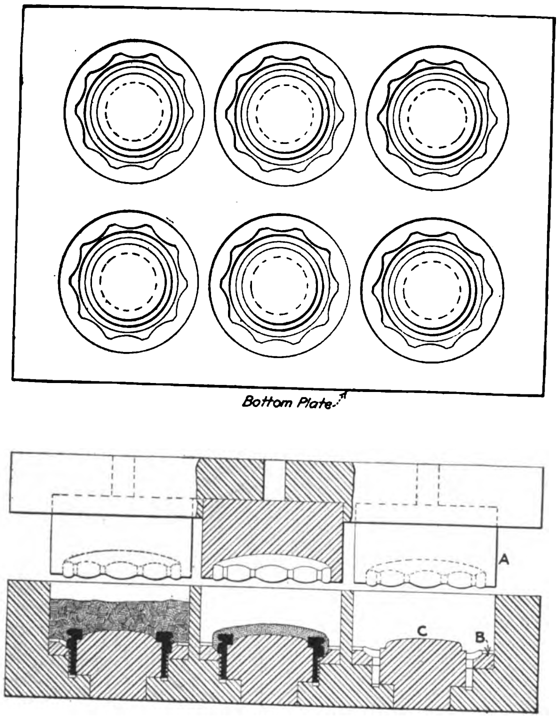

FIG. 3. MULTIPLE MOLD DIE

press. During the preceding operations the die rested upon a bench and was quite hot, the operator's hands being protected by heavy gloves. This die is not equipped with a steam plate, but is heated and cooled by the steam plate of the press. When ejecting the product the die was turned upside down in the press and placed upon a fork, points F resting upon the fork. A knockout pin was placed at E and the plug, product and top force pressed out.

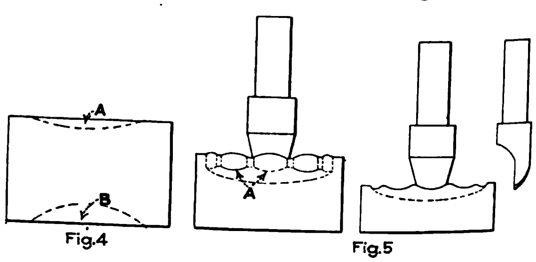
After the top and bottom plates had been planed to size, they were clamped together and the six ½-in. holes drilled and reamed through both plates. As these holes were used to locate the plates upon the faceplate of the lathe when machining the seats, it was observed that they were drilled and reamed squarely. A locating plug in the head of the lathe located the plates while machining the seats, and no trouble was experienced when the die was assembled, as the forces in the top plate line up correctly with the openings in the bottom plate.

The impressions in A and B, Fig. 3, were hubbed in a powerful hydraulic press and are of machine steel. Three hundred tons' pressure was needed to make the impressions in the forces. The chase B is of such size as will resist the terrific strain occasioned by C trying to spread under pressure. The hub is turned and milled as shown, care being exercised to have A and B concentric, also that the surface is highly polished and the corners rounded. It is imperative that these corners be rounded; otherwise a hubbing operation of this sort upon cold steel would prove a failure, as a result of the metal tearing at the sides. At Fig. 4 is shown the blank ready for hubbing. A is the surface which is to be impressed and is polished. Surface B is roughed out as shown. This cavity is filled by the descent of the stock while pressing.

There is a difference between hubbing in a press and hubbing under a drop hammer, inasmuch as a polished hub under the hammer will produce a polished impression, regardless of the finish on the surface being hubbed, while under the slow action of the press it is necessary that both the hub and the surface being impressed be polished. After the pieces have been hubbed they are machined in the lathe. The hub is trued in the chuck of the lathe and the pieces placed upon it, the tail center holding the pieces against the hub while they were being machined. It is desired to have the fin occur on the corner of the product. In order to obtain this result the hubbed pieces were milled with fly cutters as shown at Fig. 5. A templet was made to correspond with the form A and one of the fly cutters, using the templet to gage. This male cutter was then used to make the female cutter. Both cutters were applied as shown.

When assembling, the top forces were first screwed and doweled in place. The bottom impressions were then laid in their seats and the top plate, with forces brought down into its working position in the bottom plate. In this manner the bottom impressions are located so that they may be screwed and doweled in proper relation to the top forces.

As regards the superiority of one of these dies over the other, I will allow readers to form their own conclusions. In the construction of the single die about 60 hr. were consumed, while for the construction of the multiple die, including the steam and insulator plates and knockout arrangement, 400 hr. were necessary to complete the job. The multiple die will produce six radiator caps per 10 min., while six single dies being



FIGS. 4 AND 5. TWO DIFFERENT DIES FOR PRODUCING A RADIATOR CAP

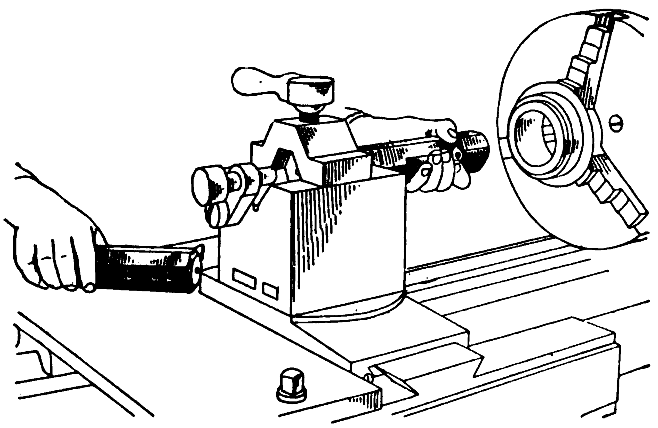
operated simultaneously by a single operator will produce six caps in 20 min. The multiple die is more readily heated and cooled than the single die, and the product is automatically ejected, thus accounting for the difference in the time required for producing the caps. A valuable feature of the single die, however, is that when repairs are necessary only one or two are tied up, whereas a breakdown on the multiple die would bring the production to zero while repairs were in progress. Also if six single dies are not quite enough to produce the desired number of pieces per day, one or two additional dies may be made, while if it is desired to increase the production in the case of the multiple die another die would mean doubling the capacity.

Letters from Practical Men

Rigid Boring-Tool Holder for the Lathe

The illustration describes a boring-tool holder for an engine lathe. This differs from the usual practice, inasmuch as the bars are made of rectangular instead of cylindrical stock.

The regular tool-post support is removed and the cast-iron V-block substituted. The gib is then screwed tightly to the cross-slide and the crossfeed handle removed, so as to make the V-block permanent. One corner of the rectangular bar is flattened for the purpose of clamping with a screw. The bars are then placed in the V-block and centered by placing a drill in the chuck, after which the corners are turned off to give clearance for the various



RIGID BORING-TOOL HOLDER

sizes of holes. The cutters are inserted diagonally with clamping and adjusting screw. In straight holes two bars are used—one for roughing, the other for finishing.

The bars are also made for holding taps, drill and dies, and they make very good substitutes for turret heads, with the advantage of being much more rigid.

Schenectady, N. Y C. K. Tripp.

A Simple Hand-Operated Bending Tool

The illustration, Fig. 1, shows a machine part made of No. 27 (0.016 in.) cold-rolled steel. The blanking and perforating are done in the usual manner on a power press, the two bends being made by the hand fixture, as shown by Fig. 2. Fixtures of this character are of more than usual interest at this time, on account of the great amount of work being required of power tools and because no set-up is required and the work is done by unskilled labor.

Referring to the bending fixture, *A* is a cast-iron base, milled on the bottom with two *L* cuts for holding in a bench vise. It is bored to contain the spring pin *C*. Screw *F* and stud *J* (which has gear teeth milled in it) are also milled dovetailed to admit the bending anvil *DE*, while another dovetail acts as the sliding surface for bending part *I*. This part, it will be noticed, has a rack milled on the bottom and carries a tool-steel anvil *M*. *A* is also milled to contain *B*.

The part *B* is also of tool steel and acts in the same capacity as the lower die in the press tool, while *DE* acts as a punch, the two making the first bend. After the

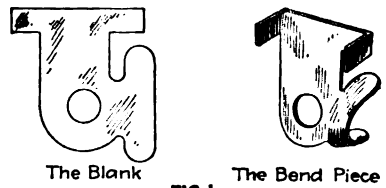


FIG. 1

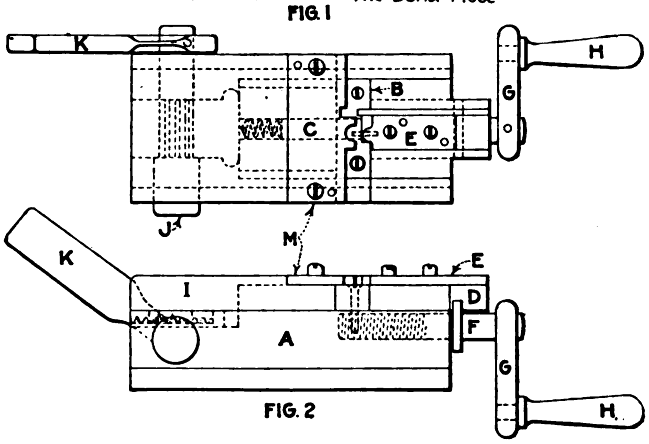

FIG. 2

A HAND BENDING FIXTURE

first bend is completed, *I* is carried forward by means of handle *K*, *E* acting as the lower die and *M* as the upper. In this way the second bend is made.

The spring pin *C* exerts a constant pressure on the piece to be bent, not only holding it while being bent, but freeing it from *B* when *DE* is returned to the starting point. George P. Breitschmid.

Arlington, R. I.

Oil-Ring Difficulties

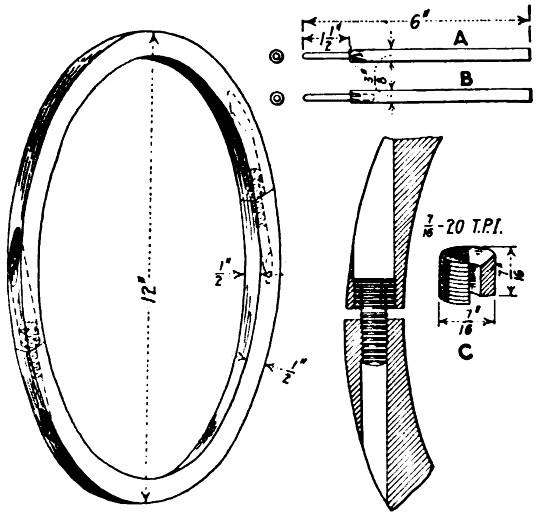
The illustration shows a job which would not be difficult in a well-equipped shop, but was so in the small shop where I was once employed, as the equipment was old and worn and there was no miller.

The rings were for oiling an 8-in. shaft and had to be fastened together, as shown, after the shafts were in place. They were first cut in two, the ends filed flat so that they would come together square, and then the halves were strapped to an angle plate and spotted for drilling. The tap holes and body size holes were put in without trouble; but when the rings were turned over to be counterbored for the screw heads, the trouble began.

Owing to the necessary length and small diameter of the pilot and the play in the drill-press spindle, the counterbore would hardly begin to cut before it would cramp and break. First, one like that at *A* was tried without success, as the pilot would break; and then one

like that at *B*, with the pilot left soft; but this would break out the side of the cutter.

I was about to give up in despair, when it occurred to me to drill through in the same way as for the smaller holes—with a drill large enough for the screw heads. This was done. Having a fine thread tap that would make a good thread in these holes, I tapped them and



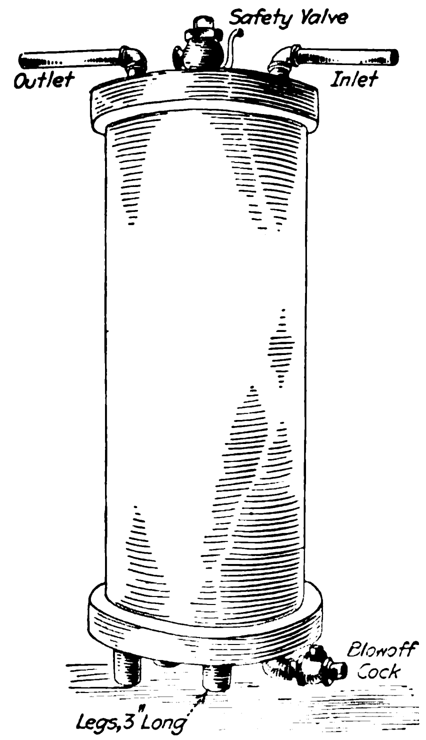
A SIMPLE METHOD OF DRILLING OIL RINGS

made plugs, as shown at *C*, with the countersink in the end, screwed them in tight, and the trick was done. Simple, wasn't it? But I didn't think so at the time.

Ilion, N. Y. HAROLD E. GREENE.

Air Tank Made of 14-In. Pipe

The illustration shows a simple but practicable air tank that we installed in a local garage. It is composed



AIR TANK MADE OF 14-IN. PIPE

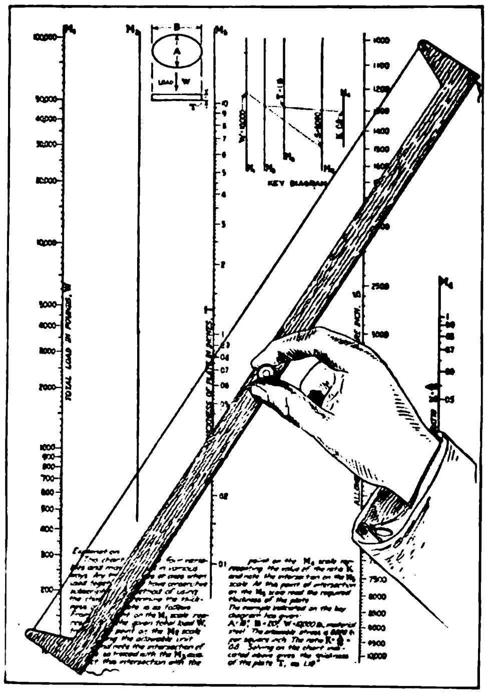
of a piece of 14-in. iron pipe 14 ft. long, with a cap on one end and a coupling on the other. A plug was made for the coupling, with four small legs about 3 in. long, to clear the blowoff cock and also to screw the plug in tight. The tank is stood on end.

The inlet and outlet for air are on the top. By placing them in this way we get pure air free from oil and water, which settle at the bottom, where a blowoff cock is placed to clean the tank. This also keeps the air lines clear.

Fresno, Calif. W. R. SCOTT.

A "Reader" for Alignment Charts

Herewith I illustrate my scheme for reading alignment charts with a black thread instead of with a straight-edge. I whittled down a cheap wooden rule as indicated, split two corners a trifle to hold the ends of the thread,



HANDY READER FOR ALIGNMENT CHARTS

put the thread in place and added a button for holding, to make the "reader" still more convenient.

I can work more quickly with this reader, as I can see both sides of the thread at the same time and no time is lost is shoving back and forth. Besides, I believe it to be more accurate, for the thread is placed "directly on top" of the mark, just as with a cross-hair on a slide rule. The finer the thread the better. N. G. NEAR.

Brooklyn, N. Y.

Repairs to Scored Air Hammer

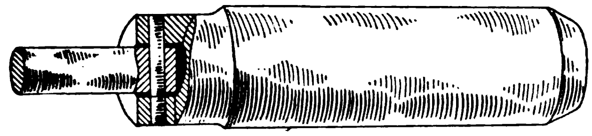
An air hammer was recently sent to the shop on trial. Either through lack of sufficient oiling or by foreign particles finding their way into the cylinder its walls and the plunger were badly scored.

Small particles of metal were embedded in the plunger and cylinder walls, gripping the plunger so that it had to be driven out. To return the hammer to the manufacturer in that condition was out of the question, and the fact that we badly needed the hammer set me thinking.

Removing the plunger and scraping the high spots off the plunger and cylinder removed the embedded particles of metal. To grind the plunger to the cylinder, I con-

structed out of odds and ends about the shop a universal socket and soldered it to the plunger. Then I rigged a couple of sash pulleys over my vise bench and hung a small portable drill from a strong cord, with a counterweight on the other end to balance it. With this arrangement I ground the plunger into place.

I fastened into the chuck of the drill the end of the rod of the universal joint to which the plunger was



REPAIR TO SCORED AIR HAMMER

soldered. By inserting the plunger, applying plenty of oil and a little flour of emery, starting the drill and working the plunger up and down in the cylinder I secured a good fit. A. H. YOCH.

Hazleton, Penn.

Machining the Form on Shells

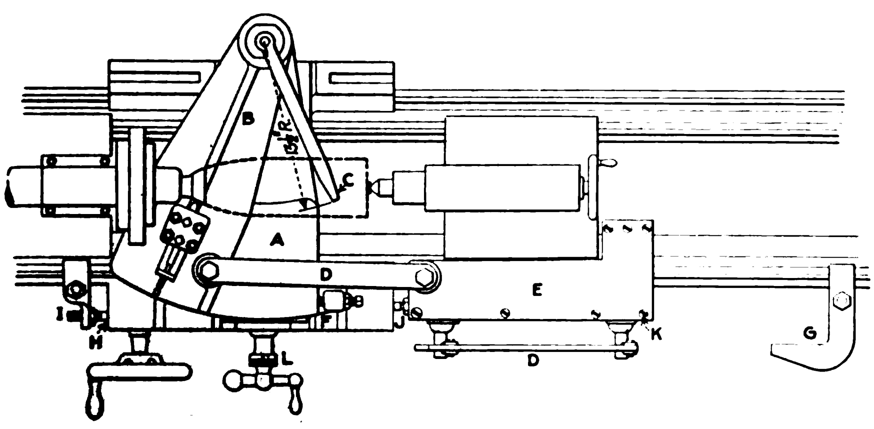
The illustration shows a lathe attachment for turning 4.5-in. shells. This outfit employs the old principle of radius and center often used on machine tools for special jobs and is giving excellent results, as it is designed to produce a continuous power feed over the entire shell and is also provided with an automatic knockout so that the operator need give the job no other attention than replacing the shells. The rig always comes to a stop when the shell is finished, thus making it possible for one man to run several lathes on this operation.

The main casting *A* is fitted to the cross-slide of the lathe carriage and has the cross-slide nut and screw attached for adjusting the cutter to the diameter of the shell. The swinging arm *B* carries the cutter. The small gage *C* is used for setting the cutter to the correct radius after each grinding and may be swung out of the way when not wanted. It is interesting to observe that the shape of the cutter in this outfit does not affect the shape of the finished shell. Hence the grinding need not be done by skilled help.

The operation is as follows: After placing the shell on centers, the nut on the auxiliary carriage *C* is closed by moving the link *D* to the right. The carriage *E* and the arm will then advance until the profile is turned and the arm strikes the stop *F*, when the main carriage will be fed along to turn the straight part of the shell, after which *D* will strike the knockout *G*. The operator removes the shell and runs the main carriage back to the stop *H*, pulls the carriage back to the stop *J*, as shown, and the cycle is completed.

When the device is used, the lead-screw nut is removed from the lathe carriage and fitted into the auxiliary carriage at *K*. H. P. HOAG.

Brantford, Canada.

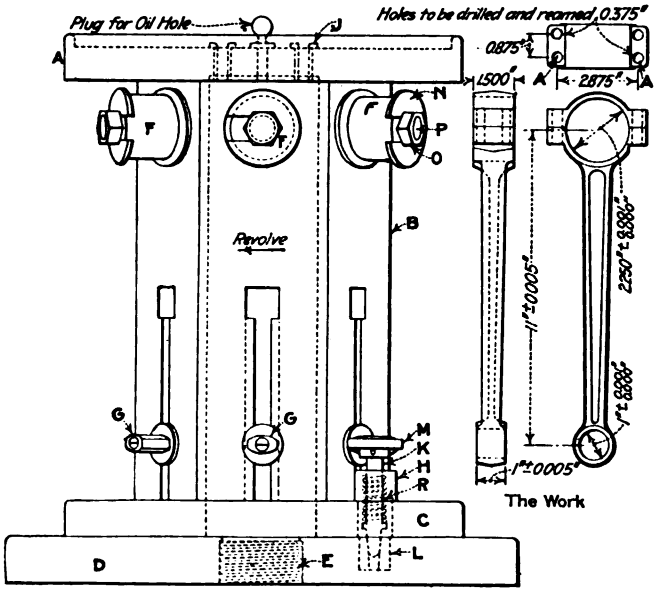


LATHE ATTACHMENT MACHINING THE FORM ON SHELLS

Continuous Drilling

Nowadays we hear a great deal about continuous milling, but very little of continuous drilling, which is of equal, if not more, importance.

The accompanying illustration shows a jig that is in use at the Detroit Motor and Machine Co., of Detroit. It comes close to accomplishing the desired end—continuous drilling. The jig is used on a 10-spindle Fox



CONTINUOUS DRILLING JIG

multiple press, of which eight spindles are used—four for $^{23}/_{64}$-in. drills and four for $3/8$-in. reamers.

A glance at the illustration will show that the upper plate *A*, which carries the drill and reamer bushings, is secured to the column *E*, which in turn is fastened to the lower plate *D*. This is also the index plate, *D* being rigidly held to the drill table. The trunnion *B* is fastened to the plate *C*, which carries an index pin *K*, and both revolve on the column *E*.

In starting to use this jig the operator places a connecting-rod on an idle face of the trunnion *B*, applies the washer *N* and tightens the nut *O* by means of a socket wrench. He then indexes the jig once, which brings the rod under the drill bushings, lowers the drill head and throws in the feed. While the drill is in operation, he places another rod on the next face of the trunnion. With every indexing a rod is taken off with four holes drilled and reamed.

It will be seen that, with the exception of lowering and raising the head, the operation is continuous, as

the operator removes the drilled rods and places undrilled ones while the drills and reamers are feeding through. Therefore, he has not many wasted intervals.

The raised rim on the upper plate *A* retains the cooling compound and is kept flooded, so that the liquid flows down the drills and reamers by gravity.

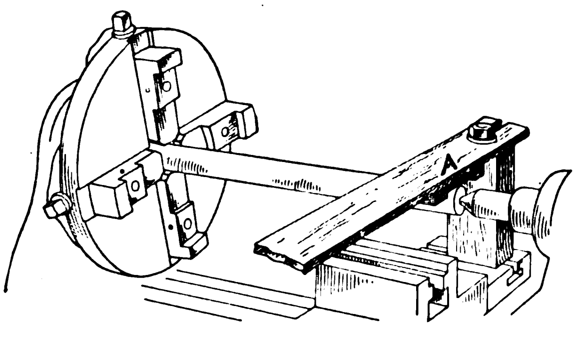
The T-slots were placed in trunnion *B* to make the jig as nearly universal as possible by taking care of any changes in rod length. The upper plugs *F* are also easily removable, to accommodate changes in the diameter of the bore. If there should be any change in the location or number of holes in the rod, the plate *A* could be removed and a suitable one made and put on.

The lower plugs *G* are made oval, to reduce the time of putting the rod in the jig. The large end of the connecting-rod is not split until after the rod is drilled.

Detroit, Mich. J. M. OLDHAM.

Good Way To File Shafting

Rig up the lathe as shown, using a 2x6-in. plank, 3 or 4 ft. long. Shim up with two or three layers of sheet rubber on felt, as at *A* Take two large files that are first broken in the middle of their length, making



METHOD OF FILING SHAFTING

four pieces, which must all be ground to about the same length. The illustration shows how this is done.

Put on the carriage feed and bear down on the end of the plank, at the same time moving it to the right and to the left to get different points on the files to work. For the same reason its position should be changed on the fulcrum bolt. Raise and tap the plank occasionally, to free the filings. M. JACKER.

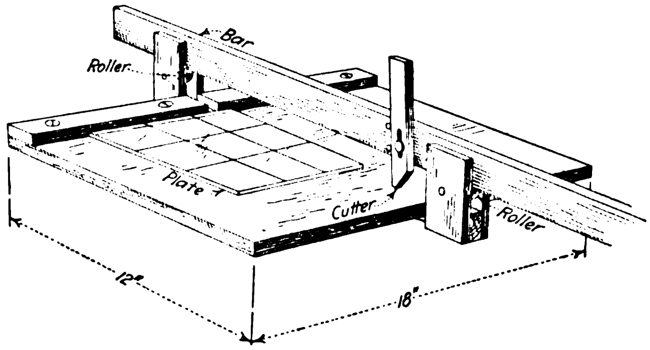
Stockton, Calif.

Glass-Cutting Experience

In trying to cut up several hundred old photograph plates into 1x3-in. strips for microscope slides, it was found that a white diamond point did not cut the surface so that the edges would break away in an even line, but left a jagged edge. The longer the point was used the worse the breaks became, until it was impossible to get the strips off without breaking a great many.

The glass plates were placed on a flat board 12x18 in. in size, having a squaring ledge at the back and lines for gaging the size of the strip. The cutter was held in an adjustable head secured to a traveling bar, the bar being guided by two upright pieces at the edges of the board and at right angles to the squaring ledge. As the bar was pushed across the board, the diamond point came in contact with the surface of the glass and scored it across.

It was decided to remove the diamond and try something else. An ordinary hand glass cutter with a knife-edged roller cutter was clamped to the bar and a few plates scored. The results was very satisfactory, as the



A GLASS-CUTTING BOARD

strips would in some cases break away by their own weight and the edges were smooth and straight, needing very little grinding to finish them ready for use.

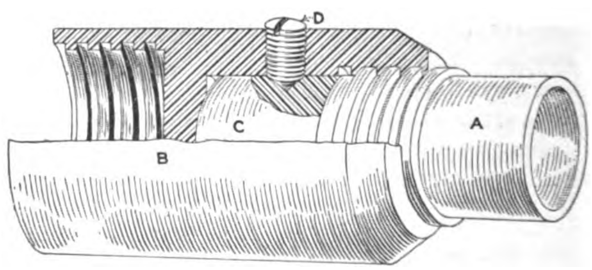
The diamond was from a finger ring and was mounted in a holder just the reverse of the ring setting, leaving a fine uniform point exposed to the work. The rollers are bought at any hardware store, but they must be sharp to give the best results. GEORGE G. LITTLE.

Rochester, Minn.

Boring Jig with Thrust Releasing Stop

In the accompanying illustration *A* represents a bushing threaded at one end on the outside and having a hole drilled and reamed from the opposite end, but not quite through the piece. On that account it was decided to hold the bushing by the threaded portion in machining the bore. After this operation it was difficult to remove it from the jig until a special holder was made.

In the illustration *B* represents the body, which screws on the spindle of the lathe and is threaded at the opposite end for holding the work. At *C* is shown a sliding stop block fitting inside of the holder and held in position by the hollow setscrew *D*.



BORING JIG WITH THRUST RELEASING STOP

It is evident that, although the pressure of the cutting tools may cause the bushing to tighten considerably against the stop block, this pressure will be removed as soon as the setscrew *D* is loosened slightly. Then the machined part can be unscrewed by hand. When this screw is again tightened, the stop is set properly for the next casting. R. R. CORNELL.

Providence, R. I.

Discussion of Previous Question

Face-Forming Tool for a Lathe

With reference to Mr. Hutchins' comment on the face-forming tool for a lathe, page 387, Vol. 44, I wish to say that the device really is practical and has successfully finished eight such pieces as are shown in the illustration. These pieces were parts of molds for producing distributor heads.

The rough dimensions of the tool were 8x2x½ in. The rough dimensions of the piece being tooled were 1⅞ in. extreme in depth by 3½ in. in diameter. The amount of cutting surface on this tool had reached the limit for one of such dimensions, a larger cutting surface requiring a sturdier tool.

Contrary to Mr. Hutchins' views, the tool is of little value for roughing, being used only for finishing. There was, however, a tendency to dig in a little, causing a slightly rough surface, if pushed too hard. All forming tools will dig in somewhat and produce a poor surface, if pushed too hard or improperly lubricated. The serious digging in of any tool—that is, digging in so deep that it breaks—is caused by its being improperly held in relation to the work. As an example, a parting tool so placed in a machine that spring in the tool will result in its advancing toward the work will cause it to chatter, dig in and break, even if it presents only $\frac{1}{16}$ in. of cutting surface to the work, while a similar tool presenting 2 or 3 in. of cutting surface, if properly placed and held in relation to the work, will remove a thin shaving chip without trouble.

It should be noticed that the tool is inclined in such a manner that it has a tendency to spring away from the work. A good lathe was used, and two wedges, of wood, were tapped under the chuck while it was in motion, thus causing the spindle to bear against the top of the bearing. The wedges, together with the inclination of the tool, eliminated all danger of chattering or digging in, such as would cause breakage of the tool. As is necessary with all forming tools, this one possessed a very keen cutting edge. The tool was hardened all over and drawn to a straw color at the cutting edge and blue elsewhere. The lathe was run at the slowest speed.

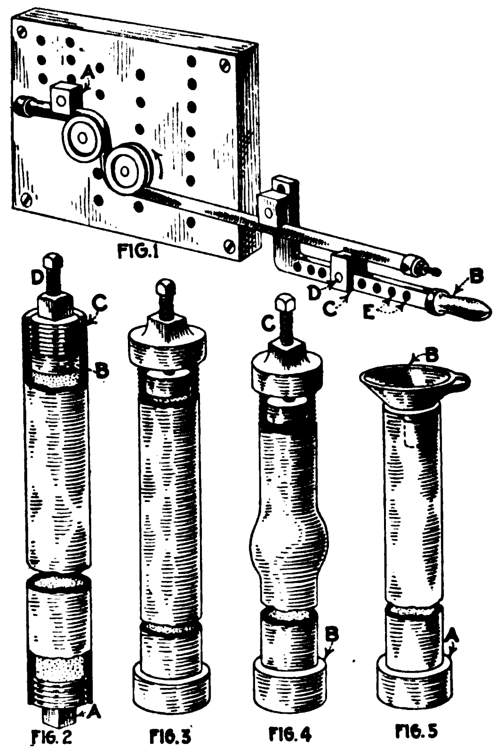
Newark, N. J. GUSTAVE A. REMACLE.

Bending Small Tubes Without Rosin Filling

I noticed with much interest the article by A. R. Nemour, on page 118. The method described is not an easy way of bending pipes, but quite complicated, so far as I can see. It must take some pains, accuracy and time to bend a spring to the required diameter so that it will fit inside a pipe and then, after it has been bent to the complicated shape, to take it out of the pipe. I do not see how the spring can be used a second time. If it can be used only once, the bending will be quite expensive; and I believe the process is also very slow.

As A. R. Nemour states in his article, experiments are necessary to get the size, the temper and the thickness of wire to be used. This requirement certainly would make a special job very expensive, and I do not think that a spring can be removed at all if the pipe has more than one bend or has some complicated curvature of bend.

Some time ago I had a number of pipes to bend. They were of different sizes and materials, also of various shapes. Some had intricate bends, and a number of different sizes of curves. The following description shows how the work was performed quickly and with little skill with a simple tool.



BENDING SMALL TUBES WITHOUT ROSIN FILLING

In Fig. 1 is shown the bending tool, with a pipe bent in position. This tool was used for bending every imaginable shape of pipe, with various diameters and of different materials. It is made of a cast-iron plate, with a number of holes, and stop block *A*, which is shaped to fit the radius. By changing the roller positions in the different holes different shapes of bends can be obtained. For short pipes an extension lever *B* was used, with blocks *C* of the same style as block *A*. The pin *D* is interchangeable in the holes *E*, to get various leverages, in order to bend short pipes more easily.

A detail of the bending equipment is shown in Fig. 2. This is a regular pipe plug *A*, for one end of the pipe to be bent, a plunger *B* and a plug *C*, which has a long adjustable screw *D* in the center. In bending a pipe all the preparation necessary is to plug one end, fill the pipe with fine dry sand, then plug the other end and com-

press the sand by the plunger and adjusting screw. In Fig. 3 is shown the same arrangement, but with a threaded collar, as shown, which is at times preferred.

In Fig. 4, at *A*, is shown a special shape that I have bent by this method, using sand and the device already mentioned. If such a shape is required, the pipe must be heated just at that point, as shown at *A*, and pounded on a hardwood block at the end *B*. After a little pounding, the screw *C* is gradually compressed until the desired form is obtained. In this case more than one heating is required, depending entirely on the shape. Such shapes can be quickly bent without any special arrangements.

In Fig. 5 is shown a pipe ready to be filled. The end *A* is plugged up, and in order to fill with sand quickly, a funnel *B* is used. The bending of pipes is done in the following way: After the sand is poured in, the pipes are plugged and the plunger made tight, as described. The bending is very simple and rapid. In bending rough pipes they must be heated at the bending point, and the sand can be compressed tightly. Seamless tubing is also heated for bending, and the sand is compressed a little more lightly than in rough pipes. Hard copper or brass tubing is heated in the same way as rough tubing; the sand should be compressed only lightly.

For soft copper or brass tubing no heating is required, if the bend is not too complicated, and the sand is to be compressed slightly. It is well to pound the tubes on a hardwood block when they are filled, in order to get a solid body of sand. Then very little adjustment is required.

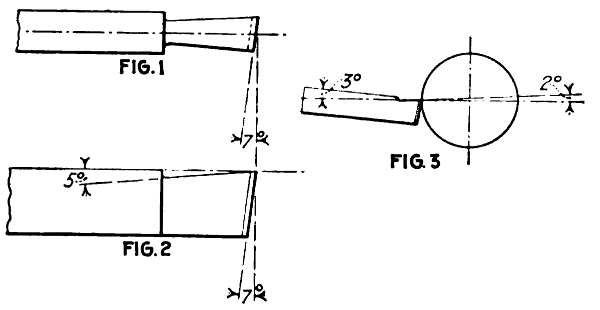
It is important to have the sand really dry before the pipe is heated. If the sand is not dry enough and both ends are plugged, it may cause trouble—either cracking the pipe or blowing out the plug. With the method just described, pipes up to 4 in. in diameter, of different materials, have been bent at a reasonable cost and in a satisfactory manner. CHARLES EISLER.

Bloomfield, N. J.

Cutting Off Steel in the Lathe

In the *American Machinist*, Vol. 44, page 294, Mr. Remacle describes a method of grinding and setting parting tools for cutting off steel. While indorsing all Mr. Remacle says, I have something to add.

In our experience with cutting-off tools, not only in the lathe, but in various automatics as well, we have



GRINDING AND SETTING CUTOFF TOOLS

long since learned to pay strict attention to angles and so to design all tools that they may be readily reground without changing the original angles. Now, while Mr. Remacle's idea removes some of the trouble caused by chatter, digging in, etc., we have found that a cutting-off tool ground and set as in the drawing will work exceptionally well and at higher speeds and feeds.

In Fig. 1 is shown a parting tool, in plan. The 7-deg. rake gives the tool a chance to enter the stock gradually and not all at once. This arrangement diminishes chatter and acts also as a "brake"—so to speak—against digging in.

Fig. 2—the tool in elevation—shows a clearance of 7 deg. and a top rake of 5 deg. This 5 deg. enables us to follow a setting practice pretty much like that described by Mr. Remacle, only we have definite angles. With the shank of the tool set at a 3-deg. center line, Fig. 3, we are using a 2-deg. top rake at the cutting edge, when the latter is set at the center of the work being cut off, because 3 deg. and 2 deg. give our original rake—5 deg.

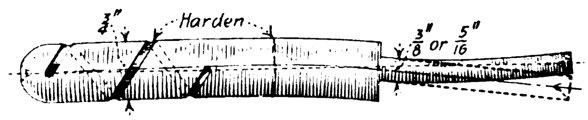
A tool-post wedge of 3 deg. should be used and the tool set to a stop, so it cannot be set wrong. All grinding should be done on top of the tool only and to a gage.

As Mr. Remacle states, the cutoff tool often is disappointing; but maybe if we paid a little more attention to grinding and setting, we should all be happier, including the neglected, unfortunate cutting-off tool.

Plainfield, N. J. J. B. MURPHY.

Grinding Die-Setting Pins

I believe that Mr. Kirchmer's article on page 205 describes the best grinding kink that has come to my notice, but why not use the stem in connection with the friction drive, even though a dog is not required? A stem 2 or $2\frac{1}{2}$ in. long provides a means by which a pin, badly distorted in hardening, may be thrown into line, when without it the pin might not grind clean all



GRINDING DIE-SETTING PINS

over. I intend to use this combination on the next set of pins. Of course, the stem and butt end of the pins are left soft, only the working part being hard. The stem center should be reamed before grinding, to insure a good bearing. W. J. WELLS.

Brooklyn, N. Y.

Cutting Downward in the Lathe

The editorial on page 255 was very interesting to me, as it brings to my mind an instance where it was almost necessary for me to cut downward.

The job was to cut the centers out of some machine-steel pieces about 8 in. square by $1\frac{1}{4}$ in. thick, the holes to finish about 3 in. in diameter. I found it impossible to tighten the bearings enough to keep the work from chattering and the cutter from "hogging" and breaking off, when it was right side up, so I turned it over and cut back of the center with the lathe running forward.

The trouble stopped immediately; and I think that, besides holding the spindle down in the bearings, another reason for the better action is that, if the cutter tends to stick or dig in, the extra force serves to throw the tool out of the work rather than into it, as the fulcrum is

in a different place, which I think is shown more clearly in the sketches.

In cutting upward, the points *A*, Fig. 1, become the fulcrums. If there is any tendency for the different members of the tool carriage to part at the points *B*, as is nearly always the case to some extent, the cutter swings forward into the work on radii from the points of fulcrum.

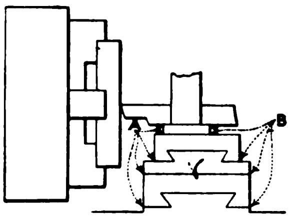


FIG. 1. POINTS OF FULCRUM WHEN CUTTING DOWNWARD

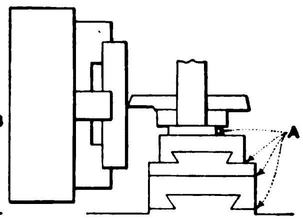

FIG. 2. POINTS OF FULCRUM WHEN CUTTING UPWARD

In Fig. 2, cutting downward, the points of fulcrum are at *A*, which causes the cutter to swing from the work on radii from these points, thus relieving it.

In cutting off work on centers or in the steadyrest I have found the same scheme to work better than cutting upward, the same reasoning with regard to the point of fulcrum being applicable. HAROLD E. GREENE.

Ilion, N. Y.

Correcting Inaccurate Spacing

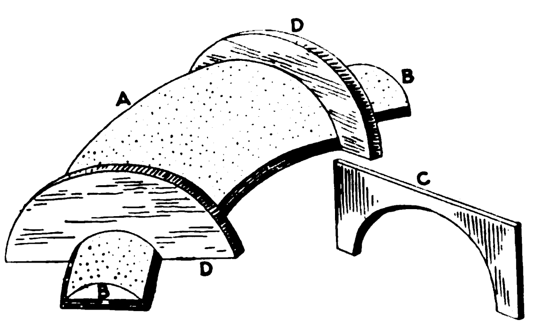
To correct the center distance between the holes *A* and *B* in the illustration on page 360, Vol. 44, one would either have to broach the inside edge of both holes or make the broach 0.0004 in. larger than the original size of the hole and broach the inside edge of the hole *A*. By making the broach 0.0002 in. larger the holes would still be 0.0001 in. too far apart center to center.

Chicago, Ill. HENRY SWINDELLS.

Economical Patterns for Temporary Work

I cannot agree with either Mr. Francisco, page 1129, Vol. 43, or Mr. Parker, page 165, in regard to the methods they use. I think a better and a quicker way to make a temporary pattern of this kind is as follows:

Cut out a body form *A* with the two core prints *BB* on a jig saw, from any thickness of board. Then cut out the two flanges *DD*, of any thickness desired, and attach them to this form. Lay the form on a flat surface and cover it with plaster of paris. While it is green, use the former *C* by drawing it over the form *A*, the sides of which will make a guide. Use a smaller form for the core prints. Form *C* is made from sheet metal about $\frac{1}{16}$ in. thick.



ECONOMICAL METHOD FOR TEMPORARY PATTERNS

This operation completes one-half of the pattern, and the other half is made similarly. The same method is used in making the core-box form. When finished, shellac and oil the form, then cover it with plaster of paris to make a good solid core box.

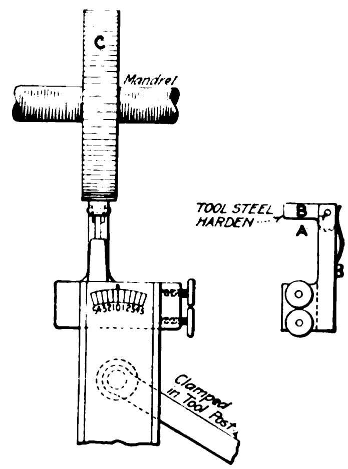
A 4-in. elbow pattern and core box of this description have been made in less than 5 hr. A. E. HOLADAY.

Naugatuck, Conn.

Gage for Testing Cutters

Mr. Smith, on page 732, Vol. 43, describes a gage for testing the truth of milling cutters. Experience on a similar subject prompts me to describe another simple method of testing the truth of cutters, gears or anything presenting an irregular surface.

It was essential that the circular form *C*, which is somewhat similar in construction to a gear, should run dead true. The indicator shown was the only one available for the job, and the contact point was too small for the broken surface of the form. By applying the adapter as shown, so that part *B* butts against the contact point of the indicator and presents a plane surface to the form, the forms were readily tested. Pin *A* was made a good fit to part *B*, thus preventing lost motion.



A GAGE FOR TESTING CUTTERS

Newark, N. J. GUSTAVE A. REMACLE.

Federal Aid for the Promotion of Vocational Education

An editorial on page 345, on the subject of Federal aid for vocational education, contains several statements on which I should like to see further discussion. Reference is made to the corporation school, and it is stated that its advocates claim that such a school is the only proper method of training for the mechanical trades. I should like to be permitted to bring out one or two arguments that rather question that statement.

I can readily see that, given a city in which there existed both a corporation school and a trade school, a boy passing through the corporation school would be of more value to that particular firm than the boy who had passed through the trade school; but I question very strongly whether this would apply when it came to the question of employment in a different shop carrying on an entirely different line of work. I may not be right about this, but it is the impression that I have formed from both personal experience and observation.

Then, too, there is the coöperation plan, as carried out in Fitchburg, Mass. I believe that this is an excellent scheme for vocational training in a city where there are enough manufacturers who are willing to coöperate to the extent that they do in Fitchburg. It makes a fine method for the boy, because he is working for wages and getting his education at the same time. The cost to the community is small. But here in my opinion is the weak spot of the system: It is open only to a selected group of boys, who have reached their second year in the high school, which on the average means that they are at least 16 years of age. Statistics show that the big majority leave school at 14 years of age, owing to the economic pressure, which I assume means that whatever they can earn will be very welcome at home.

Neither plan outlined makes any provision for the 14-year old boy. Is this right? From a great many standpoints I believe that it is; but at the same time, what is to become of this boy? Many parents can be induced to send him to a trade school for two or three years, but to ask them to continue to support him until he is 18 or 19 years of age is requiring more than they are willing to do.

While corporation and coöperation schools are good for the places that have them, what about those communities which have boys, but no schools of the aforementioned type? This is the place, it seems to me, where the public vocational school can do the most good, because a boy should not be deprived of the privilege of getting a trade education simply because there did not happen to be in his town any large manufacturing concern that was broad enough to inaugurate such a system.

The following statement, "We strongly believe that it is fully as essential to have the boy know why he performs each operation as to learn how to do it, both from the viewpoint of making him a better workman and to give him an added interest in his work," pleases me, because it is in a sense an indorsement of the method which is followed to a great extent in the Massachusetts schools and which, I believe, will turn out broader workmen—young men with a better idea of what they are trying to do—than if they learn by performing one operation on a great number of duplicate parts. By making one piece complete from start to finish, the reason for each operation and the logical sequence that must be followed cannot help but be impressed on the apprentice. And at the same time he not only learns how to manipulate his machines as may be required, but he gets a broader insight into his work, owing to the better conception of the piece as a whole.

In regard to the question how much a boy should be taught in the vocational school, there is a great difference of opinion. We must recognize the fact that there are a great many of us born to occupy the lower positions—limited to such by the amount of brains given us at birth. Whether or not a little training will enable such a one to step up to a higher position in the wage scale is a question I am unable to answer to my own satisfaction. Whether it would pay a community to spend money in training boys to become machine operators is also an open question; but I do feel that such training, if given, should have a well-defined limit, to be determined solely by the financial side of the question. That is, we should have a predetermined wage, and it should be held unprofitable for a community to train its boys to occupy positions paying less than that wage. Just what that amount should be, I will leave for some financial expert to figure; but surely it should be well above the wage of the day laborer, who gets his job whether he has had any preliminary training or not. Yet this may be a very unscientific statement to make in view of what scientific management has been able to do in increasing efficiency.

Personally, I believe that these shops should give as broad a training as it is possible for boys of that age (14 to 17) to absorb and benefit by. The shopwork should be uptodate and as thorough as it is possible to make it, while the technical side of the training should be equally as good, though it must first be practical. Later on, if there is time, it might go into the theoretical side.

It had never occurred to me than in training boys to be machinists it would be of any advantage to them to understand forging and woodworking. I had always felt that even the three years allowed to the machine shop were hardly enough, and yet I have talked with several machine-shop foremen lately who have voluntarily expressed such a belief, stating that it would tend to develop broader and more capable men.

On further questioning, while one or two differed, it was the general consensus of opinion that the shops in which the machinist was allowed to touch the fire were very few and far between, and as for permitting him to venture into the pattern shop, that was unheard of. Now these men are practical everyday machinists working at their trade; while they may not be able to give any good logical reason for their belief, it is very evident that for some reason which they are unable or unwilling to express they hold firmly to it. BURTON A. PRINCE.

Westfield, Mass.

Wanted--Data on Drill Wear

One who has had experience in the drilling department of a machine shop has no doubt been puzzled by the action of twist drills. Among a number of these taken from the same package one may stand up for three or four hundred holes without the need of regrinding, another need attention after half that amount of work has been accomplished and still another fall down after drilling a comparatively few holes.

Comparatively little information has been published on the life of twist drills, and the articles that have appeared lack uniformity. In commenting on the desirability of such data a correspondent submits the following example:

How many inches in depth should be drilled between each grinding or sharpening of a high-speed drill about 1 in. in diameter; material drilled, 40 carbon steel; speed, 400 r.p.m.; rate of feed, 3 in. per min.?

Authentic records on the life of twist drills should prove especially timely.

Editorials

Code of Factory Lighting

The code of lighting for factories, mills and other work places, prepared by the Illuminating Engineering Society, was discussed on the evening of Mar. 14 at the joint meeting of the New York section of the society and the New York section of the American Society of Mechanical Engineers. This is the first time the code has received general discussion. The articles of the code and an explanation of the purpose behind its preparation were published in the *American Machinist,* Vol. 43, p. 547.

The trend of all the discussion was favorable to the code and emphasized that it is a piece of pioneer engineering work that promises good to employer and employee alike, if its provisions are used as a basis for state laws or commission regulations. Only a few points were touched upon as possibly needing changes or improvements. But the attitude of the manufacturer toward the code is of some concern, although the Commissioners of Labor of the States of New Jersey and Pennsylvania were quoted as saying that in their opinion there would be no difficulty whatever in enforcing the laws or regulations that might be framed in keeping with its provisions. They believe that manufacturers will welcome something of this nature. As a matter of fact, improvement in factory lighting has received considerable attention in the technical press during the last five or six years, and much has already been done by way of installing better artificial lighting systems and better lamps during that period.

In spite of the improvements made by progressive shop managers there are many manufacturers who still provide in their factory buildings so low a standard of illumination and so poor a quality of light distribution that their employees are subjected not only to the risk of serious accidents, but to the hazard of permanent injury to their eyesight. A corrective force is now arising in public interest and opinion, and regulation such as is aimed at by the initiators of this code will undoubtedly soon come into effect in many states. As a matter of good business it is wise for manufacturers to provide more and better illumination than any standard likely to be enforced as a minimum requirement in any state, and the well-informed, progressive shop owner and manager will favor the wise regulation of industrial lighting and not oppose it.

But this favorable attitude is not the only one that the manufacturer should take. Even if there is no intent to favor any particular interest on the part of those who are intrusted with the duty of framing such regulations, there is a danger that unwise requirements may put manufacturers to unnecessary hardship without accomplishing any beneficial purpose, unless every engineering aspect is carefully and properly considered. Judging from other fields, the general practice will be for the state to assume the authority for such regulation, although matters of this kind are sometimes governed by municipal ordinances.

We face here, as in all such things, the possibility of many different sets of legal requirement or commission rules. The advantages of uniform practice are obvious; and it is fortunate indeed that, before industrial lighting has been surrounded by a maze of irreconcilable rules, the Illuminating Engineering Society has come forward with this code.

Its requirements will affect the manufacturer in the financial management of his plant, the mechanical engineer in installing and operating shop equipment, and the workman in regard to his personal safety, physical well-being and earning capacity. These men, taken collectively, have the right to insist that such a code shall justly safeguard the three following interests: The physical well-being of everyone against accidents and impairment of eyesight; the productive capacity of everyone, by indicating from expert experience the minimum amount of illumination necessary for manufacturing and all other processes; the competitive position of manufacturers, by imposing uniform requirements upon everyone engaged in the same line of business.

The *American Machinist* believes that the code has been drawn to cover these three interests and bespeaks for it the hearty support of manufacturers in every state where it is proposed to make use of it as a basis for state law or commission rules.

Shipping Documents for South America

The North American manufacturer who embarks in South American trade should realize at the outset that foreign business is transacted in a manner entirely different from that used in domestic transactions. Shipping from Illinois to Argentina is a far different procedure from sending a machine to Michigan. In the first case the manufacturer has to deal not only with his customer, but also with the United States Government, the Argentine Government, the railroad company and the steamship company. In the second case his dealings are only with the railroad company and his customer. There are many more parties interested in the foreign transaction than in the home traffic.

Unless the machine builder does a very large export business and maintains his own foreign department, it it wise for him to introduce still another party into the transaction of shipping from, say, Illinois to South America. This addition is a reliable export agent or forwarder. While his coming counts one more in the dealings, it simplifies the work of the manufacturer by placing numerous details in the hands of one who is experienced in their handling.

Like everything else, there are good, bad and indifferent forwarders, and manufacturers, before making permanent connections with export agents or forwarders, should investigate carefully the standing and past services of the prospective agent, precisely as they would act in making

any other business arrangement. Such an export agent should be located at the port of departure, which in the case of machinery destined for South America means New York. He should be empowered to act for the shipper in all matters dealing with foreign business.

The agent, when first engaged, sends to the manufacturer bills of lading, certificates of origin of merchandise (for Argentina), consular invoices (for Brazil) and the shipper's export declaration. These papers are sent in the form of blanks and specimens properly filled out. He may even offer suggestions in regard to packing, for the North American manufacturer is notorious the world over for improper, insufficient boxing and casing. All machinery for South America should be packed in extra-heavy boxes, in which every part should be securely braced and all fragile articles protected by padding at the corners and along the edges. The boxes, or cases, should be bound by iron bands. When such a box or case is being designed, it should be remembered that it is more than likely it will be dropped from the derrick of a steamer in some South American roadstead into a lighter tossing about in a heavy sea. Some careful manufacturers, especially the Germans, take the precaution to provide extra-large cases with rope slings, thus assuring safe hoisting means for each package. This practice might well be imitated by North American manufacturers.

After the machine builder has properly boxed his machinery in keeping with these general instructions or the instructions of his forwarding agent—not forgetting to mark his cases properly—he sends the machinery to New York, at the same time mailing to his export agent the consular invoices, bills of lading and his draft drawn to his customer's order. In case the manufacturer is selling on credit he fills out this draft with the amount and for the term specified. In case he is selling "cash against documents" he leaves the amount of his draft blank. The export agent fills in the proper amount by adding to the manufacturer's price his own shipping charges. Where the manufacturer's draft is drawn for payment on credit, as 90 or 120 days, it is customary for the export agent to make out his own sight draft on the customer to cover the shipping charges and send on both drafts with the shipment.

The export agent also arranges the certification of the consular invoice, bill of lading, insurance and cartage. The fees and expenses for these items, when added to the amount of the manufacturer's invoice, make up the total cost of the goods to the foreign buyer.

All the documents, when finally prepared by the export agent, are sent forward on the same steamer that carries the goods and are addressed to the customer's bank in South America. It is customary for the agent to ship in his own name, to avoid the formality of exhibiting his power of attorney when taking oath before the consul. It is absolutely essential that all these documents be properly prepared and forwarded on the same steamer that carries the merchandise. Otherwise, the customer is compelled to pay a fine for delay in claiming his goods at his own custom house, with the exception of Brazil, where he can file a bond guaranteed to produce the documents within 90 days. There have been cases where fines of this nature, caused by delay in the mails, have been so heavy that the customer has refused to accept the goods, putting the North American manufacturer to trouble and expense in recovering his property.

While it is true that some of the large railroad companies will accept the responsibility of handling shipments clear through to South American countries, they have to go through the same forms as the one outlined for the export agent. It is evident that the relationship between manufacturer and agent can be much closer than between the manufacturer and the railroad company. Furthermore, the reliable export houses usually have connections in every principal port of South America and can facilitate the transshipment of goods to interior points.

There are some exporting houses that buy from the manufacturer direct, paying him in cash, and assume their own responsibility for shipping, and collecting from their customers. Generally speaking, however, the manufacturers who have been best pleased with their foreign business have either acted through a branch office or through a reliable export agent. The charges for the agent's services are not excessive and are paid for by the customer, as already explained. The service is evidently well worth all that it costs.

Another way in which the agent can help his client is by keeping posted in regard to the changes in customs or shipping regulations in South America. There are many of these requirements today, as shown by a helpful pamphlet issued by the Bureau of Foreign and Domestic Commerce at Washington, D. C. It is entitled "Consular Regulations of Foreign Countries" and costs 10c. As an illustration of some of these matters, all goods shipped to South America destined for interior points should be marked "En transito para ——." In the blank space should be filled in the name of the destination. Translated, this means, "In transit for ——." As another example, all cases destined for Brazil should have both the net and the gross weight marked on the outside in kilos, not in pounds.

Using Two Loading Stations; Drilling Speeds

There are two noticeable features in connection with the special shell and fuse machines illustrated in this and the preceding issue. One is the use of two vacant stations—one for loading and the other for unloading. This practice provides for the employment of two operators in case the speed of the machine is too great for one operator.

The other is the specific information in regard to drilling small holes by revolving both the work and the drill, in connection with the steel gaine and the brass graze pellet. The steel gaine, with its drill of only 0.031 in., is run at 800 r.p.m. in an opposite direction to the drill, which has a speed of 4,500 r.p.m., giving a total equivalent drill speed of 5,300 r.p.m. In the brass work, however, the drill speed is a third higher and the work speed 50 per cent. more—6,000 and 1,200 r.p.m. respectively, or a total of 7,200 r.p.m.

These speeds are evidently the result of much experimenting, and the relation between the drill and the work speeds is of particular interest. Here is a subject that has not had the study that might well be devoted to it, partly because of the lack of incentive and partly because we seldom seem to have the time. The drilling of ordinary holes is more of a problem than we are apt to think, and doubly so when the holes are many diameters deep.

Shop Equipment News

Special Lathes for Making Large Shells

The demand for lathes suitable for the rapid production of heavy shells and the success of single-purpose machines for use in that work have led the Root & Van Dervoort Engineering Co., East Moline, Ill., to design and build a line of such machines.

The machines are excellent examples of simplicity of design combined with great strength and rigidity. The headstock is the same on all the lathes, the bed, carriage and feed being suited to the work to be done. The spindles are of cast iron, hollow, to allow either 8-in. or 9.2-in. shells to be held inside by air-controlled collet chucks for boring. The bearings are also of cast iron, of ample size, as can be seen from the dimensions, the front being 14 in. and the rear $7\frac{1}{16}$ in. in diameter, with a total spindle length of $40\frac{1}{8}$ in. They are driven by a 4-in. double belt with gear ratios of 6 to 1 and 8 to 1. These can of course be changed, should others be desired.

Two sizes of pedestal lathes are made—one with a bed 4 ft. 5 in.; the other, 2 ft. longer. These are for cutting the band groove and trimming the end to weight. The lathe for boring and turning has a 10-ft. bed and is supported at the outer end. It has a regular carriage, with a large feed screw and rack, stops for the tool slide, trips for the feed and other conveniences, such as an open-side tool post of heavy design, not shown.

The illustrations show these lathes as set up in a shop for manufacturing shells rather than for exhibition. Fig. 1 shows the chain feed and special three-screw chuck.

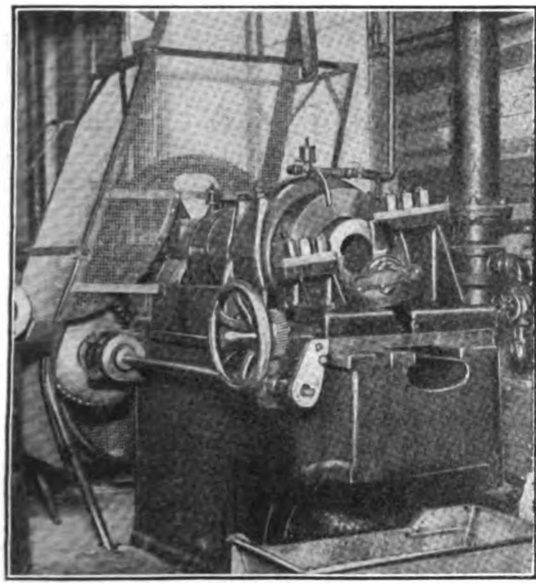


FIG. 1. CUTTING-OFF MACHINE

Spindle bearings, front, $14 \times 8\frac{5}{8}$ in.; rear, $7\frac{1}{16} \times 7\frac{1}{8}$ in.; length of bed, 4 ft. 5 in.; belt, 4 in. double; gear ratio, 8 to 1; weight, 4,500 lb.

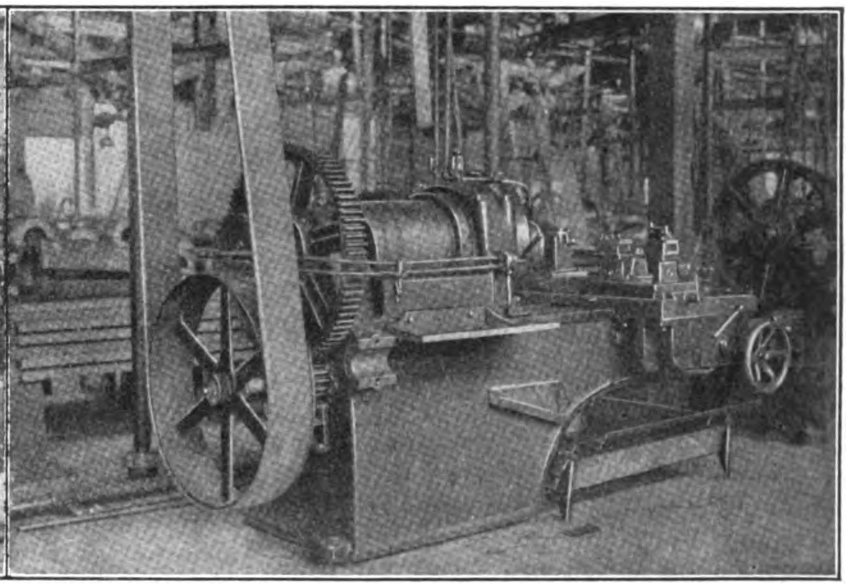

FIG. 2. LATHE FOR TURNING BAND GROOVE

Spindle bearings same as Fig. 1; length of bed, 6 ft. 5 in.; air chuck; belt, 4 in. double; spindle cast iron in cast-iron bearings; special turret and back tools; gear ratio, 6 to 1; weight, 4,800 lb.

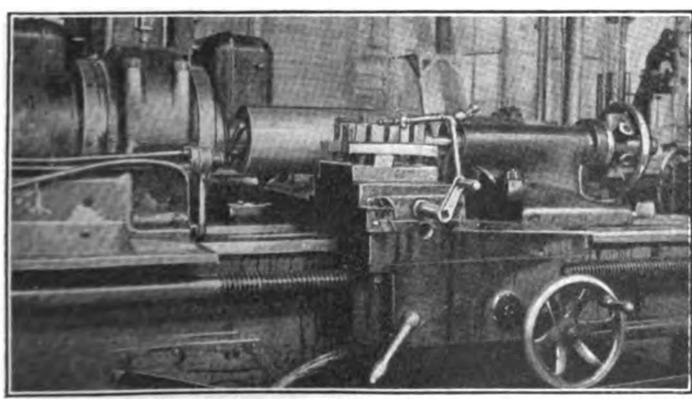

FIG. 3. TURNING OUTSIDE OF SHELL

Spindle and gear ratio same as Fig. 2; special expanding mandrel; length of bed, 10 ft.; weight about 7,500 lb.

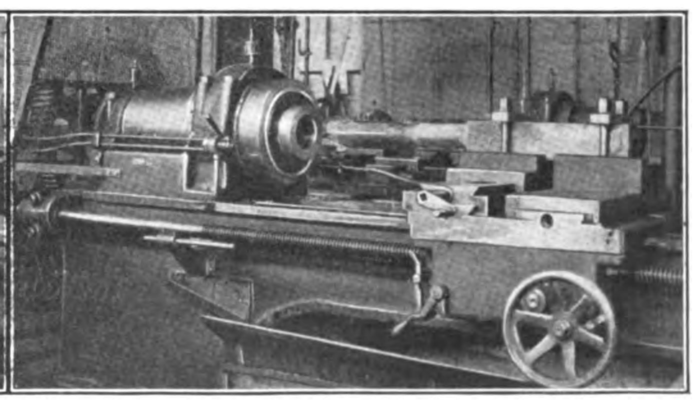

FIG. 4. BORING LATHE

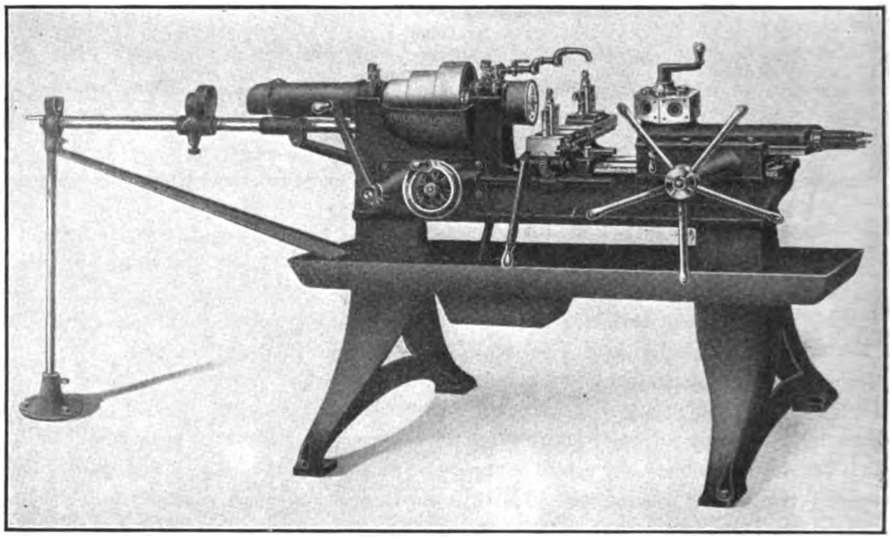
Spindle and gear ratio same as Fig. 2; no tailstock; bed and weight approximately same as Fig. 3

A special carriage is shown in Fig. 2, for cutting and waving the band groove. This illustration also shows the air pipes and valves for the chucks and gives a good idea of the driving gears. Fig. 3 is a close view of the turning lathe, to show the tailstock, in which the handwheel is stationary and is also provided with holes for a bar, if necessary. It gives a good idea of the spindle bearing, the mandrel screwed into the spindle and the four-bolt tool post. The open side is supplied if preferred. Fig. 4 shows the boring lathe with a bar in place and a shell in the chuck. It also illustrates the carriage control and trip. This line is really more than a number of lathes. It is rather a method of large-shell manufacture for which machines and special tools have been worked out and can be supplied ready to begin production. It will be noted that in each of the machines illustrated especial attention has been given to securing rigidity of cutting tool support and the avoidance of light and complex parts or attachments. This has resulted in increased pulling power.



MILLHOLLAND NO. 2 SCREW MACHINE

Bar-stock capacity through auto-chuck, 1 in.; swing over bed, 13½ in.; swing over cutoff, 6 in.; cutoff travel, crossfeed, 5½ in.; cutoff, longitudinal, 9 in.; diameter holes in turret, 1¼ in.; center of holes in turret to top of slide, $2\frac{3}{8}$ in.; diameter of hexagon across flats, 7¼ in.; greatest distance end of spindle to turret, 15 in.; width of drive belt, 2¾ in.; friction pulleys on countershaft, 12x4 in.; speed of countershaft for steel, 230 r.p.m.; for brass, 560 r.p.m.; hole in spindle, $1\frac{3}{32}$ in.; thread on spindle nose, 3¼ in.; diameter, 8 pitch; net weight, 1,275 lb.; crated, 1,450 lb.; boxed for export, 1,650 lb.; measurement, boxed, 72 cu.ft.

Light Automatic Screw Machine

The machine shown, which is built by the W. K. Millholland Machine Co., Indianapolis, Ind., embodies many of the features of the previously described product of this company, but is much lighter.

The headstock and bed are cast solid, with a heavy web connecting the front and back bearings. This construction enables the machine to perform heavy work without chatter or vibration. The bearings are die-cast under hydraulic pressure. The spindle is made of high-carbon, hammered steel, with large-size bearings accurately ground and fitted. The automatic chuck is telescoped into the spindle nose, reducing the overhang to less than 3 in. from the face of the front bearing and less than 1¼ in. from the end of the spindle.

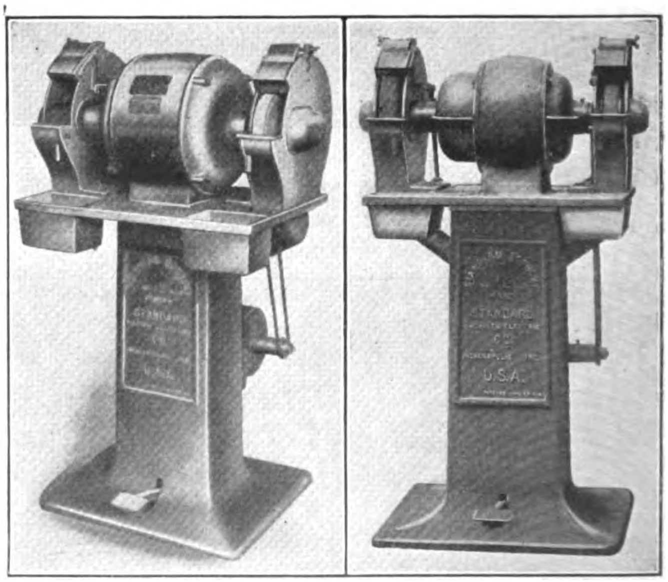
By drawing the hand lever toward the operator the stock is automatically fed forward, and by pushing the lever back the automatic chuck grips the stock and simultaneously centers it to run true. The collets are removable and interchangeable and can be supplied to hold round, square or hexagon stock. All parts of the chuck mechanism are hardened, and they are ground on the bearing points, making them almost indestructible. Special collets can be supplied to hold castings or forgings.

The turret mechanism is automatic in its functions, the indexing and stops being entirely automatic in their action. The turret is hexagon in shape, drilled and tapped to hold special fixtures besides the tools that fit in the tool holes in the faces. The stops on the turret are quickly and accurately adjusted for any desired length. The cutoff slide is provided with a lever cutoff, but a screw feed can be furnished, if desired. The longitudinal adjustment of the cutoff carriage has a device for accurate multiple-shoulder cutting.

The oil pan is made from heavy-gage sheet steel. The oil pump delivers a full stream of coolant while running in either direction. Special turret tools will be designed and supplied for any class of work for which the machine is suited. A standard set of tools can be furnished, if specially ordered. A double friction countershaft accompanies each machine.

Two Motor-Driven Grinders

The grinders here shown are of two types—alternating- and direct-current motor driven. Fig. 1 shows the alternating-current and Fig. 2 the direct-current type. They are made by the Standard Machine and Electric Co.,



FIGS. 1 AND 2. ALTERNATING- AND DIRECT-CURRENT GRINDERS

Motor, 3 hp., 3 phase, 60 cycle, 220 or 440 volt; maximum size of grinding wheel, 12x2 in.; wheel collars, 5½x1¼ in.; length of arbor, 26 in.; diameter of arbor where wheel goes, 1¼ in.; floor to center of arbor, 39 in.; base, 20x23 in.; speed, no load, 1,800 r.p.m.; speed, full load, 1,720 r.p.m.; exhaust fan, 6x2 in.; weight, complete, 575 lb.

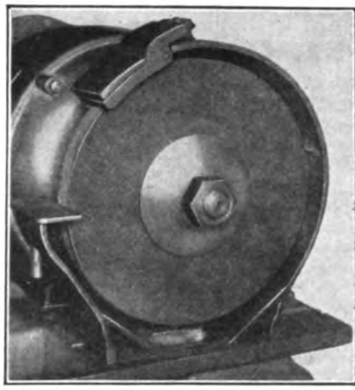


FIG. 3. HOOD WITH NEW WHEEL IN PLACE

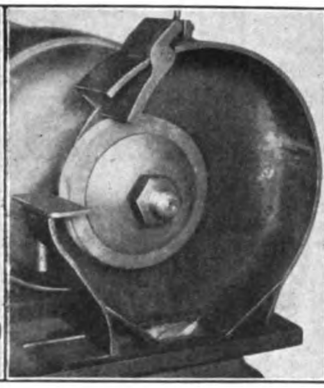

FIG. 4. POSITION OF HOOD PARTS AS WHEEL WEARS

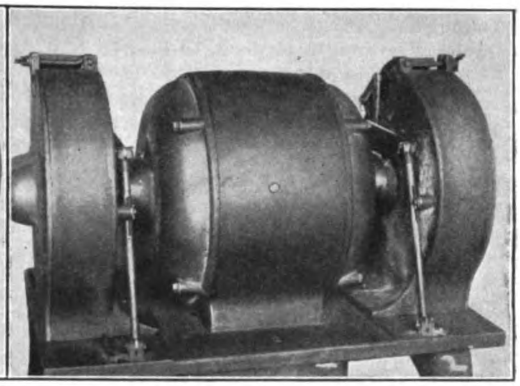

FIG. 5. ARRANGEMENT OF LEVERS FOR BREAKER OPERATION

Indianapolis, Ind. With the exception of being fitted for the use of different current, they closely resemble each other.

One of the principal features is that the machines are running only while in actual use. As the operator goes to the machine to grind, he steps on a foot treadle, the wheels instantly commence to move and quickly get up to full speed. As he leaves, the release of the treadle opens the switch and stops the machine.

Arrangements are provided so that a sudden forcing of the work on a wheel will not cause a burn-out. All of the electrical apparatus is combined in the machine itself, with suitable fuse blocks on the back of the column, where they are easily accessible. In setting up a machine only two wires need to be connected for the direct and three for the alternating type. Both the motor spindle and the exhaust fan are equipped with a double row of ball bearings. The electric starting action is purely mechanical. The exhaust fan is belted direct to the spindle and starts with it.

Attention is called to the wheel hoods. The work rests are quickly adjusted to the wheel as it wears, by loosening a hand bolt and sliding the hood along. The same operation automatically adjusts the spark and dust breaker guard at the top. As a rule, this has to be adjusted separately by the operator and in consequence is seldom moved at all, leaving a large open space above the wheel.

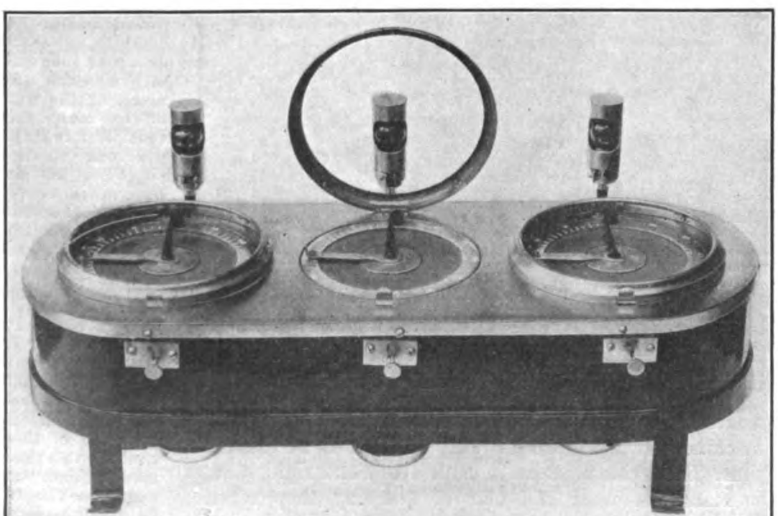
The action of this breaker is plainly illustrated in Figs. 3, 4 and 5. In Fig. 3 the hood is shown with a new wheel on the spindle. As this wheel is worn down, the work rest is pushed along, so as to be close to the cutting part of the wheel, and the breaker assumes the position shown. The position of the breaker makes it necessary for it to travel in faster the more the wheel wears, while the work guard is moved in exact proportion to the wear. This action of the breaker is accomplished by means of a series of levers, arranged as shown in Fig. 5. All parts of the hoods proper are easily removed by the loosening of convenient wing nuts.

Automatic Timing Reminders

The type of instrument described herewith was designed for use where a predetermined time is required, as notably in the case of heat treating steel. The instrument is made in a number of styles, singly or in groups, as shown.

In operation it is simply necessary to set a lever at the number of seconds or minutes it is desired to have work treated, and at the expiration of the predetermined period a bell will ring or a light flash, or the instruments can be arranged to serve both signals. An automatic check is thus kept on the time required for certain processes or operations. The attendant is relieved of the necessity of paying any attention to the time and is enabled to devote attention to other duties.

The hand that normally stands at zero is placed in motion by raising a small lever on the side of the case. The hand travels around the dial until it comes in contact with a lever that has been previously set at the time the operator wishes to be signaled. When the signal is given, the hand releases itself and returns to zero automatically. It will be apparent that the little attention required permits the operation of many instruments by one attendant.



AUTOMATIC TIME REMINDERS

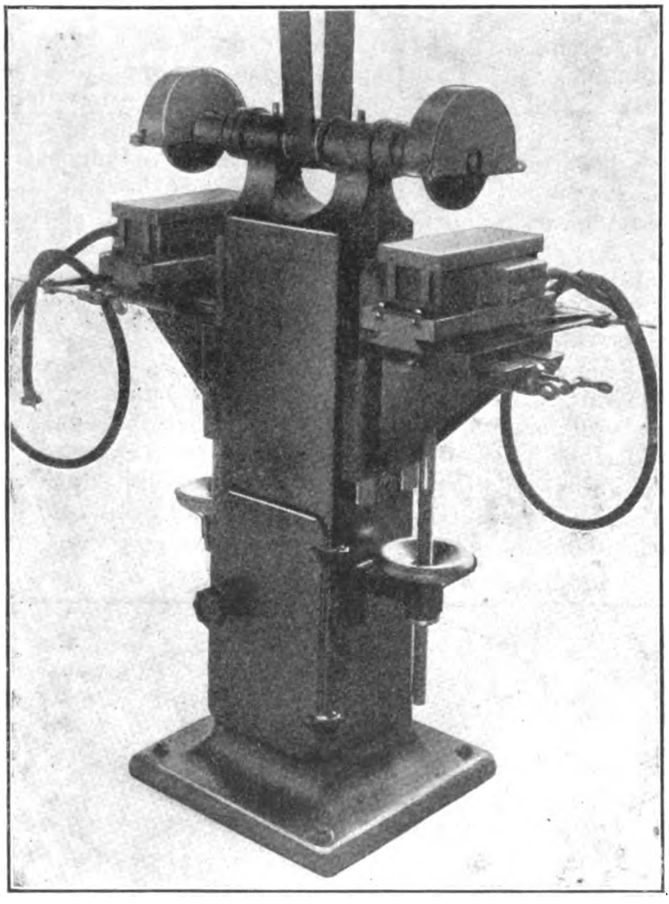
A single instrument is about 9 in. in diameter and 6 in. high. The weight is about 15 lb.

While this class of instrument was designed primarily for application in hardening rooms, there are other classes of work in which they can no doubt serve a useful purpose, such as dipping, electroplating and other electrolytic and chemical processes. The triple type of instrument shown is especially well adapted for a process applied to a certain product in which different times are used for certain elements, as in the case of preheating, soaking and quenching.

These instruments are made in a variety of styles for any special purposes by C. H. Brown, 47 Butternut St., Detroit, Mich.

Double-End Surface Grinder

The grinder shown is intended for the lighter forms of plain surface grinding frequently encountered in manufacturing. Both the table feed and the crossfeed are hand operated, and the screw dials are graduated to read in thousandths. The table traverse movement is by hand lever only. The general construction of the machine



DOUBLE-END PLAIN SURFACE GRINDER
Table, 5¼ in. wide by 12 in. long; extreme stroke, 5½ in.; crossways, 10¾ in. long by 6 in. wide; table movement, 4¼ in. without overhang; vertical ways, 6 in. wide by 16 in. long; knee, 8 in. long on the ways; spindle, 1⅜ in. in diameter by 24 in. end to end; base, 19x19 in.; column, 9x10 in. at base and 7x10 in. at top; overall height, 48 in.; weight, 675 lb.

makes it take up but little more floor space than a single machine, yet two operators can work on it at the same time. The whole machine is made heavy and rigid enough to stand the wear and tear of everyday shop service. It may be had with plain table or fitted with magnetic chuck or vise, as ordered.

It is made by the Stenotype Co., Indianapolis, Ind.

NEW PUBLICATIONS

AUTOMOBILE REPAIRING MADE EASY—By Victor W. Page. One thousand and sixty pages, 5¼x8 in.; 479 illustrations. Published by the Norman W. Henley Publishing Co., New York City.

This is a new, 1916 edition of a book that should help almost anyone to become familiar with many details of automobile construction and repair. It is profusely illustrated to show many of the different motors, clutches and other parts and has numerous double-page inserts. It also contains much that seems very elementary in the way of showing pliers, vises and similar tools, and many of the illustrations have a familiar look. But the average garage repairman should be able to find much of value about cars with which he may not be familiar, while owners can get many suggestions that should help keep their cars out of the repair shop. The book includes ignition, starting and lighting systems and tire repair.

THE WELDING ENGINEER. L. A. MacKenzie, editor. The Welding Engineer Publishing Co., Chicago, Ill. Domestic subscription, $2 per year.

The issue before the reviewer is No. 1, Vol. 1, of a technical journal founded to meet the needs of those who are interested in the art of welding. The editorial announcement states:

> In the past the problems of the welder have been treated by many of the leading trade journals of this country with beneficial results. The time has arrived, however, when the industry has reached a point where no one of the existing trade papers can devote sufficient space to welding topics to keep the interested reader fully advised on welding subjects. In other words, the welding industry has become a specialized field, and a specialized trade paper is needed.

The standard journal size of 9x12 in. has been adopted, and the make-up and illustrations in this first number are above the average of new trade publications. The 16 pages of editorial matter cover a wide range of welding practice, in which the leading article treats of welding high-speed steel bits to carbon-steel shanks. The usual features of an alphabetical index to advertisements and a buyers index are included.

ENGINEERING AS A CAREER—Edited by F. H. Newell and C. E. Drayer. Two hundred and fourteen 5x7½-in. pages; cloth bound. D. Van Nostrand Co., New York City. Price, $1.

Reviewed by DEXTER S. KIMBALL*

This interesting book is an effort to present to young men and their advisers some facts and advice concerning engineering as a life work. It consists of 22 short essays on as many phases of industrial life, closely connected with some form of engineering. Nearly all these papers have been written by eminent practicing engineers, the remainder being the work of educators. Each article discusses some field of engineering, with the view of showing what this field is like, what the chances of success are and what characteristics a boy must have, to do well in this line. Most of the articles were first published in the "Cleveland Plain Dealer" and in the "Scientific American" in response to questions asked from time to time about the opportunities and requisites for success in the engineering professions.

It is axiomatic that a collection of articles from such a group of men contains much of interest and profit for young men who are thinking of engineering as a profession. While much of the advice offered is of a standard type, there are offered many facts and illustrations of a practical character that illuminate the several fields of engineering as they appear only to those who have had actual experience in them. Of course, as one of these writers points out, it is doubtful of how much value advice of this kind is to young men, and it may be doubtful how much they will profit by it. But the fact remains that the engineering field becomes more complex daily, and it is only by means of this kind that it is possible to give young men some idea of what their opportunities may be.

It is interesting to notice that, while these papers were written by men in widely different fields and while, as might be expected, their conclusions are not always the same, there are some points on which practically all agree. A great many of them, for instance, state specifically that a college training, if not absolutely essential, is highly desirable and is in any case a great asset. There is, in fact, an undercurrent of approval of the technical school and its methods that is extremely interesting in view of the opposite opinions that are held by many manufacturers and industrial leaders. The articles on Vocational Guidance, by James F. Barker, and that on Incomes of Technically Trained Men, by David E. Rice,

*Professor of Machine Design and Construction, Sibley College, Cornell University.

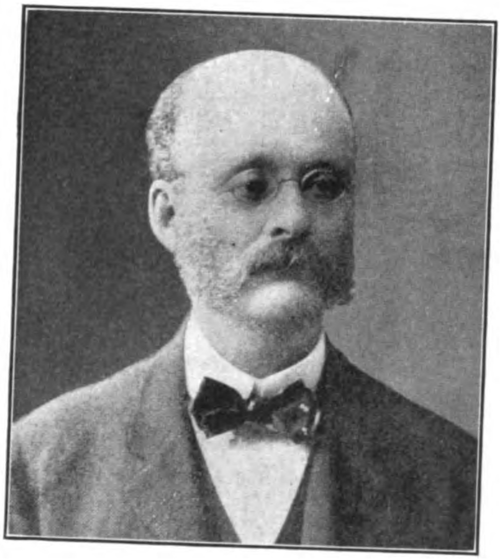
are of particular interest in this respect, as they give some statistics and mathematical examples on the advantages of technical training. We are in need of more data of this kind.

The book will be valuable to young men generally, to parents, to teachers in high schools who are concerned with vocational guidance and to teachers in higher technical schools. All the articles are well written and may be read with pleasure and profit by many other people who wish to know something about the most interesting occupations of modern life.

Melville H. Barker

Melville Hazen Barker, general manager of the American Tool and Machine Co. and one of the most familiar figures in the machine-tool building industry, died at his home in Dorchester, Mass., on Mar. 9, after a brief illness.

Mr. Barker's career in the machinery-building field made him one of its most respected members. For more than 20 years he acted as general manager of the American Tool and Machine Co. In addition to his long business career Mr. Barker's activity in the affairs of the National Metal Trades Association, of which he was a charter member, brought him much prominence. He had been continuously a member of the administrative council of this association since its organization in 1897 and served a term as its president in 1907.



MELVILLE H. BARKER

Mr. Barker was born in Bridgton, Me., 70 years ago.

PERSONALS

John S. Atkinson, for three years with the Cleveland Twist Drill Co., has taken the position of general tool foreman with the Stenotype Co., Indianapolis, Ind.

Forrest E. Cardullo, formerly designer with the Curtiss Motor Co. has accepted the position of chief draftsman of the Pierce?Arrow Motor Car Co., Buffalo, N. Y.

Clement F. Street has been awarded the John Scott Legacy Medal and Premium by the Franklin Institute for his development of the Street locomotive stoker.

R. T. Pollock, until recently assistant general manager of the New England Westinghouse Co., Springfield, Mass., has become vice-president and works manager of the Stenotype Co., Indianapolis, Ind.

B. G. Welchans who has been connected with the Canadian-Westinghouse Comuany, and previously with the engineering divisions of the Bethlehem Steel and American Locomotive Companies, has been appointed general superintendent of the Stanley G. Flagg & Co. plant at Pottstown, Penn.

Arthur C. Wright, recently manager of the Commonwealth Small Arms Factory, Lithgow, N. S. W., Australia, and previous to that foreign connection superintendent of the old Hopkins & Allen plant in Norwich, Conn., is now works manager of the New England Westinghouse Co., E. Springfield, Mass.

H. L. Harrison, formerly connected with the Barber-Colman Co., Rockford, Ill., and more recently superintendent of the munition department of the American Car and Foundry Company's plant at Berwick, Penn., has become production engineer of the Hazelton (Penn) plant of the International Steam Pump Co.

Arthur Churchill, for the past few years at the head of the small tool department of Charles Churchill & Co., Ltd., London, has been elected managing director, succeeding his brother the late Charles Henry Churchill. Willis Churchill who has been associated with the firm for over thirty years has been elected a member of the board of directors. Messrs. Walter Chamberlain and J. W. W. Gabriel remain as active members of the board.

TRADE CATALOGS

B. C. Ames Co., Waltham, Mass. Folder. Bench lathe and fixtures. Illustrated.

W. & B. Douglas, Middletown, Conn. Circular. "Connecticut" high duty lathe. Illustrated.

The Titanium Alloy Mfg. Co., Niagara Falls, N. Y. Catalog. Titanium aluminum and bronze castings. Illustrated, 48 pp., 3½x8½ in.

International Oxygen Co., 115 Broadway, New York. Catalog. I. O. C. bipolar oxygen and hydrogen generators. Illustrated, 24 pp., 8½x11 in.

FORTHCOMING MEETINGS

A course of free lectures on military engineering will be given under the auspices of a committee representative of the four national engineering societies, by Captains Robins, Coiner and Ardery, Corps of Engineers, U. S. A. This course will be under the direction of Major-Gen. Leonard Wood and is designed to assist those who desire to enter the engineering battalion which will be formed at Plattsburg next summer. All engineers interested in preparedness will be welcome, but attendance at these lectures does not imply obligation to subsequent camp duty. Through the cordial attitude and coöperation of the United Engineering Society, the auditorium of the Engineering Societies Building has been placed at the disposal of the army officers. These lectures will be given weekly, having begun on Feb. 14, under the following divisions:

March 27, 1916—The construction, operation and maintenance of railways under military control and the construction and operation of armored trains.

American Society of Mechanical Engineers. Spring meeting, April 11-14, New Orleans, La., Calvin W. Rice, secretary, 29 West 39th St., New York, N. Y.

National Metal Trades Association. Annual meeting, Apr. 27-28, New York, N. Y., Hotel Astor. H. D. Sayre, secretary, Peoples Gas Building, Chicago, Ill.

American Society for Testing Materials. Annual meeting June 27 to July 1, 1916, Hotel Traymore, Atlantic City, N. J. Edgar Warburg, secretary, University of Pennsylvania, Philadelphia, Penn.

American Society of Mechanical Engineers. Monthly meeting first Tuesday. Calvin W. Rice, secretary, 29 West Thirty-ninth St., New York City.

Boston Branch National Metal Trades Association. Monthly meeting on first Wednesday of each month, Young's Hotel. W. W. Poole, secretary, 40 Central St., Boston, Mass.

Providence Association of Mechanical Engineers. Monthly meeting fourth Wednesday each month. J. A. Brooks, secretary, Brown University, Providence, R. I.

New England Foundrymen's Association. Regular meeting second Wednesday of each month. Exchange Club, Boston, Mass. Fred F. Stockwell, 205 Broadway, Cambridgeport, Mass.

Engineers' Society of Western Pennsylvania. Monthly meeting third Tuesday; section meeting, first Tuesday. Elmer K. Hiles, secretary, Oliver Building, Pittsburgh, Penn.

Rochester Society of Technical Draftsmen. Monthly meeting, last Thursday. Secretary, R. H. Barnes, Taylor Instrument Companies, Rochester, N. Y.

Superintendents' and Foremen's Club of Cleveland. Monthly meeting third Saturday. Philip Frankel, secretary, 310 New England Building, Cleveland, Ohio.

Western Society of Engineers, Chicago, Ill. Regular meeting first Wednesday evening of each month, excepting July and August. J. H. Warder, secretary, 1785 Monadnock Block, Chicago, Ill.

Philadelphia Foundrymen's Association. Meetings first Wednesday of each month. Manufacturers' Club, Philadelphia, Penn. Howard Evans, secretary, Pier 45 North, Philadelphia, Penn.

Technical League of America. Regular meeting second Friday of each month. Oscar S. Teale, secretary, 35 Broadway, New York, N. Y.

Prices--Materials and Supplies

IRON AND STEEL

Pig Iron—Quotations were current as follows at the points indicated:

	Mar. 17, 1916	One Month Ago	One Year Ago
No. 2 Southern foundry, Birmingham	$15.00	$15.00	$9.50
No. 2 X Northern foundry, New York	20.75	19.75	14.25
No. 2 Northern foundry, Chicago	18.50	18.50	13.00

SOUTHERN STATES

J. W. Hoopes, Denbigh, Va., contemplates equipping a general repair shop.

The Quantico Co., Quantico, Va., recently organized, plans to construct a steel plant of 7 units. Eldredge E. Jordan, Real Estate Trust Co., Washington, D. C., is Pres.

The Southern Structural Steel Corporation, Burlington, N. C., recently incorporated with $50,000 capital stock, will construct a plant at Burlington.

The Chattanooga Steel Co., Chattanooga, Tenn., plans to construct a plant.

MIDDLE WEST

The Save-a-Life Fender Co. will build a 50x100-ft. factory at Belpre, Ohio.

Bids will soon be received for the construction of a 5-story, 50x80-ft. factory for the American Diamalt Co. at Cincinnati, Ohio. Estimated cost, $25,000.

Work will soon be started on the construction of a 1-story, 130x140-ft. addition to the plant of the Ajax Manufacturing Co., manufacturer of nut and bolt machinery, at Cleveland, Ohio. Noted Mar. 9.

The Cleveland Lathe and Machinery Co., Rockefeller Bldg., Cleveland, Ohio, is in the market for an 18-in. engine lathe and a 10-in. sensitive drill press.

The Cleveland Wire Spring Co., 3864 Hamilton Ave., Cleveland, Ohio, plans to enlarge its plant at Cleveland.

The contract has been awarded for the construction of a 1-story, 28x126-ft. addition to the plant of the Foster Bolt and Nut Manufacturing Co., 3550 East 72nd St., Cleveland, Ohio.

Plans have been prepared for the construction of an addition to the plant of the Lake Erie Iron Co. at Cleveland, Ohio.

The S. & M. Welding Co., recently organized, will build a plant on East 55th St., Cleveland, Ohio.

Plans have been prepared for the construction of a 40x 100-ft. factory at Columbus, Ohio, for the Lamneck Co., manufacturer of heating equipment. A. P. Lamneck is Pres. Noted Feb. 3.

The Reliance Textile Co., 2d and Russell St., Covington, Ohio, will build a 1-story, 90x150-ft. addition to its plant at Covington.

The Stevens Manufacturing Co., manufacturer of tools, dies and fixtures, 3d and Canal St., Dayton, Ohio, plans to con-

struct a plant at Dayton. Estimated cost, $150,000. Fred Stevens is Pres.

The Thomas Manufacturing Co. will construct an addition to its plant at Dayton, Ohio, for the manufacture of automobile accessories.

The Crescent Metal and Manufacturing Co. plans to construct a plant at Fremont, Ohio.

The American Steel Grave Valut Co. has awarded the contract for the construction of an addition to its plant at Church and Bloomer St., Galion, Ohio. Noted Feb. 24.

The Wogaman Bros Co., manufacturer of gasoline engines, contemplates constructing additions to its plant at Greenville, Ohio.

The Ohio Tractor Co. will build a plant at Marion, Ohio.

The Meteor Motor Car Co. plans to equip a section of its plant at Piqua, Ohio, for the manufacturer of automobile bodies.

L. A. Woodard, Vice-Pres. of the William Tod Co., Youngstown, Ohio, has purchased the plant of the Canton-Hughes Pump Co., Wooster, Ohio, and contemplates enlarging the plant.

The Youngstown Sheet and Tube Co. has awarded the contract for the construction of a factory at Youngstown, Ohio.

The Hayes Wheel Co. will build an addition to its plant at Anderson, Ind. Estimated cost, $20,000.

The Remy Electric Co. contemplates constructing an addition to its plant at Anderson, Ind. Estimated cost, $50,000.

The Standard Plating and Brass Foundry Co. contemplates constructing a factory at Anderson, Ind.

The National Car Coupler Co. plans to construct an addition to its plant at Attica, Ind. Estimated cost, $75,000. J. W. Harrison is Gen. Mgr.

The Foster Machine Co. plans to build an addition to its plant at Elkhart, Ind.

The Majestic Furnace and Foundry Co. will build a 1-story, 50x75-ft. addition to its plant on Erie St., Huntington, Ind.

The Indianapolis Cordage and Implement Co. contemplates constructing an addition to its plant at Indianapolis, Ind. Estimated cost, $500,000.

The Huron Implement Co., manufacturer of farm tools, will build a 50x150-ft. foundry and a manufacturing building at Bad Axe, Mich.

The United States Register Co. plans to build a 3-story factory at Battle Creek, Mich. L. Mobile, 3300 Humboldt Ave., S., Minneapolis, Minn., is Vice-Pres.

E. M. Clark & Son, Detroit, Mich., plans to construct a factory on South Main St., Clarkston, Mich., for the manufacture of brass fixtures and ornamental fencing.

The Detroit Shipbuilding Co. contemplates constructing an addition to its machine shop at Detroit, Mich.

The Detroit Steel Products Co. is constructing shops Nos. 4, 5 and 6 at Detroit, Mich. Estimated cost, $60,000. Noted Feb. 24.

The Detroit Vapor Stove Co., 407 Franklin St., Detroit, Mich., will build a plant at Kercheval Ave. and Waterloo St., Detroit.

The Scripps-Booth Co., manufacturer of automobiles, Detroit, Mich., has been reorganized with a capital of $1,000,000. Plans are being prepared for the construction of an addition to its plant at Detroit. Noted Sept. 23.

We have been advised that the Charles A. Strelinger Co., Detroit, Mich., is constructing a 6-story warehouse, general office, salesrooms and machine tool demonstrating plant at Larned, Randolph and Bates St., Detroit.

The contract has been awarded for the construction of a 100x105-ft. factory at 8th and Fairbanks Ave., Holland, Mich., for the Michigan Foundry Co. John Glupker is Mgr. Noted Mar. 9.

The Sparks-Withington Co., manufacturer of roller bearings and pressed metal products, will build an addition to its plant at Jackson, Mich.

The Lane Motor Truck Co. plans to build a factory at Kalamazoo, Mich. M. H. Lane is interested.

The J. A. Richards Co. is constructing a factory on Pitcher St., Kalamazoo, Mich., for the manufacture of steel cut dies and jig-saws. J. A. Burke is Pres.

The Continental Motor Co. is constructing a machine shop at Muskegon, Mich.

The Detroit Valve and Fittings Co. will build a 50x72-ft. addition to its annealing room at Wyandotte, Mich.

The Malleable Iron Co., 1801 Direres Parkway, Chicago, Ill., will construct an addition to its plant at Chicago. Estimated cost, $4,000.

The Tri-City Railway Co. plans to construct car shops at Rock Island, Ill.

Work will soon be started on the construction of a factory at Springfield, Ill., for the Sangamo Electric Co., manufacturer of electric meters.

The Kohler Co., manufacturer of enameled plumbing ware, plans to construct a 1-story, 75x200-ft. addition to its factory at Kohler, Wis.

The Liebel & Tetzlaff Manufacturing Co. plans to construct a 30x30-ft. addition to its machine shop at Luxembourg, Wis.

Bids will soon be received for the construction of a 1-story foundry and machine shop on Kefe Ave., Milwaukee, Wis., for the Claus Automatic Gas Cock Co., 2601 Vliet St., Milwaukee. Estimated cost, $20,000. Noted Mar. 16.

The Crary Tool Co. will establish a factory at Milwaukee, Wis.

The Pawling & Harnischfeger Co., manufacturer of cranes and hoists, will build a 2-story addition to its pattern shop at Milwaukee, Wis.

The Ewald Works plans to construct a garage and machine shop addition to its plant at Oakfield, Wis.

The Thom Auto Co. plans to construct a garage at Merritt St. and Jefferson Ave., Oshkosh, Wis.

James Morgan, proprietor of the Morgan's Garage, contemplates constructing a 2-story, 60x140-ft. garage and machine shop at Rhinelander, Wis.

Carpenter & Freyer plans to construct a garage and machine shop on Main St., Waukesha, Wis.

WEST OF THE MISSISSIPPI

The Martin Manufacturing Co., Mason City, Iowa, contemplates building a factory at St. Paul, Minn., for the manufacture of tinware. Estimated cost, $150,000.

Bids will be received about Apr. 1 for constructing a 1-story garage for T. J. O'Connell, Waterloo, Iowa. Estimated cost, $35,000.

The Pioneer Auto Co. plans to build a garage at 326 East Superior Ave., Duluth, Minn.

The Minneapolis General Electric Co., 15 South 5th St., Minneapolis, Minn., will build a 5-story addition to its plant on 5th St. Robert F. Park is Gen. Mgr.

The Packett Motor Car Manufacturing Co., recently incorporated, plans to build a factory at St. Paul, Minn. Henry Orne, 880 Grand St., is Pres.

The Twin City Frog and Switch Co., St. Paul, Minn., is building a factory for the manufacture of railway truck appliances.

Press reports state that the Hudson Motor Car Co. will lease garage and business building to be built at Sherman and Walnut St., Hutchinson, Kan.

The Lord Auto Co., 17th and O St., Lincoln, Neb., has awarded the contract for an addition to its garage. Estimated cost, $20,000.

Ira L. Bendon, Sidney, Mont., agent for the Ford, Dodge and Overland cars, will build a commercial garage and machine shop at Sidney.

The contract has been awarded for a 2-story garage for Edward Isben, Jefferson City, Mo. Estimated cost, $15,000.

Laciny Bros., 2524 North 25th St., St. Louis, Mo., will construct coppersmith, machinist, brass finisher and sheet iron departments. The company is in the market for lathes, drill presses, vises, taps, dies, sheet metal cutters, small tools, measuring instruments, etc.

Fred Medart Manufacturing Co., St. Louis, Mo., has awarded the contract for a 2-story factory for the manufacture of steel ladders. Estimated cost, $40,000. Noted Mar. 9.

F. C. Fahrendorf, Cameron, Tex., will build a machine shop and garage.

Bids will soon be received for 1-story garage for Jeffs Machine and Auto Co., Inc., Cushing, Okla. Estimated cost, $15,000.

WESTERN STATES

Albert Schubach is at the head of a new corporation which has leased the Lindstrom Shipbuilding Yards at Aberdeen, Wash. The new corporation plans an expenditure of $15,000 to improve and enlarge the plant.

The Ferris Motor and Machine Co., 815 East Pike St., Seattle, Wash., is in the market for milling and power hack saw machinery and annealing furnace. Noted Mar. 2.

Barbare Bros. plans to construct an addition to its shipbuilding plant at Tacoma, Wash. Estimated cost, $20,000.

The Blewitt Harvester Co. plans to construct a factory at Pendleton, Ore., for the manufacture of harvesters. Estimated cost, $100,000.

Plans being prepared by E. Kroner, Arch., Worcester Bldg., Portland, Ore., for the construction of a garage and machine shop at 29th and Thurman St., Portland, for A. L. Carson.

The Oakland Launch and Tugboat Co. plans to construct a machine shop at East Oakland, Calif. (Oakland post office).

We have been advised that work will be started about May 15 on the construction of a plant at Los Angeles, Calif., for the Homer Laughlin Engineering Corporation, for the manufacture of drop forgings. Estimated cost, $200,000. The company will be in the market for equipment for the manufacture of automobiles and drop forging machinery. Noted Feb. 17.

The Keystone Iron Works will construct a foundry at 114 College St., Los Angeles, Calif.

Plans are being prepared by Thomas Preston, Arch., Investment Bldg., Los Angeles, Calif., for the construction of a 50x130-ft. garage and machine shop at Main and 28th St., Los Angeles, for Robert G. Schroeter, 735 Security Bldg., Los Angeles.

Lisle Esler, San Bernardino, Calif., plans to construct a garage and machine shop at 2nd and F St., San Bernardino.

Plans are being prepared for the construction of a garage and machine shop for the California Baking Co., Ellis and Pierce St., San Francisco, Calif. Estimated cost, $16,000.

The contract has been awarded for the construction of a 1-story machine shop on Fremont St., San Francisco, Calif., for E. M. Otto. Estimated cost, $12,000.

CANADA

The Canada Iron Corporation plans to construct an addition to its plant at Three Rivers, Que.

The Pollard Manufacturing Co., manufacturer of machinery, plans to construct an addition to its plant at Niagara Falls, Ont.

GENERAL MANUFACTURING

NEW ENGLAND STATES

Bids will soon be received for the construction of a factory on Islington St., Portsmouth, N. H., for the Morley Button Co. Noted Feb. 17.

The contract has been awarded for the construction of a 2-story, 92x500-ft. factory at Lawrence, Mass., for the Menomac Spinning Co. Estimated cost, $400,000. Noted Nov. 25.

The Appleton Manufacturing Co., manufacturer of cotton goods, has awarded the contract for the construction of a 5-story, 75x191-ft. plant at Lowell, Mass. Estimated cost, $100,000.

The contract has been awarded for the construction of an addition to the plant of the American Tire Fabric Co. at Newburyport, Mass.

Contract will soon be awarded for the construction of a weave shed at Hope, R. I., for the Hope Mill Co., manufacturer of shirting. Noted Mar. 16.

The Cowan Truck Co. plans to build a 1-story, 100x200-ft. factory on Appleton St., Providence, R. I.

Bids have been received for the construction of a 2-story, 77x120-ft. mill at Woonsocket, R. I., for the Sidney Worsted Co.

Bids will soon be received for the construction of a 3-story, 84x220-ft. addition to the plant at Baltic, Conn., of the Baltic Mills Co., manufacturer of cotton goods. Noted Jan. 13.

The American Velvet Co. plans to construct a factory at Stonington, Conn.

SOUTHERN STATES

The Lynchburg Hosiery Mills, Lynchburg, Va., plans to install new machinery.

The Corrugated Box Co., Parkersburg, W. Va., plans to construct a 1-story factory. Estimated cost, $10,000. E. Waldschmidt, Mgr.

The Acme Hosiery Mills, Ashboro, N. C., will install new machinery in its plant during 1916. Noted Feb. 24.

The Star Hosiery Mills, Spartanburg, S. C., recently incorporated with $100,000 capital stock, will construct a 2-story mill.

The Berryton Mills, Berryton, Ga., manufacturer of hosiery, plans to construct a 2-story addition to its factory. Estimated cost, $20,000.

J. A. Kendrick, Greenville, Ala., and associates plan to build a cotton mill at Greenville.

Loudon Hosiery Mills, Loudon, Tenn., contemplates building a 5,000-spindle mill.

MIDDLE ATLANTIC STATES

Plans have been prepared for a 1-story factory on the Buffalo River at Katherine St. and the Erie R.R., Buffalo, N. Y., for the Buffalo Potash and Cement Corporation, 51 Hamburg St., Buffalo. Estimated cost, $25,000.

The Niagara Oxygen Co., Inc., 570 Carroll St., Buffalo, N. Y., will construct a plant at Philadelphia, Penn.

The Niagara Searchlight Co., Niagara Falls, N. Y., contemplates building an addition to its factory. Estimated cost, $8,000.

The Mutual Chemical Co. of America contemplates building a chemical factory at Jersey City, N. J. E. H. Simpson is Mgr.

The S & K Co., Chicago, Ill., manufacturer of leather, has acquired a site on 3rd St., Newark, N. J., on which it will construct a branch manufacturing plant.

The plant of the Ryan Leather Co., Newark, N. J., recently destroyed by fire will be rebuilt. Estimated cost, $35,000. Thomas Ryan is Pres.

The Consolidated Lamp and Glass Co., Corapolis, Penn., will build a 2-story factory. Estimated cost, $15,000. Edward Cornelius, Pittsburgh, is Arch.

The Security Silk Co., Morris Run, Penn., will construct a silk mill.

Bids will soon be received by Day & Zimmerman, Arch., 611 Chestnut St., Philadelphia, Penn., for a 3-story factory at Emerald St. and Allegheny Ave. for the Cleveland Worsted Mills, 8932 Broadway, S. E. George Hodgson, is Gen. Mgr.

Dill & Collins, 6th and Cherry St., Philadelphia, Penn., manufacturer of paper, has awarded the contract for constructing a factory. Estimated cost, $30,00. William Steel & Sons Co., is Arch.

Bids will soon be received for a 1-story factory for the Baltimore Engine Oil Co., Baltimore, Md. Estimated cost, $50,000. Walter M. Gieske is Arch.

MIDDLE WEST

The Portage Rubber Co., Akron, Ohio, has awarded the contract for the construction of a 3-story factory at Barberton, Ohio.

Bids will soon be received for a factory for the Cleveland Worsted Co., Cleveland, Ohio, for the manufacture of worsted. Day & Zimmerman is Arch.

The Linde Air Products Co., East 12th St., Cleveland, Ohio, will construct an addition to its plant at Cleveland.

The Ocoee Woolen Mill plans to build a factory at Cleveland, Ohio. W. H. Durkee, Supt. of Cleveland Woolen Mills, is Mgr.

The H. C. Godman Co. has taken over the plant of the Columbus Clock Co. on Thurman St., Columbus, Ohio, and will install machinery for the manufacture of shoes.

Plans are being prepared for the construction of a 2-story, 60x135-ft. factory on East 5th St., Dayton, Ohio, for the Monarch Tag Co. Estimated cost, $35,000. Fred Kohnle is Pres. and Gen. Mgr.

The Valentine Packing Co. contemplates construction a packing plant on Mulberry St., Terre Haute, Ind. Estimated cost, $100,000.

The Michigan Limestone and Chemical Co., Alpena, Mich., plans to improve its plant at Calcite, Mich.

The Detroit Sulphite Pulp and Paper Co., 2607 Jefferson St., Detroit, Mich., plans to construct a 1-story factory on Jefferson St., Detroit. Estimated cost, $30,000.

The Western Thread Co. plans to construct an addition to its plant at Elgin, Ill. W. R. Swartwout is Mgr.

John A. Heller, R. J. Connery and associates contemplate constructing a packing plant at Quincy, Ill. Estimated cost, $50,000.

Plans are being prepared by W. E. Bennett, Arch., for the construction of a 2-story, 50x100-ft. factory at 6th and State St., La Crosse, Wis., for the Fisk Rubber Co., Chicopee Falls, Mass.

Bids will soon be received for the construction of a 4-story, 90x225-ft. packing and cold-storage plant at Madison, Wis., for the Farmers' Coöperative Packing Co. Estimated cost, $375,000. Noted Nov. 4.

The Jung Shoe Co., 302 North 8th St., Sheboygan, Wis., plans to construct a 3-story, 30x135-ft. addition to its plant at 8th and Virginia St., Sheboygan. Henry Jung is Pres.

The West Bend Woolen Mills plans to construct additions to its factory at West Bend, Wis.

WEST OF THE MISSISSIPPI

The Ft. Madison Produce and Storage Co. Ft. Madison, Iowa, will build a plant at Ft. Madison. Estimated cost, $40,000.

The Wichita Carriage Works, Wichita, Kan., has awarded the contract for a factory. Estimated cost, $10,000.

The Gas Engine Efficiency Co., Kingshighway and Manchester St., St. Louis, Mo., contemplates building an oil refinery at St. Louis.

John T. Milliken & Co., 316 Clark Ave., St. Louis, Mo., will build a 4-story factory at 3rd and Cedar Ave., St. Louis, for the manufacture of chemicals. Estimated cost, $100,000.

The Corsicana Cotton Mills, Corsicana, Tex., will build a 2-story addition to its plant. Estimated cost, $100,000.

Fire recently destroyed the cotton plant of Arthur, Storrs, Granger, Tex. Loss, $25,000.

Fire recently destroyed the plant of the Stock Cotton Gin Co., Hamlin, Tex. Loss $10,000. W. H. Birdwell, Mgr.

The Oriental Textile Mills, Houston Heights, Tex., plans to build additions to its plant. Estimated cost, $6,000.

W. S. Noble, Rockdale, Tex., will build a canning factory at Milano.

Posttex Cotton Mill Co. Post, Tex., has awarded the contract for a 1-story addition to its bleachery. Estimated cost, $4,250.

Fire recently destroyed the plant of the Western Cotton Gin Co., Seymour, Tex.

WESTERN STATES

The Seattle Box Co. plans to construct a factory at 401 Spokane St., Seattle, Wash.

The contract has been awarded for the construction of a plant at Grants Pass, Ore., for the Oregon-Utah Sugar Co. Estimated cost, $600,000. Noted Jan. 13.

CANADA

Frank D. Law is interested in a company which contemplates constructing a factory at Brampton, Ont., for the manufacture of rubber, tires, etc.

Fire recently destroyed the packing plant of the Gordon Ironsides at Moose Jaw, Sask. Loss, $50,000.

Talks With Our Readers

By the Publisher

"THE OUTSIDE point of view" is a healthy one for each and all of us to get once in a while.

Just because we are in the machinery business is no reason why we shouldn't be interested in a whole lot outside of it.

In "Advertising and Selling" HERBERT N. CASSON writes, along this line:

"It is physically impossible for a man to see more than two sides of a square house at one time. It is necessary to project oneself mentally to imagine the other sides. But to have it under really close observation, you must have someone else help you, from a different vantage point than your own.

The same thing is true of business. No organization can hope to see all its sides unaided. It must have outside point of view, or work on a distorted basis.

This is the rock on which thousands of stubborn business men split. And this is the magnificent opportunity which scores of brainy men have seized to wrest leadership from those too dull to see their own benefit.

It is a matter of history that general improvements come from outside and that detail improvements come from inside.

For instance—

Field was a merchant, yet he laid the first ocean cable.

Bell was a professor of elocution, yet he invented the telephone.

Carnegie was a railroad official, yet he became the richest steel maker in the world.

Judge Gary is a lawyer, yet he is at the head of the Steel Corporation.

Allis was an auditor, yet he created the Allis-Chalmers Works at Milwaukee.

Ingersoll, who gave the world good cheap watches, was not a watchmaker.

Selden, who secured the first automobile patent, was a lawyer.

Eastman, creator of the Kodak, was a bank clerk.

Harriman, the greatest of American railway organizers, was a stock broker.

Even in the larger affairs of national history we find this extraordinary law. Cromwell, for instance, was an outsider; he was not born of royal blood; and Napoleon, who put kings up and pulled kings down until they sent him to St. Helena, was an outsider.

The most desirable thing in the world is *balance*. Balance means sanity, it also means success. It is the balanced man and the balanced business that win—aided by the outside point of view to achieve such balance."

Manufacture of Punchings

By C. W. Starker*

SYNOPSIS—A careful explanation of the features in the design of punchings for electric motors, generators and transformers that affect manufacture. Different kinds of dies and methods of production of such punchings are described and their uses and limitations pointed out. The matter of economical scrap is also considered.

In the manufacture of electrical apparatus the principal active parts of motors, generators, transformers, magnets and other electric devices are usually built in laminated form—from thin sheet-steel punchings, insulated from one another—instead of as a solid body of iron or steel. The object of this laminated construction is to reduce by such subdivision the losses from eddy currents.[1] Typical examples of laminated stator and rotor cores are shown in Fig. 1.

The work of the punch shop becomes therefore of particular importance to the designer and others interested in the manufacture of electrical apparatus. Viewed from the standpoint of cost, it may be stated that between 13 and 25 per cent. of the factory cost of the average alternating-current motor is in the punchings.

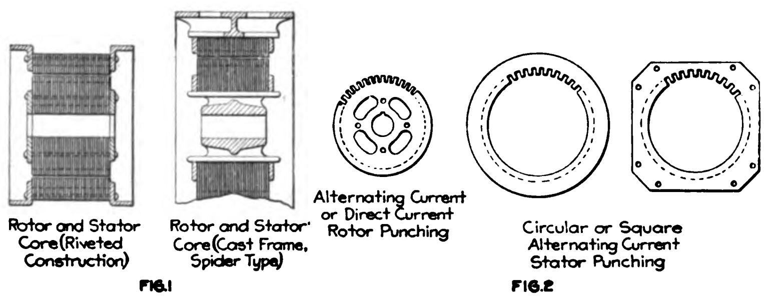
While all the problems arising from the various branches of punch-shop work are interesting, they are so varied that only those features of design and manufacture necessary to a full understanding of the class of punchings used in the stator and rotor cores of alternating-current motors or generators and of direct-current armatures will be considered in this article. Typical cases of such punchings are shown in Fig. 2.

The raw material for the punchings is received from the mill or storeroom in sheet form and is then slit into strips of a width corresponding to the size of the punching to be made, plus a certain margin. This work is done on a machine such as illustrated in Fig. 3. Further operations in producing punchings depend entirely on the kind of tool available. It will be well, therefore, first to consider the various types of dies generally used. There are three distinct types—1, simple; 2, combination; 3, compound.

1. By the simple type is understood a standard round-hole die used in connection with a slot die. Their construction will be described later, but Fig. 4 is shown to illustrate the successive steps in making a punching with round-hole dies. These steps are, for rotor punchings: Split or shear, center-hole, keyway, trim, slot; and for stator punchings: Split or shear, center-hole, trim, outside keyway, punch out center, slot. The center hole and keyway are sometimes punched in the same operation.

2. There are two different forms of the combination dies. The most commonly used form blanks the punchings completely at one blow; that is, inside and outside diameter, including rivet—or vent holes, if any—but not including the slots, which are punched out in a separate operation. This will be made plain by referring to Fig. 5. In the other form of combination dies the punchings are blanked complete, including slots, but the center is not punched out in this operation. A round-hole die completes the punching. There are therefore two operations required in both cases. The two steps are indicated in Fig. 6. The center is usually punched out before slotting, except that with smaller punchings and thin tooth tips it may to advantage be punched out after slotting.

3. Compound dies make a complete punching in one operation, provided the tooth tip is $\frac{1}{16}$ in. wide or more, Fig. 7. In cases where the tooth tip is less than this the



FIGS. 1 AND 2. TYPICAL EXAMPLES OF CORES AND PUNCHINGS

die is made with at least a $\frac{1}{16}$-in. tip, to give it sufficient strength at that point. The teeth must then be trimmed off in a separate operation, to obtain the required tooth tip and punching diameter. This question of tooth tips will later be referred to more in detail.

The selection of one or the other of these dies depends on a number of considerations. The principal questions are tool cost and quantities required. However, the size of die and punching, limitations of manufacturing equipment, thickness and hardness of the sheet steel must also be considered.

The advantage of simple dies is the low cost of tools. Round-hole dies of suitable diameter being usually available in a large punch shop, the only new tool required is, as a rule, a slot die, the cost of which is small. Simple dies are used where the activity is small or for very large punchings where compound dies would be too large for the presses; that is, the power required in punching would exceed the permissible load on the presses. This limitation generally applies to punchings approximately above 35 in. in diameter. The disadvantages of this type are principally the many operations, therefore the high cost of the punching and the consequent delay to production.

The so-called "set-up" cost—the expense for installing and lining up the dies in the press for each operation,

*Engineer, Westinghouse Electric and Manufacturing Co.

[1]Eddy currents are local currents in the iron or parts of the circuit interlinked with an alternating or pulsating flux. They cause heating and are sources of loss as well as possible danger to windings. As an analogy may be cited a whirlpool in which a stream of water retards its flow. The eddying may be prevented by providing a series of comparatively narrow channels.

including the time lost to production in making these preparations—is of course greatest for simple dies. The expense must be distributed over the number of punchings made in one set-up. This is one reason why quantity production is essential in all punch-shop work. Orders for five or ten punchings, as in the case of certain special parts such as finger plates, blowers and the like, result therefore in enormously high punch-shop costs. The remedy is either larger quantities by grouping orders together and stocking the parts separately or by standardizing a design so that the same detail may be used interchangeably and therefore in larger quantities. Where this is not possible, a construction different from punching should be used.

Combination dies are, as a rule, well adapted to standard apparatus that have large activities, particularly the type of combination die first mentioned, which blanks out the center. A semifinished punching of this sort can have any number of slots punched into it, thereby permitting the use of a common blanking die in connection with various dies for punching different numbers of slots. The tool cost, while considerably higher than for the simple die, is comparatively low with this form of combination die.

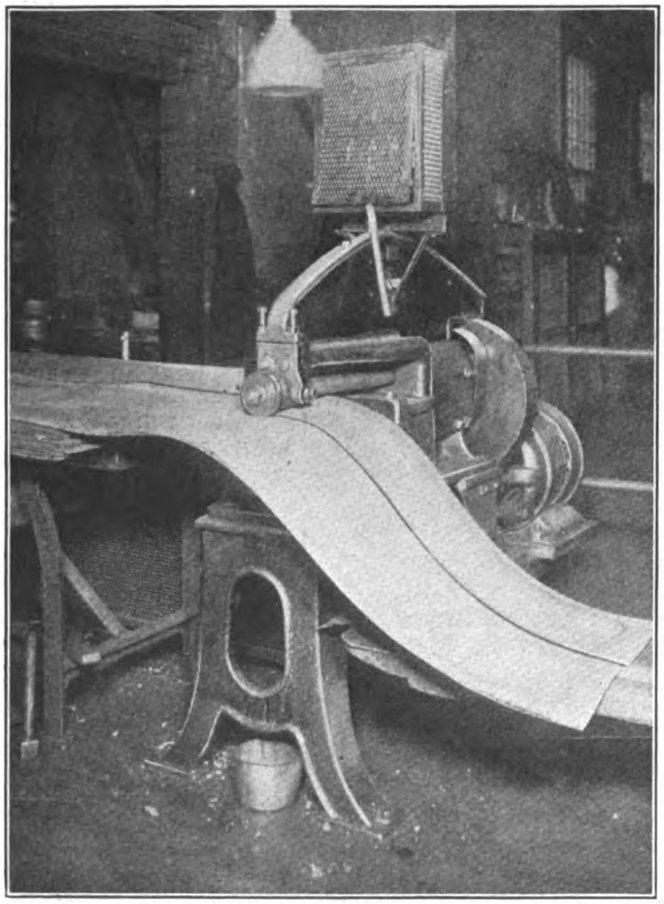


FIG. 8. ADJUSTABLE SLITTING MACHINE FOR SHEET MATERIAL

Combination dies that punch out slots are well suited to punchings having less than $\frac{1}{16}$-in. tooth tip. The small tooth tip does not affect the strength of the die, as the center is punched out in a separate operation. The activity should be large when such a die is used, as one that punches out the slots at the same time with the blanking is of course more expensive and good only for a given number of slots. This type is, from some points of view, preferable even to a compound die, as it leaves a plain circle coming out of the center, while a compound die leaves centers with teeth sticking out along the periphery. Such a center is illustrated in Fig. 8. These teeth are the material punched out as slots. Centers from large punchings are used wherever possible in making smaller punchings, and obviously a center with such teeth along the periphery, known as "toothpick scrap," is more difficult to handle and therefore requires a higher rate to be paid for labor in using it up.

Compound dies give the cheapest method of making punchings when the tooth tip is $\frac{1}{16}$ in. or more, as only one operation is required. A disadvantage is the fact that it leaves "toothpick scrap," as stated. The cost of a compound die is high, and the activity therefore must be large to warrant the tool cost. The relation in tool cost for the three different types of dies and also the relative cost of punchings produced with each type are more conveniently and clearly shown by a curve, such as Figs. 9 and 10. Identical conditions, as material, labor, rates, shape of punchings, etc., must of course exist, and curves are prepared for a given set of facts. The figure is intended merely to illustrate the relation without giving actual costs, which depend on the various factors mentioned.

It is interesting to observe that, contrary to general assumption, the compound die is less expensive than the combination die of the type that punches out the slots. In manufacture, however, the more expensive combination die has the advantage, not only of leaving plain center scrap—no toothpicks—but it is found to have a considerably longer life, particularly where the narrower tooth tip is wanted, for the reason that this tip is not cut in the same operation with the center.

The cost of the punchings made by the different dies is graphically shown in Fig. 10. For a given type of punching we may take from the curve for a certain outside diameter the cost of the raw material less scrap allowance, shown in the curve next to the horizontal line, expressed in dollars per hundred pieces. The vertical distance between this curve and the adjacent one represents the labor plus overhead expense for the punching, if it is stamped out complete in one operation by a compound die. The distance between the material curve and curve No. 2 represents the cost of labor plus indirect factory expense, if the sheet is punched out complete with the compound die: but an additional trimming operation is required on account of the narrower tooth tip, as already explained. In the same way curve No. 3 shows the cost for the type of combination die that punches out the center, curve No. 4 for the combination die that punches out the slots and curve No. 5 for simple dies.

In drawing conclusions from these curves it is to be understood that, while the labor rates are fairly well fixed, the value of material varies for different designs of punchings, and other conditions may enter to alter the costs; but for a given case such curves give as definite data as practicable on the cost relation of a punching made with different types of dies.

It will be noticed that all the labor-cost curves given show a kink at a certain diameter. The reason for this is that above this diameter a helper is usually employed, which of course increases the cost. On the other hand,

at about the same diameter the slitting operation is no longer required, as the full width of the sheet may be used. These two features may offset one another or even cause the cost figure to drop.

In connection with the dies used on punchings for rotors and stators mention may also be made of the so-called radius cutter. This is an attachment to a slot die, whereby centers may be cut out when slotting teeth, in cases where there is no round-hole die of the proper diameter available.

Circular punchings are used on electrical machines up to a certain size. On larger machines they are uneconomical and are therefore divided into segments. Fig. 11 illustrates typical cases of segmental punchings for stators and rotors.

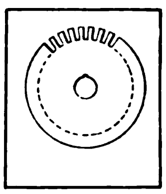

FIG. 8 "TOOTH-PICK SCRAP CENTER"

FIGS. 4 TO 8. DETAILS OF VARIOUS FORMS OF PUNCHINGS

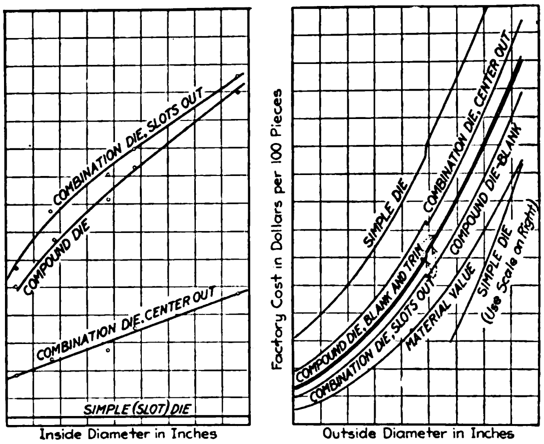
The dividing line between the two is determined largely by the relative cost and by manufacturing conditions. There may be considerations of design that make the full-circle punching desirable even on larger machines, but as a rule, the stated conditions are the determining factors. The cost is dependent on several items—the material in the punching and the labor in making it, to which should also be added the labor in building up the core, either in full circles or from segments, and finally the labor and material for dovetails in the frame, or spider, that becomes necessary with segmental punchings. The same considerations apply to the question of how many segments per circle should be used. The choice between four and six or more segments per circle is determined largely by the cost and manufacturing conditions, although design conditions, such as the number of segments, should also be taken into account.

Considering the punching alone and the labor and material involved in producing it, a curve can be prepared by calculating on a number of examples the cost of a bundle of punchings, say 1 in. thick, for various inside and outside diameters, first as full circles, then with 4, 6, 8 segments, etc. The intersection of these lines, then, would give the economical dividing line between full circles and segments and for various numbers of segments per circle. Such a curve is shown in Fig. 12.

All the cost figures are to be based on the same material value, labor rates, types of dies, etc.; and as it is merely the relative cost we are interested in, it is not necessary to consider the actual cost in dollars. As the inside diameter of the punching is a factor in the cost, the curves are prepared for different widths of rim. A 2-in. rim, for example, means an inside diameter 4 in. less than the outside diameter.

These curves show that there is quite a consistent change in the point of intersection; that is, of equal cost for circular punchings and segments or for various numbers of segments per circle. If we connect these intersections by separate curves, we come to the simple lines in Fig. 13. The principal break in the curve—the jump in the cost—occurs where the size of punching becomes such that, according to punch-shop practice, a helper is required in addition to the man operating the punch press. These curves can be used by the designer to determine roughly for any diameter, within the range of ordinary practice, which form of punching will be cheapest. Assuming, for instance, a certain outside diameter and 3-in. width of rim, a vertical line at that outside diameter and a horizontal line at 3-in. rim give a point of intersection. If this point lies to the left of the line *AB*, a circle will be cheapest; if between *AB* and *CD*, 4 segments; between *CD* and *EF*, 6 segments; and to the right of *EF*, 8 segments will be cheapest.

In using this curve a considerable margin should be allowed at one side or the other of the curve, as in these curves only the punchings are considered and additional cost for dovetails, etc., as previously stated, would have to be considered separately for closer calculation. However, for ordinary purposes they form a sufficiently accurate basis and guide for the designer. Further, such standardized cost data have the advantage of leading to uniform and consistent cost calculations and save the time of repeatedly going over the same ground. The curves are made up for compound dies. Similar curves can be prepared for various combinations; for example, using combination dies on the circular punchings as compared with compound dies on the segments—a case which



FIGS. 9 AND 10. APPROXIMATE COSTS OF DIFFERENT TYPES OF DIES AND STATOR PUNCHINGS USED

may quite frequently occur in practice on account of the relative tool cost, which will be referred to later.

Aside from these cost considerations there are, as already stated, manufacturing limitations to be taken into account in deciding between circular punchings and segments or between various numbers of segments per circle. These limitations are: First, the size of sheet available—that is, carried in stock—which usually has a maximum width of 39 in. Circular punchings are therefore limited to about 38 in. in diameter, allowing ½ in. on a side for margin. Segmental punchings usually do not come up to this width. The general rule followed in practice is to keep the long chord within 30 in. as maximum and 20 in. as minimum. In the second place, punchings from circles are limited by the throat space of the press. Presses available even in large manufacturing plants usually do not permit more than 30-in. diameter of punchings. Third, the upkeep of the dies must be considered and the tendency of large dies to alter their shape, both in getting out of round and in a certain amount of warping. The limitation in this respect is also usually placed around 30-in. diameter.

In deciding between full circles and segments a further and most important factor is the relative cost of dies.

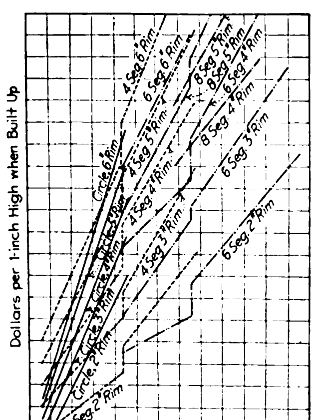


FIG. 12. FACTOR COST OF CIRCULAR VERSUS SEGMENTAL PUNCHINGS

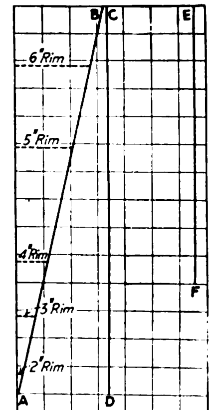

FIG. 13. CIRCULAR VS. SEGMENTAL PUNCHINGS

In the larger sizes the cost of a compound, or even combination, die may be very high, as compared with the cost of a segmental die. Then, too, the activity on these larger machines is comparatively small, so that investment in tools must be kept low. With segmental punchings the activity and number of pieces are greater than with circles, according to the number of segments per circle. For segmental punchings compound or combination dies may be used, the latter blanking the segment with dovetails and vent holes, if any, in the first operation, the slots being indexed in a second operation.

In referring to dimensions of tips and slots the work of tooth tip was mentioned. The shapes of slots most commonly used in alternating- and direct-current motors and generators are shown in Fig. 14. From the standpoint of electrical performance it is desirable to limit the width of the tooth tip to a minimum; that is, a narrow strip of iron between the surface of the core or punching and the top of the slot wedge used for holding the winding in place is desired. This tip under conditions affects the performance, as it may increase the magnetic leakage and thereby reduce the torque of the motor. The reason for this is—to give a popular explanation—that the lines of force tend to follow the path of least resistance and therefore pass from tip to tip instead of passing

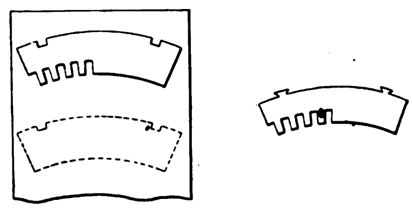

FIG. 11. SEGMENTAL PUNCHINGS, 4 AND 6 PER CIRCLE

through the air gap between stator and rotor, as intended, in order to produce relative motion between stator and rotor—that is, torque.

On the other hand, from a manufacturing standpoint a $\frac{1}{32}$-in. tooth tip (in fact, anything less than $\frac{1}{16}$ in.) is a most undesirable proposition, as obviously such thin projections on the punch will not stand up very long in manufacture, thereby necessitating frequent expensive renewals, which unduly burden the overhead expense of the punch shop. In present shop practice this difficulty is being avoided by punching the tooth tip wider at first and then trimming it in a separate operation. This practice of course means another die and additional cost for every punching.

Here is therefore a case where designer and punch shop must compromise, resorting to this narrower tip only where the additional cost of the punching is offset by an equal gain in copper or iron in the machine which otherwise would be required in order to obtain the desired performance with the wide tooth tip. A decision along this line is also influenced by the number of poles of the motor and by the construction of steel wedges, if such are used.

While speaking of designing slots with a view to economical manufacture, two more particulars may be mentioned briefly. The narrowest point of the tooth at the end between the slot grooves should not be less than $\frac{1}{16}$ in. for material 0.0172 in. or 0.0281 in. thick and not less than ⅛ in. for heavier material, as 0.0375 in. and 0.0625 in. At the root of the tooth its width should not be less

than $\frac{1}{16}$ in. for 0.0172-in. and 0.0281-in material for punchings below 6 in. in diameter and $\frac{3}{32}$ in. as the minimum for punchings above 6 in. in diameter. For heavier material, 0.0375 in. and 0.0625 in., this dimension should not be less than $\frac{1}{8}$ in.

The other point is the radius in the corner of the slot. Such radii are often specified on drawings as small as 0.016 in. and 0.031 in., although the slot cell, wires or bars usually have well-rounded corners and there is no necessity for the small radius. If the die is built up in such a way that two pieces of steel are joined at the root of the tooth, it would be easiest and cheapest to leave the corner entirely square, and it is difficult to make a radius in this case. However, it is impossible to give any general rule along this line, as the construction chosen for a given die by the tool designer depends on many factors, principally on the relative proportions of the design of punchings (small teeth, obstructing keyways, vent holes, etc.) and on accessibility for machining. This latter item involves in turn the tool equipment available (size of head on the boring mill or shaper) and questions of production. It is therefore necessary to allow the tool designer to use his judgment or to confer with the engineer on the individual case. Drawings generally specify $\frac{1}{32}$-in. radius. From the standpoint of the punch shop some radius is usually necessary to prevent the material from dragging in the die.

Frequently, it is desirable to make the rotor punchings from the sheet used in making the stator punchings. This method results not only in a saving of material, but also

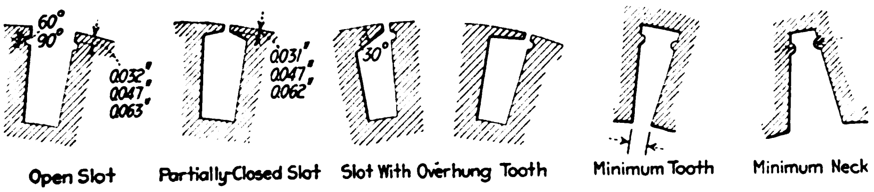

FIG. 14. SHAPES OF SLOTS COMMONLY USED IN MOTORS AND GENERATORS

in labor, as one operation—that of center holing and keyseating for the rotor—is avoided, this latter operation being part of the operation for the stator punchings. This method means that rotor and stator must be made of the same thickness and grade of material and required in similar quantities. Quite often rotor punchings could be made of slightly heavier material, 0.0281-in., instead of 0.0172-in. thickness usually employed in the stator. This is principally on account of the lower frequency occurring in the rotor with correspondingly less serious iron losses.

A core built up of the heavier material is cheaper than the light iron. The price per pound of the two materials varies in a ratio of about 0.0185 to 0.0286 by the sheet; or if the ratio of good punching material to scrap in a punching is considered, it averages about 0.064 for the heavier material and 0.088 for the lighter material. The labor per punching is about 50 per cent. greater for the heavier iron, but there are fewer punchings required per inch width of core. For 0.0172-in. iron it is customary to figure on 56 punchings per inch, taking the film of insulating enamel on the punchings into consideration, while 0.0281-in. iron requires only about 32 punchings per inch.

The difference in cost is considerable. For an average diameter of rotor approximating 12 in. it amounts to 25 to 30c. per inch-width of core, which may be equivalent to approximately one-fourth of 1 per cent. of the factory cost of the machine. However, as it is necessary to dispose of the light-iron centers from the stators which accumulate in actual manufacture, rotors are in practice made very largely of the light iron; and then it becomes very desirable to make the stator and rotor from the same sheet. This method has several limitations. In general it can be followed:

1. When both rotor and stator are made by simple dies—round-hole dies and slot dies—and the air gap is $\frac{1}{32}$ in. or more on one side. This applies to punchings having a tooth tip of $\frac{1}{16}$ in. as well as to those having the thinner tip. With round-hole and slot dies this point has no influence.

2. When the rotor is made with compound die and the air gap is $\frac{1}{16}$ in. or more on a side and there is no trimming operation. The reason for this is that a compound die leaves "toothpick scrap," and at least $\frac{1}{16}$ in. must be allowed on the outside to hold toothpicks and center together. This rule applies only to tooth tips of $\frac{1}{16}$ in. or more. With less than $\frac{1}{16}$-in. tip, the center cannot be used for the corresponding rotor, but must be used up on the next smaller diameter.

3. When the stator punching is made with a combination die of the type in which, as described before, the center is punched out in a separate operation, leaving plain circle scrap, and when simple dies are used on the rotor, the air gap to be $\frac{1}{32}$ in. or more on one side. In other words, this air gap can be made the limit and the center for the rotor still used, even though the stator tip is less than $\frac{1}{16}$ in., since the dies used on the stator as well as on the rotor do not require resorting to the heavier tip, with the additional trimming operation. This rule therefore applies to both the $\frac{1}{16}$-in. tip and the smaller tip. Whenever compound dies are used on the stator and rotor, an additional trimming operation on account of the tooth tip is necessary. Sufficient material—$\frac{1}{16}$ in. on a side—must be left for the trimming operation on the stator, plus $\frac{1}{16}$ in. on a side for the toothpick center, making a total of at least $\frac{1}{8}$ in. on a side. In other words, this method of using the center from the stator for making the rotor punchings would in this case be feasible only if the air gap is $\frac{1}{8}$ in. or more on a side, which as a rule is not the case on present-day alternating-current machines.

When this method of making rotor punchings from the centers of the stators is used, it is necessary to arrange a system whereby orders for stator and rotor punchings are placed with the punch shop at the same time. The saving that may be accomplished by the method described varies of course with the size of machine and other conditions.

⁂

Development of Welding Process—In summarizing the development of the welding process, H. R. Smartley, Jr., in a paper read before the International Engineering Congress, states that it was early found that welds having a breaking strength equivalent to that of the metal itself could be produced, but the sacrifice of elongation and reduction of area materially lessened the apparent value of such welds. Present practice is directed toward securing a weld of good tensile strength, as compared with the strength of the plate, with high ductility, since thereby the service conditions are better fulfilled.

Punches and Dies for Making Talking-Machine Details

By Robert Mawson

SYNOPSIS—In this article are shown some punches and dies of modern construction. They are made separate from the main body of the tool and attached with dowels and screws, so that any necessary repairs can be made quickly and cheaply. The tools are all of the compound type, first piercing and then blanking out the part.

On page 450 are shown some of the jigs used by the Rex Talking Machine Corporation, Wilmington, Del., in manufacturing its machines. In this article are shown punches and dies used in producing other parts. Like those shown in the previous articles, they are good examples of high-grade small-tool design and manufacture.

In manufacturing details for talking machines it is necessary that the parts be produced cheaply. Wherever it is possible and the pieces are of a suitable nature, punches and dies are used. If these tools are properly designed and made, the parts will be manufactured at a minimum cost and will be interchangeable.

On some details the tool can be designed of the compound type. This style of punch and die enables the perforating or piercing of one part and the finish-blanking of another element in one stroke of the press.

In manufacturing the punch and die it is advisable to make the various elements separate. For example, if the shank of the punch is made as a separate element, it may be of a cheaper material. The tool-steel punches should then be attached securely by means of screws and dowels. The base of the die is often made of cast iron, and the stripper plate and die are fastened to it.

The stripper may be made of machinery steel, using screws and dowels to hold it down in position on the die bed. The tool-steel die element is inserted in the cast-iron die bed and is kept in position by means of setscrews or keys. By manufacturing the tools in this manner, if any of the parts break, it is easier to repair them than if they are of unit construction.

This method of making punches and dies also lends itself very well to a small strap, where the tools are only occasionally used. Under such conditions the shank of the punch and the bed of the die may serve for many operations. It is only necessary to make separate punch stripper plates and die elements, which are accurately located by similar dowel holes and attached by setscrews or other means. In the illustration are good examples of such punch and die design.

The punch and die shown in Fig. 2 is interesting, as it illustrates the best method of blanking out a long piece with the smallest amount of waste. The punch and die shown in Fig. 4 illustrates the manufacturing of a gear with the holes and teeth cut completely. When such parts are made in this manner, the subsequent operation of cutting the teeth is obviated. As this is often a rather lengthy operation, requiring another machine, with its operator, on thin stock, the method illustrated is worth studying.

The gears produced with the tools shown work sufficiently well for the purpose for which they are used. This is done by placing the punch at an angle, as shown.

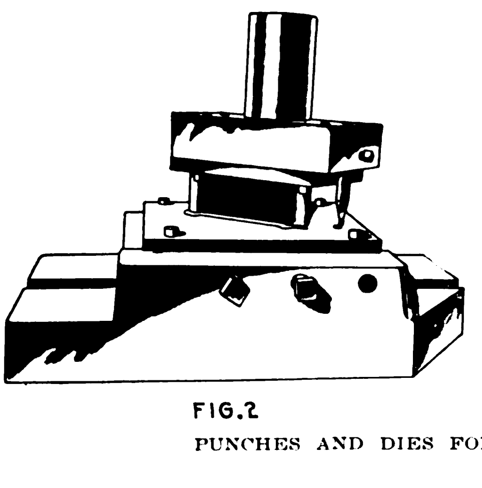

FIG. 2

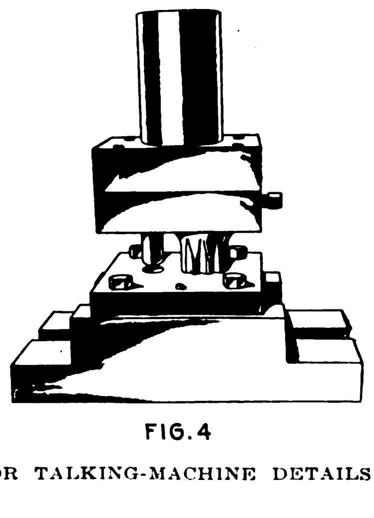

FIG. 4

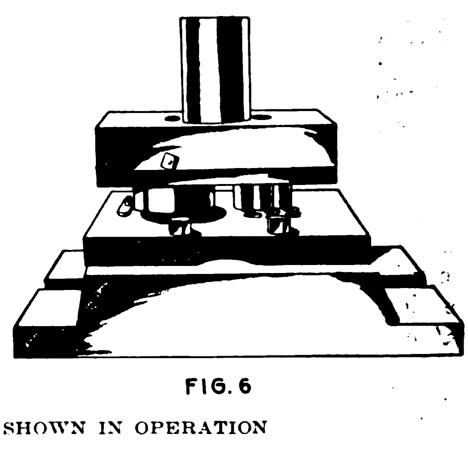

FIG. 6

PUNCHES AND DIES FOR TALKING-MACHINE DETAILS SHOWN IN OPERATION

FIGS. 2 AND 2-A

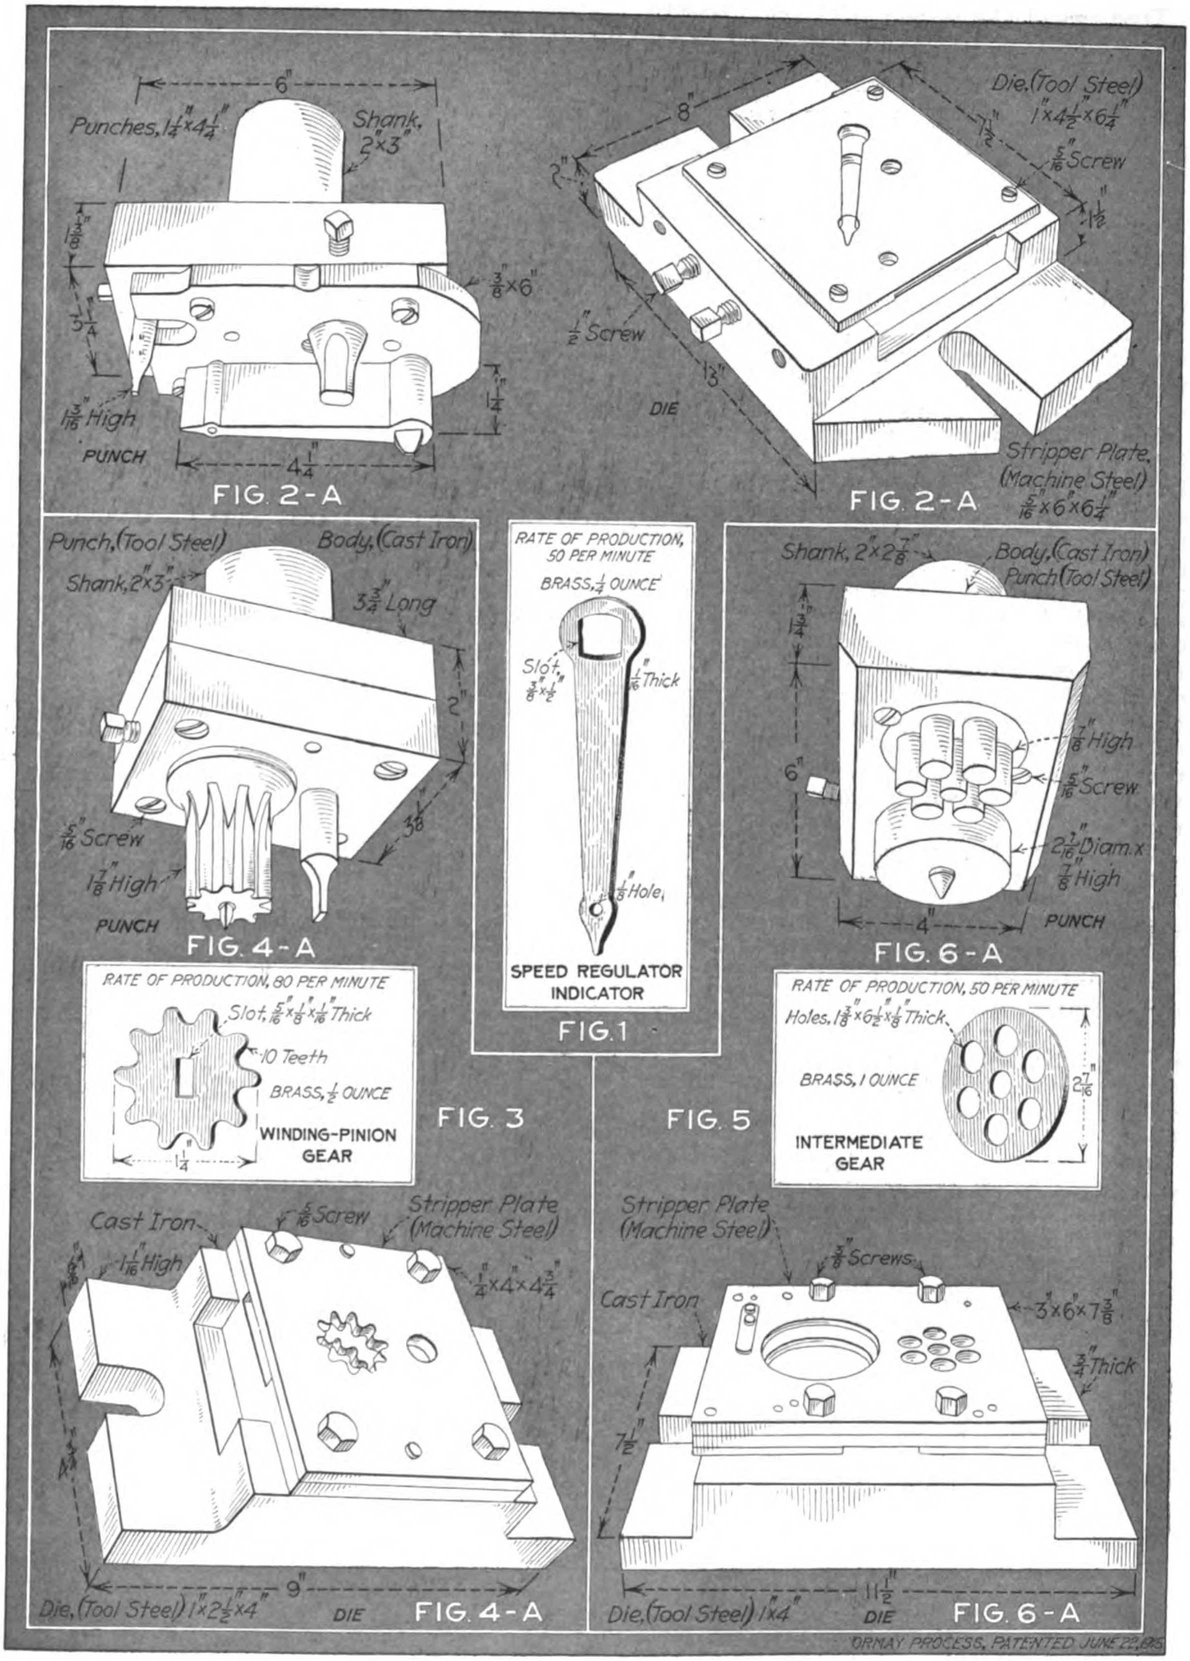
Operation—Slotting, piercing and blanking speed-regulator indicator, Fig. 1. The stock is fed into the die under the stripper, and the tool is made of the compound type. The slotting and piercing tools are set in advance of the blanking punch. The stock is thus slotted and pierced; and when it is fed forward to the second position, the punch is made to descend and the piece is blanked out to the desired shape.

FIGS. 4 AND 4-A

Operation—Slotting and blanking winding-pinion gear, Fig. 3. The stock, which has been cut to the correct width, is fed in from the end. The compound punch pierces the slot of the first blank. The stock is then fed along and the punch blanks out the gear. One strike of the press thus pierces out one blank and punches out a finished gear.

FIGS. 6 AND 6-A

Operation—Piercing and blanking intermediate gear, Fig. 5. The stock, which has been previously cut to the correct width, is fed into the end of the die from the right, under the stripper. The first punch pierces the seven holes. When the stock has been fed forward against a stop pin, the second punch blanks out the gear. Teeth are cut on the periphery of the gear blank in a later operation. The gear is completed in two operations.



DETAILS OF PUNCHES AND DIES USED IN TALKING-MACHINE WORK

Determining Working Limits for Interchangeable Parts

By J. C. P. Bode

When determining working limits for interchangeable parts there are several important questions to be considered, and on the answers depends success or failure.

The first question is, How large can the limits be? Because from a manufacturing standpoint we know that the larger the limits the more economically we can produce. Large limits allow tools to be used longer, and unskilled labor can be employed to greater advantage than when a higher degree of accuracy is required. Cutters, drills, reamers, etc., can be ground down further when the limits are large, and money will be saved in making the jigs, fixtures, dies and gages.

In fixing limits we must consider the purpose the piece is to serve in the finished machine, and whether it need be a close fit in order to work to best advantage. Many a piece has been given a certain dimension just because it has to be made some reasonable width or length within a sixteenth of an inch. In making an interchangeable part we should always, if at all possible, locate from the same point. The nature of the part may make it necessary to locate from an unimportant point. Still we must keep our limits low, because we use this side, hole or slot for locating purposes. We must determine what the errors and differences would be and what they would amount to if carried all through the subsequent operations. We must make sure that even the extreme case would be acceptable with reference to every step in manufacturing.

While it is not common practice, it would be well to give limits for the toolmaker's use. Many a man has spent extra hours to make a fixture dead right when he might have made it in far less time had he possessed an idea of the degree of importance of that fixture. Give him limits in questionable points. It often saves a great deal of time, worry and money.

Much depends on the system or rule followed in expressing limits. Shall it be plus limits, minus limits, or both for the same figure? My experience has been that, with a few exceptions, the only safe way is to give a limit in only one direction.

If we have a hole to drill or bore into which another piece must fit, we should give a plus limit only, and there will never be a question about fit. The piece fitting in this hole, however, should have a minus limit. This is a simple example; and while it would not require extra time to fix a plus and minus limit in this case, there would be a much greater chance for mistakes. If, for example, our diameter is 4 in., we allow 0.002 in. limit; if we give a plus limit for the hole and a minus limit for the plug, we would have 4 in. plus 0.002 in. for the hole, and for the plug we would have 4 in. minus 0.002 in. It will be seen at once that the basic diameter, 4 in.—which is the ideal diameter—appears in both cases, whereas this true diameter will not appear both times, if a "plus or minus" limit were given. We would then have for the hole 4 in. plus or minus 0.002 in. and for the plug 3.988 in. plus or minus 0.002 in. The plus and minus plan leads to no end of mixups when it comes to a combination of dimensions.

Still there are cases where plus or minus limit is the only right thing to give—as, for instance, distances between holes. If the toolmaker bores his jig and the correct figure between holes is 6 in., allow a difference of 0.002 in. not only because that gives you a tolerance of 0.004 in., but also because the toolmaker does not know just which way he is going to be out a little. If you give this 6 in. plus 0.002 in. he will probably aim at 6 in. plus 0.001 in. which will permit him to be out 0.001 in. in either direction.

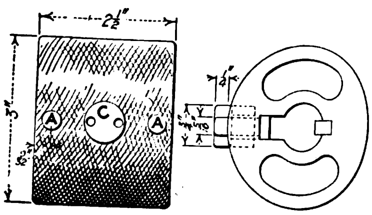
The ideal time to determine limits is after all operations have been laid out; but this is often impractical. So the man who puts on the limits should have a good knowledge of manufacturing methods, and even he may often have to change his limits for manufacturing reasons which were not evident at first. Close coöperation between the tool designer and the man designing the actual components of a machine is very much to be desired, and in following the rules laid down here one will be pretty sure to get things right.

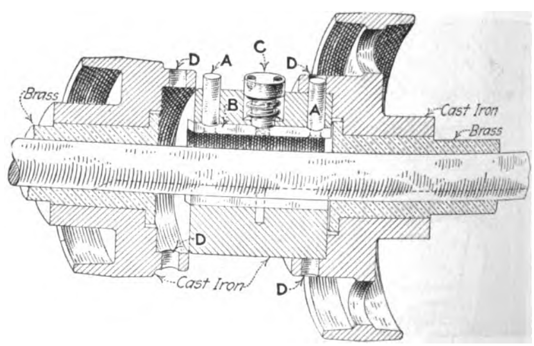
A Simple Positive Clutch

By G. B. Olson

The illustration shows a clutch used on the spindle and on the countershaft of a high-speed drilling machine. The original design called for cone type friction clutches, but on account of the small diameter they were not satisfactory. I also tried several types of expanding band clutches without success.

The clutch shown was then designed and has proved a complete success. It is made of a 3-in. diameter by 2½-in. cast-iron body, cored to make it lighter and also





A POSITIVE TWO-SPEED DRIVING CLUTCH

to assist in balancing. The driving pins *A* are of $\frac{5}{16}$-in. drill rod, hardened at the upper end, while the lower end is riveted into a piece *B* of $\frac{3}{16}$x$\frac{7}{16}$x3-in. cold-rolled steel *B*.

To change from one speed to another the center button *C* is pressed down and the whole center piece moved sidewise to clutch into either pulley. The driving pin then enters one of eight holes *D* in the pulley and the spring holds it in position.

Manufacturing 12-In. Shrapnel--I*

By Robert Mawson

SYNOPSIS—In these, the first authentic, articles describing the operations followed in manufacturing 12-in. shrapnel are shown not only photographic illustrations, but detailed drawings of the attachments to machines, jigs, fixtures, gages and other necessary equipment. In the manufacture of this shell, owing to its size and the fact that it is made from a solid bar, it was found that ordinary machine tools were not strong enough to take the cuts desired. Therefore, it was necessary either to add cutting-bar supports or to design special machine tools. This set of articles forms a comprehensive treatise on the making of this shell.

The manufacture of the 12-in. shrapnel shell calls for many interesting methods, owing to its size and the accuracy of finish demanded. These conditions ordinarily would warrant the highest degree of mechanical thought and experience. When the problem must be tackled by either changing over present shop equipment or designing special machine tools without any precedent for guidance, the task becomes much more difficult.

Owing to the fact that time was at a premium, tools already in service that could be used to perform any machining operation were utilized. On some operations, however, the strains set up were so enormous that one-purpose machines were designed, built and are being used.

In Fig. 2 are shown samples of each stage of manufacture from the blank cut to length to the finish-machined shell ready for filling and charging with the bullets, rosin and powder. A detailed illustration of the shell is shown in Fig. 1. The sequence of operations is as follows:

1. Lay off ends of billet for center and center punch.
2. Square center and countersink.
3. Rough-turn and cut blanks to length.
4. Rough-bore.
5. Second bore.
6. Bore powder chamber and bore for diaphragm.

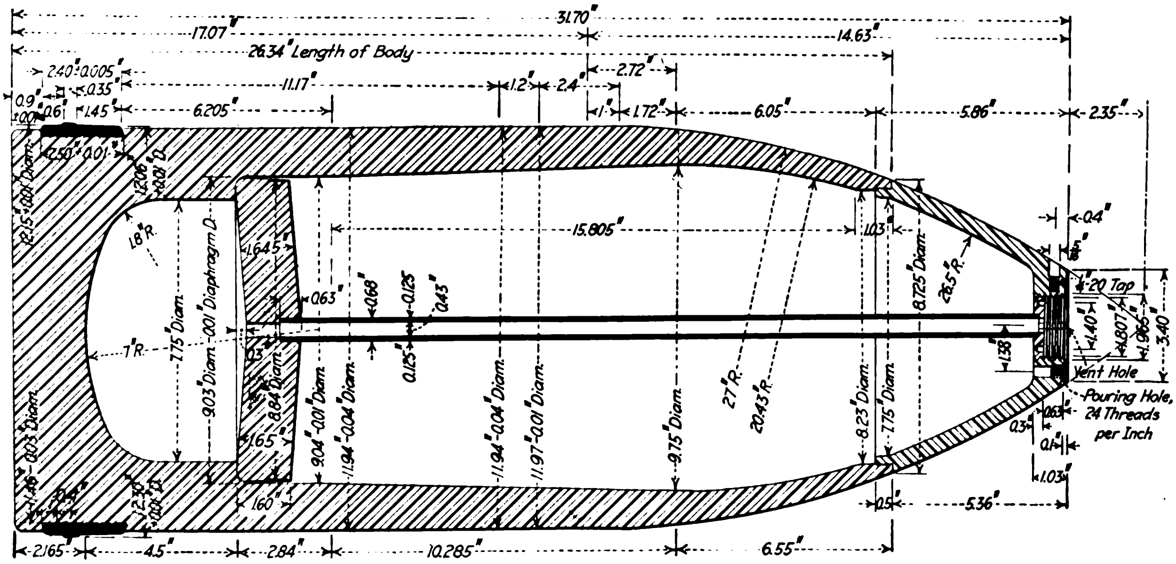


FIG. 1. DETAILED ILLUSTRATION OF 12-IN. SHRAPNEL SHELL

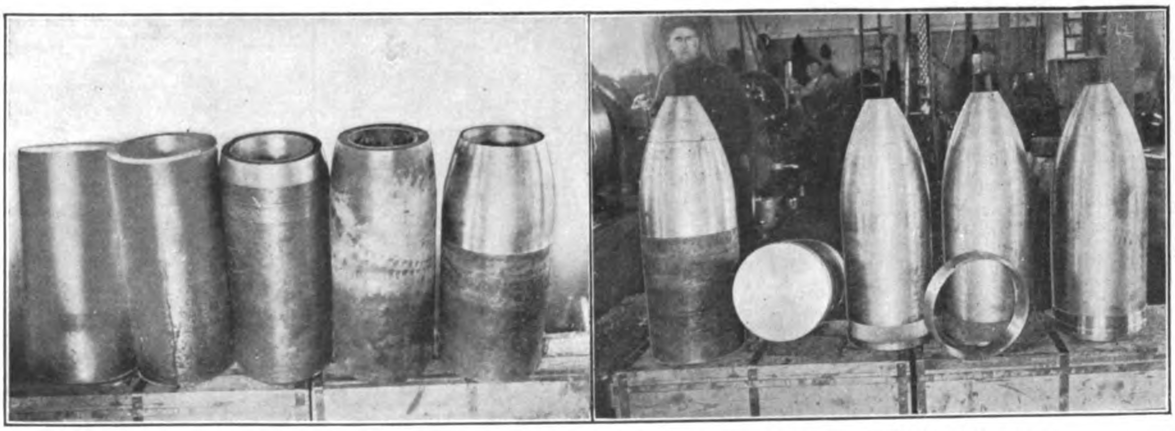

FIG. 2. VARIOUS STAGES OF 12-IN SHRAPNEL FROM ROUGH TO FINISHED SHELL

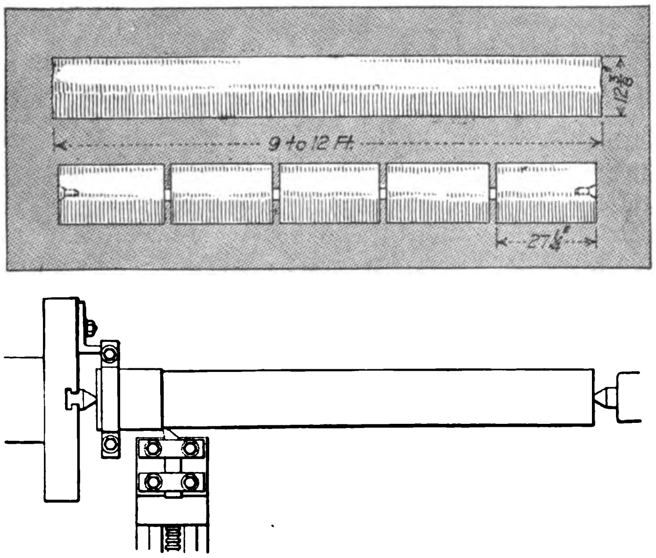

FIG. 3. OPERATION 3. ROUGH-TURNING AND CUTTING THE BLANKS

Machine Used—Bement-Miles lathe. using ½-in. width cutting-off tool.
Special Fixtures and Tools—None.
Gages—None.
Production—4 in 12 hours.
Lubricant—Turn dry and use 50 per cent. lard oil and 50 per cent. kerosene oil when cutting off.
Note—Between Grinding of Tool—Two.
Lathe operates at 6 r.p.m. with a feed of 0.125 in. per rev.
References—Fig. 3.

7. Fit in diaphragm.
8. Nosing.
9. Turn inside form.
10. Open end faced and thread cut to suit adapter.
11. Fit in adapter and turn part of outside and machine contour.
12. Face back end and turn rest of body on outside.
13. Turn channel and knurl.
14. Force on copper band.
15. Turn copper band to shape
16. Final inspection.
17. Remove plug, adapter bottom and adapter.
18. Fit in spider to hold powder tube central.
19. Fill in bullets and rosin.
20. Remove spider, place on adapter, fill with bullets to required weight.
21. Insert adapter bottom.
22. Fill with powder through powder tube.
23. Fill powder tube with pellets.
24. Final weighing.
25. Screw in plug and grease ready for packing.

The steel from which the blanks are made comes to the works in billets averaging from 9 to 12 ft. in length and approximately $12\frac{3}{8}$ in. in diameter. Its chemical analysis is: Carbon, 0.47 per cent.; manganese, 0.68 per cent.; phosphorus, 0.022 per cent.; sulphur, 0.035 per cent. The physical analysis is: Tensile strength, 90,000 to 110,000 lb. per sq.in.; elastic limit, 50,000; elongation, not less than 8 per cent.; reduction of area, not less than 21 per cent. For the operation of rough-turning the outside of the billet and cutting the blanks to length, which follows the centering operations, the billet is held on the centers of a lathe and driven with a dog attached to the faceplate. A diagrammatical illustration of this operation is shown in Fig. 3. The bar is rough-turned to $12\frac{1}{16}$ in. and cut into lengths of about $27\frac{1}{4}$ in., no gage being used.

The blank is then held in the special chuck, Fig. 4, for the next operation, which is rough-boring to $5\frac{1}{2}$ in. in diameter. The boring bar, head and cutter for this operation are shown in Fig. 5. The depth gage, which is of the pin type may be seen in Fig. 6. The bar is supported and

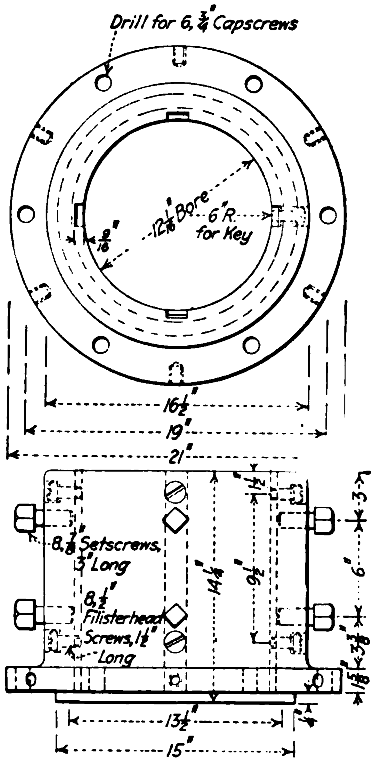

FIG. 4. HOLDING CHUCK FOR LATHE

guided through special clamps fitted on the lathe carriage. A detail of this attachment is given in Fig. 7.

It will be observed that the guide clamp is fitted with a $\frac{7}{8}$-in. key that is set into a keyway machined in the boring bar, thus holding the bar from rotating. The outer end of the shell is supported by a steadyrest, a detail of which appears in Fig. 8. Fig. 9 shows the lathe set up for performing this rough-boring operation. A diagrammatical view of the surface machined and manner in which the shell is held is given in Fig. 10.

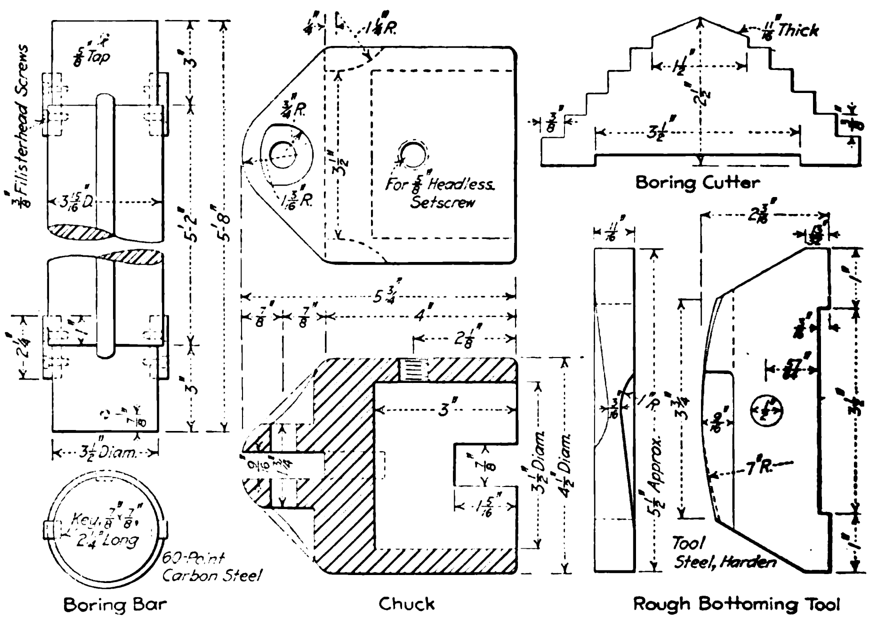

FIG. 5. DETAIL OF BORING BAR, HEAD AND CUTTER

For the next operation the blank is held in a chuck similar to that in Fig. 4. This operation is opening out the bored hole to 7.6875 in., using a boring bar like that in Fig. 5 and the head and cutter of Fig. 11. This tool is fed into the shell to the same depth as the roughing cutter—24½ in. The cutter is then removed and the 9.07-in. tool, Fig. 12, inserted in the same head. This cutter is then fed into the shell for approximately 16 in., measuring from the open end.

The next operation—the sixth—is performed with the shell in the same setting on the lathe. The powder cham-

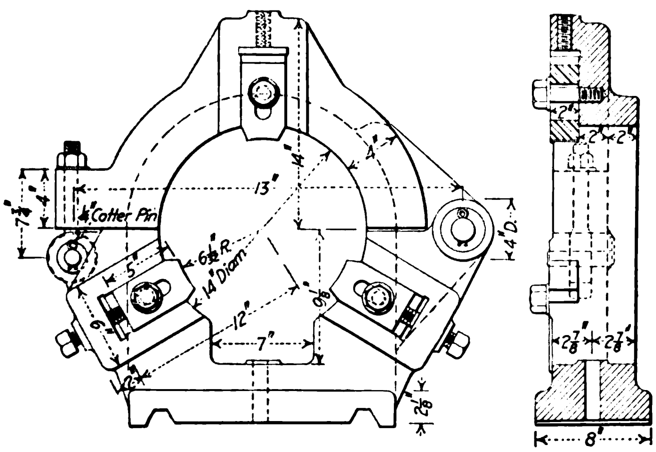

FIG. 8. STEADY REST FOR BORING

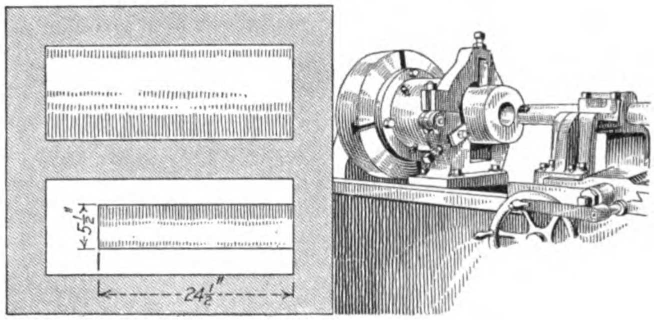

FIG. 10. OPERATION 4: ROUGH BORING

Machine Used—Bement-Miles lathe.
Special Fixtures—Steady rest, supports for boring bar, boring bar, head and cutter.
Gages—None.
Production—One in 8 hours.
Lubricant—"Exanol."
Note—Between Grinding of Tool—Average two shells.
Note—Lathe operates at 30 r.p.m. and feed of 0.014 in. per revolution.
References—Figs. 4, 5, 6, 7, 8 and 9.

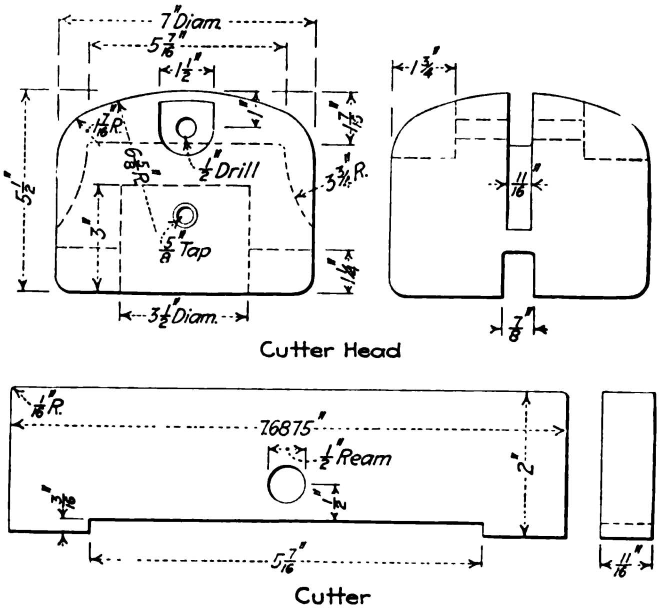

FIG. 11. BORING CUTTER AND HEAD

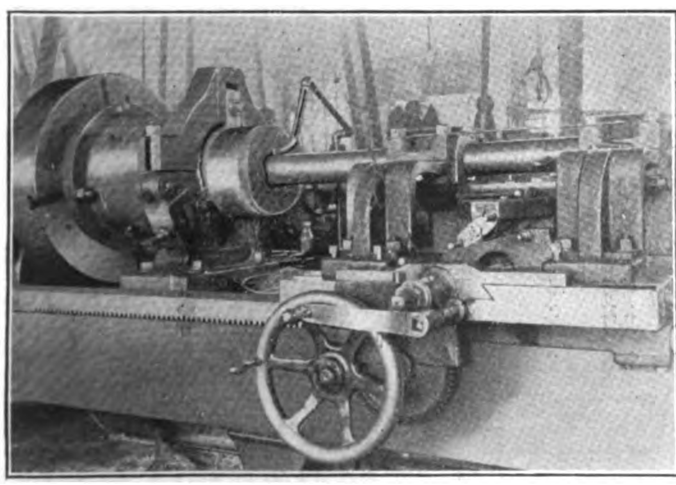

FIG. 9. ROUGH-BORING THE SHELL

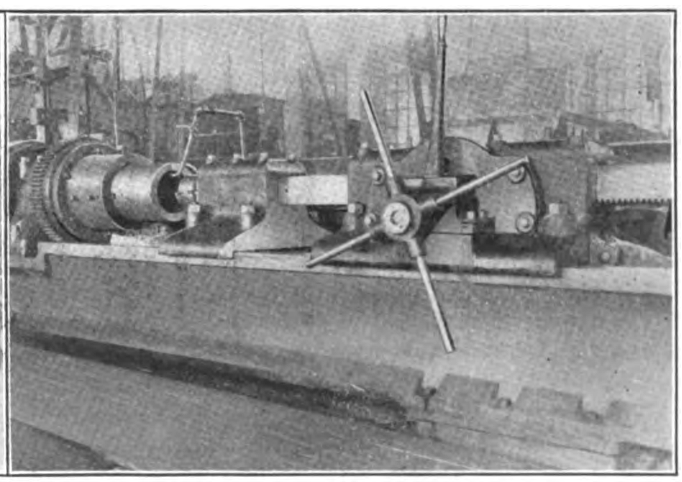

FIG. 17. SECOND BORING OPERATION

ber is rough- and finish-bored with a bar similar to that in Fig. 5 holding the head and cutters, Fig. 13. The gage, Fig. 6, is for testing the depth of the bored hole. The machined contour of the powder chamber is measured by the gage shown in Fig. 14.

The next suboperation is machining the surface to suit the diaphragm. A boring bar similar to the one in Fig. 5 is used, holding a head like that illustrated in Fig. 11. The boring cutter appears in Fig. 15. The gage for testing this bored hole, so that the correct depth of powder chamber will be obtained, is illustrated in Fig. 16.

The lathe employed in boring the powder chamber and machining for the diaphragm is shown in Fig. 17 and a diagrammatical view of the work in Fig. 18. Before the shell is removed from the chuck, the front end is chamfered down for about 3 in., thereby facilitating the nosing-in operation, which follows. The shell at this stage is detailed in Fig. 19. For the nosing operation, for which it is transferred to the blacksmith shop, the shell is heated in a special crude-oil furnace, Fig. 20. It will be observed that the furnace is designed to heat four shells at once, and the approximate temperature is 1,600 deg. F. The average consumption of crude oil is 10 gal. per hr.

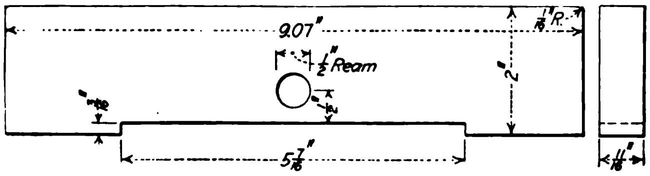

FIG. 12. DETAIL OF BORING CUTTER

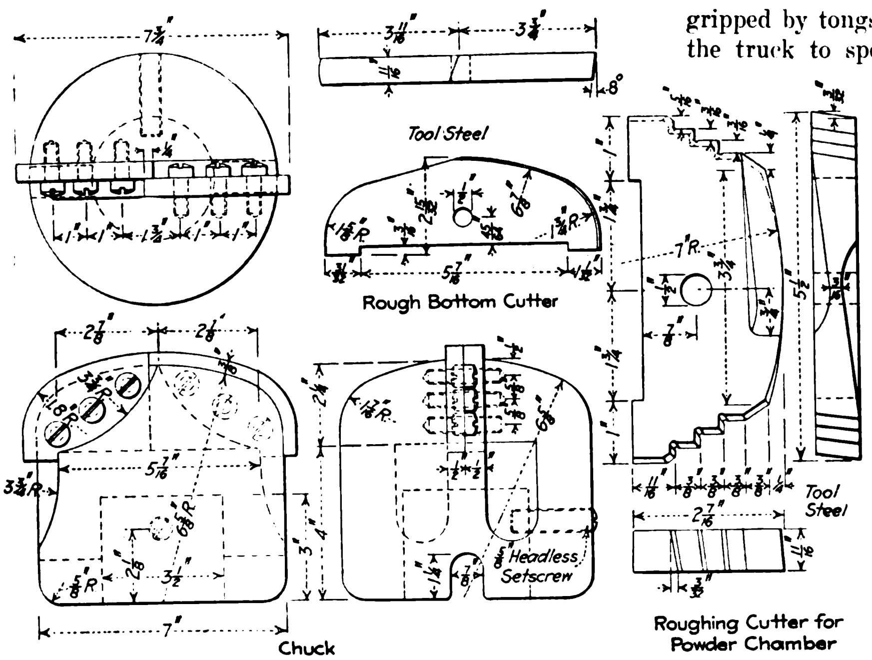

FIG. 13. CUTTER AND CHUCK FOR POWDER CHAMBER

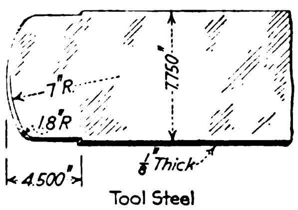

FIG. 14. GAGE FOR POWDER CHAMBER

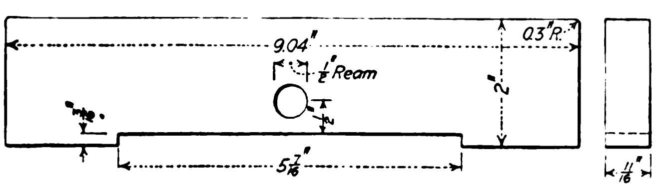

FIG. 15. BORING CUTTER FOR DIAPHRAGM SURFACE

The operation of inserting the diaphragm and nosing is given in diagrammatical form in Fig. 21. After a shell has been heated to the desired temperature, it is gripped by tongs, as shown, and transferred by means of the truck to special dies attached to a steam hammer. The diaphragm, the manufacturing of which will be described in another article, is then slid inside the shell. A rod placed in the hole bored to receive the powder tube holds the shell squarely.

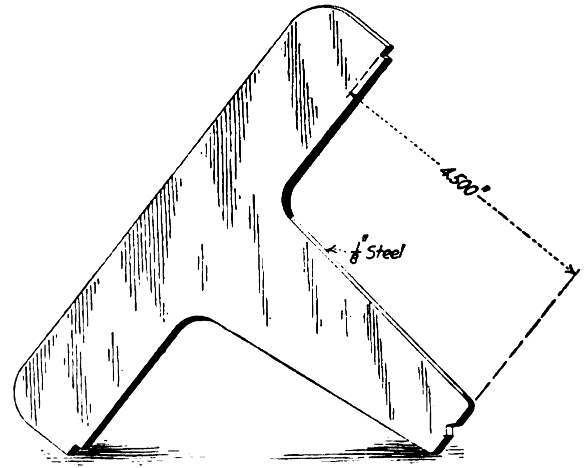

FIG. 16. GAGE FOR DEPTH OF POWDER CHAMBER

In Fig. 22 is one of the shells held between a diaphragm in position and the dies. The shell is then placed in the furnace and heated a second time. When the correct temperature is reached, the shell is placed between the dies of the steam hammer in a manner similar to that described. The tup of the hammer carrying the upper die is forced down on the end of the shell until the correct nosing is obtained.

Fig. 23 presents a view of the steam hammer with a shell in position for being nosed and also illustrates the dies

the air; then it is returned to the machine shop for the subsequent operations.

A vertical hydraulic press was modified and forming dies fitted for the nosing operation; but the steam hammer has been giving such good results that the press is not used. However, the press might be found to be the better method on smaller shells.

Fixtures for Sword Bayonets

By C. D. Corwin

During the past summer the writer was called upon to design for rapidly milling sword bayonets several fixtures suitable for use on the Briggs high-duty miller.

The bayonet is made from $\frac{5}{16}$x1⅛-in. specially rolled steel stock, complying with specifications. The first operation after cutting to proper length is to clamp several pieces side by side and gang mill the tang and 1½ in. of blade edge, to give the shape shown at *A*, Fig. 2.

Four of these pieces are then clamped side by side in the fixture shown in Fig. 3, and the shape of the cutting edge is milled. It will be noticed that, as the work proceeds against the cutter, the profile pieces marked *R* slide over the rollers *H*, lifting the table *P* the proper amount to enable the cutter to give the correct shape to the bayonet. As soon as the point of the bayonet has passed the cutter a sufficient distance, a positive stop on the knee of the machine throws out the feed.

The four blades are then removed by loosening the three nuts *T*, and four new ones are put in and locked. The lever *L* is then thrown over to the right, permitting the left end of the fixture table to swing downward sufficiently to give the cutter clearance above the blanks. A quick-return mechanism tripped by the operator causes the miller table to run to the left until automatically stopped at the correct position under the cutter. The lever *L* is then thrown to the left, which raises the fixture table to the cutting position, whereupon the feed mechanism is engaged and the cut starts. The blanks after this cut appear as at *B*, Fig. 2.

Two of the blades are then placed on the table of the fixture shown in Fig. 4, at the left or No. 1 position, and a cut is taken on one side, changing the shape from a rectangle to that at *C*, Fig. 2. These two pieces are then shifted to position No. 2, Fig. 4, wh[illegible] their shape is changed from that at *C* to that at *D*, Fig. 2. All four cuts are carried on at the same time. The pieces then go from this fixture to a similar one with slightly different table, where they are given the slope shown at *E*. Fig. 2. At the same time two other blades are milled from the section *E* to *F*, Fig. 2.

The bayonet now has the sections shown at *G*, Fig. 2, with the blade tapering toward the point. Next, the bayonets are fitted for the hilt attachments and afterward hardened and ground to a cutting edge.

A description of the two types of fixtures may be of interest. In Fig. 3 at *A* is the knee of the Briggs miller, upon which the table *B* rides, being driven by a nut and feed screw, not shown. Fastened rigidly to the knee are two brackets *C* and *D*. These support the shaft *E*, upon which are pinned two roll carriers *F*.

Passing through the upper end of the roll carriers is a shaft *G*, with a head turned on one end. This shaft serves as the journal for the two rollers marked *H*, while its head forms the pin to which one end of the link *I* is attached. The link *I* is operated by the crank *J* keyed to the shaft *K*, which carries at its outer end the shifting handle *L*. A spring *M* serves to hold the handle *L* securely in the running position and also prevents any small vibration.

Two pins *N* serve as stops for the handle. When this is to the left, the link and centers are so arranged as

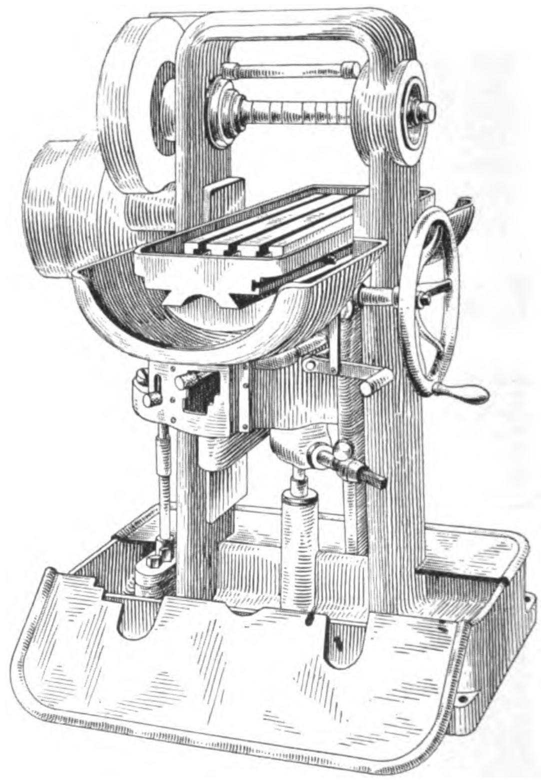

FIG. 1. MILLER ON WHICH THE SWORD BAYONET MILLING WAS PERFORMED

to lock the mechanism. A raised boss on the bracket *C*, met by a boss on crank *J*, forms a rigid stop for the link while the cut is being taken.

Mounted on the table at the right is shown a bracket *O*, definitely located in the center of the table and positioned longitudinally by means of two tongues at right angles to each other and fitting into the grooves of the table. Through the bracket *O* passes the shaft *Q*, upon which the fixture table *P* can swing. At *R* are the two

profile plates of steel, which slide over the rollers H and are so shaped as to give the proper lift to the fixture table. At S is a bracket accurately positioned. It serves to take any side thrust, as well as to act as a guide for the fixture table. There are three bolts T, threaded on one end to

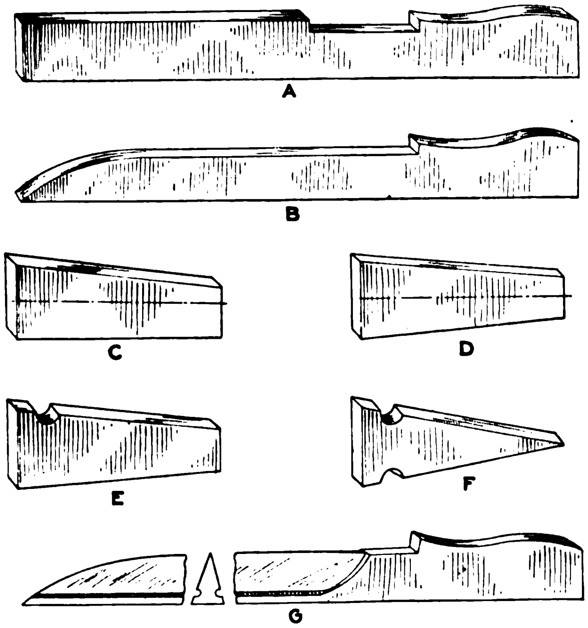

FIG. 2. CHANGES IN THE SHAPE AND SECTION OF SWORD BAYONETS

receive hexagon nuts and hold the blanks fast in position.

In designing the fixture it was necessary to make three tables, each with its own profile plates, because the bayonets taper from near the hilt along the back edge toward the point, as shown at G, Fig. 2.

In the fixture of type 1 the bayonets are held from the sides at three points and positioned from the tang end,

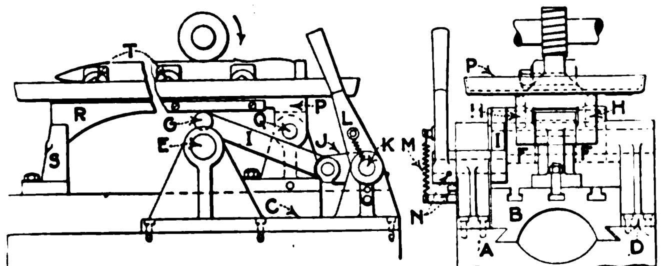

FIG.3

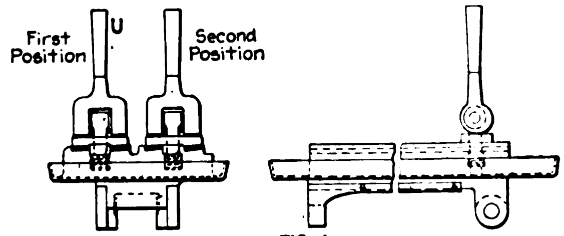

FIG.4

FIGS. 3 AND 4. DETAILS OF MILLING FIXTURES FOR SWORD BAYONETS

Fig. 3—Edge milling fixture fitted with Type I table. Fig. 4—Fixture for the flat sides

while on tables of types 2 and 3 they are held down at the tang by means of two cam clamping handles, shown in Fig. 4. Each handle holds two bayonets, and the positioning is done by means of a pin fitting against the tang projection. The clamping handles are made up as shown in Fig. 4, in which U is the handle proper, with its lower end forming a cam.

All tables have ample troughs around them and two outlets with flexible hose connection to the tank at the base of the machine. This tank forms the reservoir for the cooling fluid, which is pumped to the cutters by means of a small twin-gear rotary pump driven from the feed shaft of the machine.

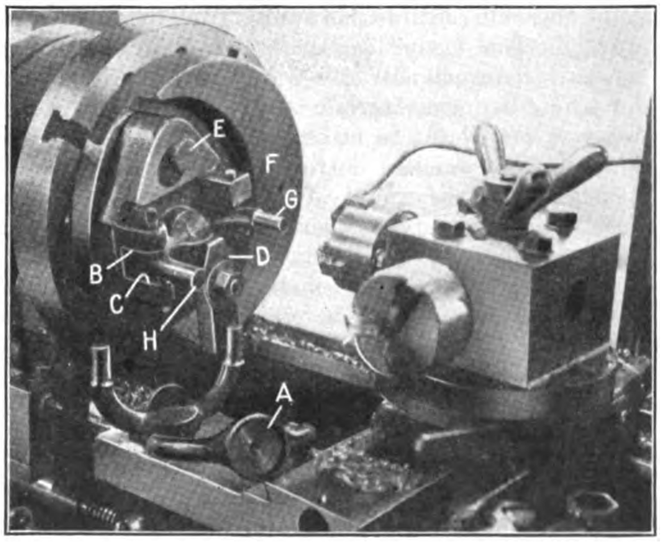
The fixtures were so designed that one set of patterns answered for all castings except the two extra types of tables; and this pattern was made up of three pieces, so that with slight alterations it served for all fixtures. The profile plates, rollers and pins upon which any appreciable wear might occur were made of steel, hardened and ground.

The successive cuts, changing the bayonet from a rectangular shape to a sharp triangle, necessitated a little different rest for each position of the blank and a slightly different profile plate. Otherwise, tables of types 2 and 3 are identical.

Machining Forged Fork Ends

By E. V. Thomas

The ends of the drop-forged forks on Henderson motorcycles are machined in the indexing lathe fixture shown. The crown of the fork is first machined out, as at A, in another machine. This hollowed-out crown is then used to locate by in the indexing fixture, where it is placed



MACHINING FORGED FORKED ENDS

over a locating plug. The sides of the fork rest between guides B and C and are centered by setscrews in the guiding jaws. The entire forging is clamped in with the strap clamp D.

The indexing part of the fixture is offset enough to bring each fork end in turn central with the lathe spindle. The lockpin for the indexing part may be seen at E. As the weight of the forging and carrier is considerably to one side of the center of rotation, the counterweight F is used to balance it. Two three-jawed hollow mills are employed in the turret to machine the ends. One roughs the end, and the other gives a finishing cut. With one end finished as at G, the carrier is indexed and the end H brought in line with the hollow mills.

Casehardening Small-Shop Steels--II

By John H. Van Deventer

SYNOPSIS—This article deals with the subject of quenching case-carbonized articles and with the heat treatment of such pieces to secure maximum toughness. Pack-hardening is discussed and also the casehardening of alloy steels and cast iron. A combination quenching tank for hardening and coloring is illustrated.

All blacksmiths are by nature and training more or less experimenters, and very few have not some "secret" formula for accomplishing wonderful results in hardening. Cast-iron hardening has received a good part of their attention in this respect with varying degrees of success. While it has been an easy matter to make cast iron extremely hard on the surface—in fact, as hard as the hardest tool steel—no one has as yet found a way to add the element of strength to this hardness without which its use is limited to gages, templets and other things that do not require much strength.

Some amusing results often accompany such experiments. One blacksmith of my acquaintance, who had obtained very fair results with cast-iron hardening, was always searching for some chemical or compound to add to the quenching bath to make this "grip" the metal more forcibly. This "grip" is a noticeable thing in hardening cast iron; not only can you feel it on the end of the tongs, but when certain solutions are used, it becomes so forcible as to make itself heard—making one think that a miniature torpedo was exploding beneath the surface of the water. I was passing through his blacksmith shop one day when a new mixture was being tried out. As soon as the blacksmith plunged the red-hot casting into the barrel containing this mixture, there was a violent explosion in which blacksmith, barrel, quenching mixture and casting were indiscriminately mixed. The experimenter picked himself up, felt of the various parts of his anatomy to see what was missing and, finding himself intact, exclaimed regretfully: "Say, what a fine mixture that would be if you could only get a barrel strong enough to hold it!" I do not know what caused this explosion, but having seen it, can be sure that it happened and also that it put an end to the experimenting of this particular blacksmith, who afterward stuck to the tried and tested formulas. Probably the heat of the casting was all that was needed to set up some powerful chemical reaction between the elements in the bath.

An old formula that has done good service in the matter of surface-hardening cast iron is as follows: To 20 gal. of water add 1 pint of oil of vitrol, 2 pecks of salt, 4 lb. of alum, ½ lb. yellow prussiate of potash, ½ lb. cyanide of potash and 1 lb. saltpeter. This bath can be kept in a covered wooden barrel. The casting is heated cherry-red and then plunged into this bath, which hardens its surface. Sometimes it is necessary to repeat this performance two or three times to get the surface sufficiently hard.

The quenching tank is an important feature of apparatus in casehardening—possibly more so than in ordinary tempering. One reason for this is because of the large quantities of pieces usually dumped into the tank at a time. One cannot take time to separate the articles themselves from the casehardening mixture, and the whole content of the box is dropped into the bath in short order, as exposure to air of the heated work is fatal to results. Unless it is split up, it is likely to go to the bottom as a solid mass, in which case very few of the pieces are properly hardened. A combination cooling tank is shown in Fig. 1. Water inlet and outlet pipes are shown and also a drain plug that enables the

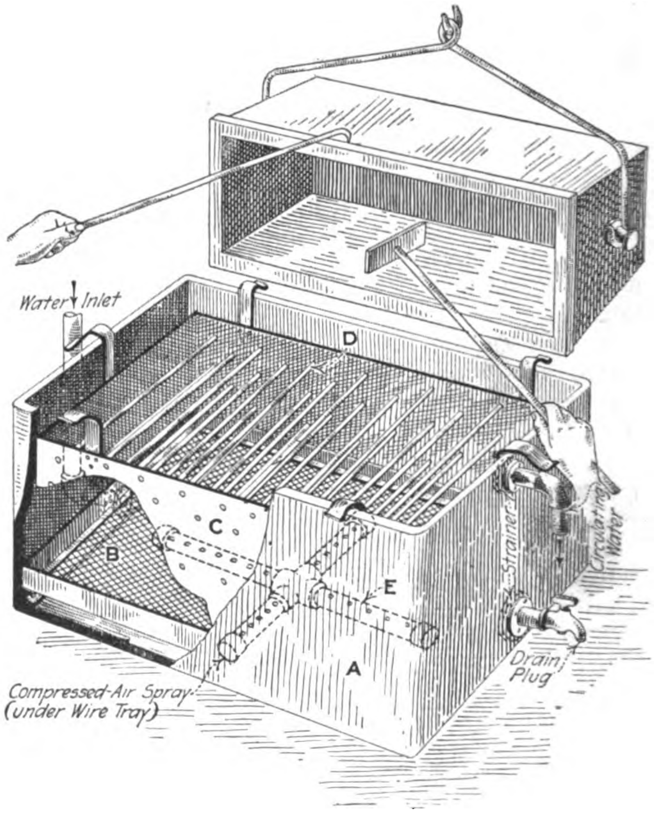


FIG. 1. COMBINATION COOLING TANK FOR CASEHARDENING

tank to be emptied when it is desired to clean out the spent carbonizing material from the bottom. A wire-bottomed tray, framed with angle iron, is arranged to slide into this tank from the top and rests upon angle irons screwed to the tank sides. Its function is to catch the pieces and prevent them from settling to the tank bottom, and it also makes it easy to remove a batch of work. A bottomless box of sheet steel is shown at *C*. This fits into the wire-bottomed tray and has a number of rods or wires running across it, their purpose being to break up the mass of material as it comes from the carbonizing box.

Below the wire-bottomed tray is a perforated cross-pipe that is connected with a compressed-air line. This is used when casehardening for colors. The shop that

has no air compressor may rig up a satisfactory equivalent in the shape of a low-pressure hand-operated air pump and a receiver tank, for it is not necessary to use high-pressure air for this purpose. When colors are desired on casehardened work, the treatment in quenching is exactly the same as that previously described except that air is pumped through this pipe and keeps the water agitated. The addition of a slight amount of powdered cyanide of potassium to the packing material used for carbonizing will produce stronger colors, and where this is the sole object, it is best to maintain the box at a dull-red heat.

The old way of casehardening was in nine shops out of ten to dump the contents of the box at the end of the carbonizing heat; in fact, this plan still exists in many shops that should know better. Later study in the structure of steel thus treated has caused a change in this procedure, the use of automobiles and alloy steels probably hastening this result. The diagrams reproduced in Fig. 2 show why the heat treatment of casehardened work is necessary. Starting at *A* with a close-grained and tough stock, such as ordinary machinery steel containing from 15 to 20 points of carbon, if such work is quenched on a carbonizing heat, the result will be as shown at *B*. Here we have a core that is coarse-grained and brittle and an outer case that is fine-grained and hard, but is likely to flake off, owing to the great difference in structure between it and the core. Reheating this work beyond the critical temperature of the core refines this core, closes the grain and makes it tough, but leaves the case very brittle; in fact, more so than it was before. This is remedied by reheating the piece to a temperature slightly above the critical temperature of the case, this temperature corresponding ordinarily to that of steel having a carbon content of 85 points. When this is again quenched, the temperature, which has not been high enough to disturb the refined core, will have closed the grain of the case and toughened it. Thus, instead of but one heat and one quenching for this class of work, we have three of each, although it is quite possible and often profitable to omit the quenching after carbonizing and allow the piece or pieces and the case-carbonizing box to cool together, as in annealing. Sometimes another heat-treatment is added to the foregoing, for the purpose of letting down the hardness of the case and giving it additional toughness by heating to a temperature between 300 and 500 deg. Usually this is done in an oil bath. After this the piece is allowed to cool.

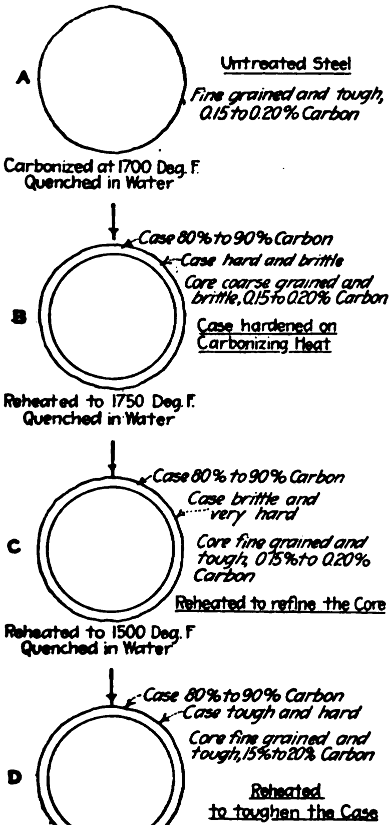

FIG. 2. WHY HEAT TREATMENT OF CASEHARDENED WORK IS NECESSARY

It is possible to harden the surface of tool steel extremely hard and yet leave its inner core soft and tough for strength, by a process similar to casehardening and known as "pack-hardening." It consists in using tool steel of carbon contents ranging from 60 to 80 points, packing this in a box with charred leather mixed with wood charcoal and heating at a low-red heat for 2 or 3 hr., thus raising the carbon content of the exterior of the piece. The article when quenched in an oil bath will have an extremely hard exterior and tough core. It is a good scheme for tools that must be hard and yet strong enough to stand abuse. Raw bone is never used as a packing for this class of work, as it makes the cutting edges brittle.

Casehardening Treatments for Various Steels

Plain water, salt water and linseed oil are the three most common quenching materials for casehardening. Water is used for ordinary work, salt water for work which must be extremely hard on the surface, and oil for work in which toughness is the main consideration. The higher the carbon of the case, the less sudden need the quenching action take hold of the piece; in fact, experience in casehardening work gives a great many combinations of quenching baths of these three materials, depending on their temperatures. Thin work, highly carbonized, which would fly to pieces under the slightest blow if quenched in water or brine, is made strong and tough by properly quenching in slightly heated oil. It is impossible to give any rules for the temperature of this work, so much depending on the size and design of the piece; but it is not a difficult matter to try three or four pieces by different methods and determine what is needed for best results.

The alloy steels are all susceptible of casehardening treatment; in fact, this is one of the most important heat treatments for such steels in the automobile industry. Nickel steel carbonizes more slowly than common steel, the nickel seeming to have the effect of slowing down the rate of penetration. There is no cloud without its silver lining, however, and to offset this retardation, a single treatment is often sufficient for nickel steel; for the core is not coarsened as much as low-carbon machinery steel and thus ordinary work may be quenched on the carbonizing heat. Steel containing from 3 to 3½ per cent. of nickel is carbonized between 1,300 and 1,400 deg. F. Nickel steel containing less than 25 points of carbon, with this same percentage of nickel, may be casehardened by cooling in air instead of quenching.

Chrome-nickel steel may be casehardened similarly to the method just described for nickel steel, but double treatment gives better results and is used for high-grade work. The carbonizing temperature is the same, between 1,300 and 1,400 deg. F., the second treatment consisting of reheating to 1,400 deg. and then quenching in boiling salt water, which gives a hard surface and at the same time prevents distortion of the piece. The core of chrome-nickel casehardened steel, like that of nickel steel, is not coarsened excessively by the first heat-treatment, and therefore a single heating and quenching will suffice for ordinary work.

Device for Filling Wristpins for Casehardening

By E. V. Allen

The wristpins in the pistons of the motors on Henderson motorcycles are approximately ½ in. in diameter and 2½ in. long, with a hole through them lengthwise. They are made of mild steel and pack-hardened. To prevent

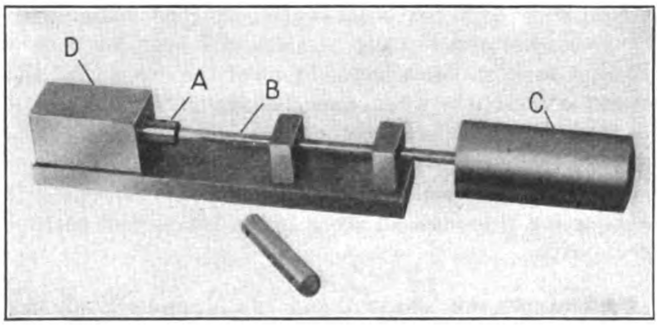

FIG. 1. DEVICE FOR REMOVING CLAY

the hardening of the inside of the pins, the holes are filled with a clay mixture. As the inserting of this clay by hand took considerable time, a filling device was made, which is shown in Fig 2.

The clay mixture is placed in the pointed holder *A* and is squeezed out through the nozzle by screwing down on the handwheel *B*. The pin to be filled is placed at *C* and brought up snugly to the nozzle by the screw *D*. To facilitate the insertion and removal of the pins in the locating V-block, finger spaces are cut in the block at *E* and *F* on each side of the pin.

One filling of this device will suffice for a large number of pins, and no trouble is experienced in having air spaces left inside the pin or in having the clay fall out,

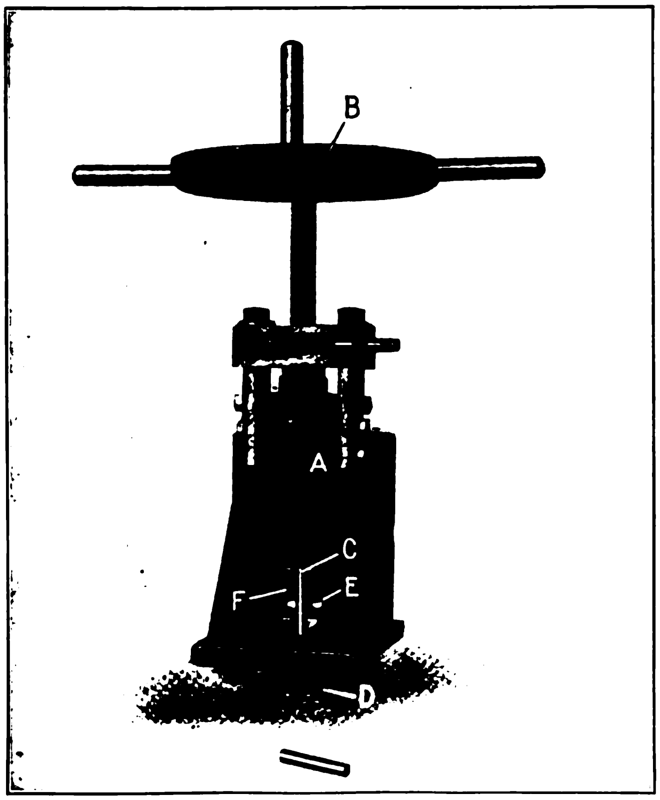

FIG. 2. WRISTPIN FILLING DEVICE

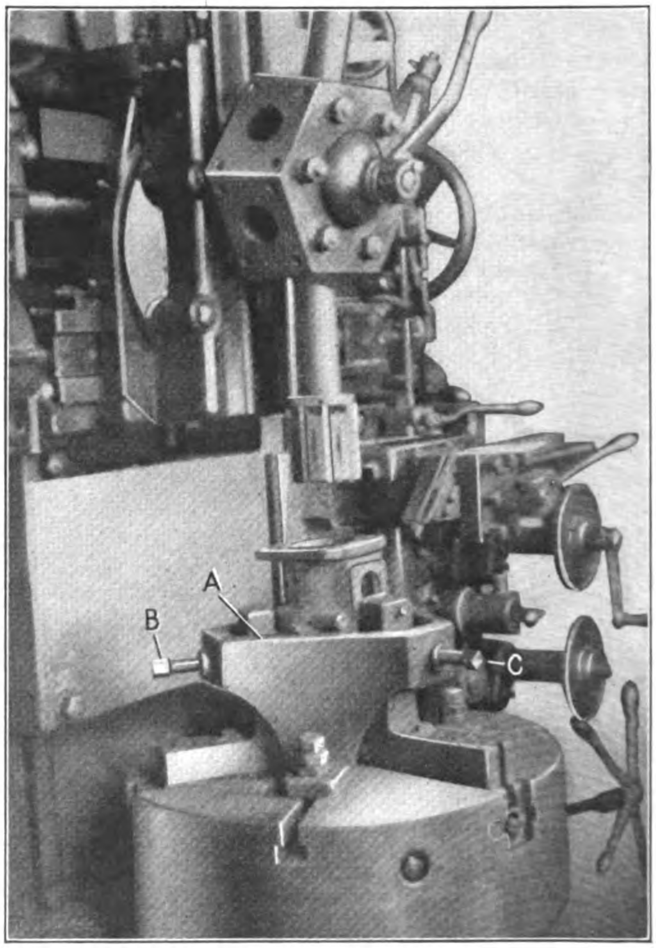
as is frequently the case with that put in by hand. A latch device makes it possible quickly to remove the plunger for refilling.

After the pins have been hardened, the clay is punched out with the contrivance shown in Fig. 1. The pin is placed at *A*, and the plunger *B* is rammed into the hole by the weight *C*, the clay being forced out through a hole in the outer end of the block *D*.

Special Chuck-Jaw Supports

In chucking motor-cylinder castings on a Bullard machine the Caille Perfection Motor Co., Detroit, Mich., uses special extension chuck jaws. These, as shown, extend up so high that, unsupported, they would spring.



SPECIAL CHUCK-JAW SUPPORTS

This difficulty is remedied by using a cast-iron supporting bracket *A*. After the chuck jaws have been run in to the work, the screws *B* and *C* are screwed in to back up the end of the chuck jaws, thus avoiding chatter.

Employment Managers' Problems—The selecting, hiring, training and promotion of workers as a phase of industrial management was considered by an "employment managers' conference," called as a preliminary to the ninth annual convention of the National Society for the Promotion of Industrial Education. In the official announcement of the conference the following significant comment was made: It has been found that only a few employers have "blue-printed" the jobs which were being filled in such a way as to bring about a fair selection of competent workers. More friction, waste, disaffection and ill will are probably bred in the failure to give this subject the thought that it requires than come from almost any other source. The conference emphasized that the "overturn" in working forces of industrial plants each year constitutes a positive waste.

Inclined Plane in Tool Design

By Walter G. Groocock

SYNOPSIS—These interesting applications of the wedge, or inclined-plane, principle to the design of tools for cutting metal show what a useful method this is of securing short movements with considerable power. The wedge, or incline, is in fact one of the fundamental principles of mechanics, and it is difficult to find a tool or machine that does not utilize it in some way.

The use of the inclined plane as a means for moving a cutting tool is not a new idea. The principle is used quite frequently in machine-tool design, as for instance in the ordinary taper-turning attachments for both center and turret lathes. Then there are such special cases as the tangent bar used on ordnance work for rifling and also for making slight changes in the lead of screws, as in the case of the Holroyd screw-milling machine. Another variation of the tangent bar is found on the Loewe relieving lathe for correcting minute differences in the gear ratio of the relieving train of gears.

But while all these particular cases are interesting, this article refers to those adaptations of the principle that apply directly to boring, threading and recessing bars and to such taper-turning tools as are self-contained. I have had, both as tool maker and designer, many such tools pass through my hands, and a few of them may demonstrate the possibilities of various types.

The bar shown in Fig. 1 was designed for use on a boring machine. It is particularly useful either for recessing or threading holes and is shown adapted to both these classes of work. As drawn, it was intended for use as a "stump bar"—that is, a bar with its outer end unsupported. In Fig. 1, *B* is the bar proper, which is threaded at *A* to fit into an adapter on the nose of the boring-machine spindle.

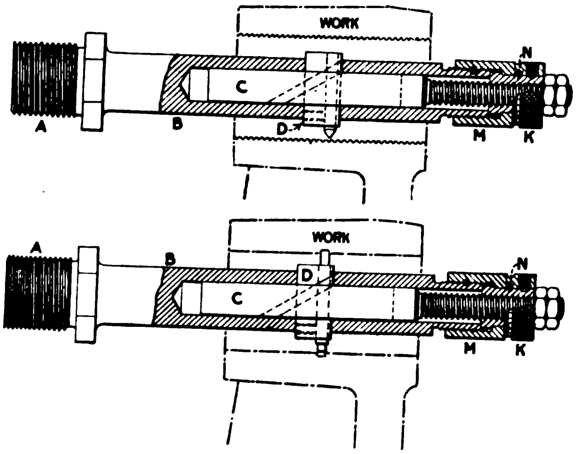


FIG. 1. BORING BAR FOR USE ON BORING MACHINE

It may of course be made with a cone instead of a screw. But as a stump bar, if fitted with a cone instead of a screw and particularly when used for screw cutting, it must be secured to the machine spindle either by means of a key or a draw-bolt.

The outer bar *B* is drilled to take the rod *C*, which actuates the tool box *D*. The actuating rod *C* is slotted (see details in Fig. 2) in such a manner that the inclined projections *T* fit into grooves *G* of tool box *D* and force it up or down the rectangular slot of the main bar when the actuating bar *C* is moved.

The end of the main bar, opposite the chuck of the boring machine, is threaded to fit the retaining collar *M*, this collar being fastened in position by a pin. The rod *C* is threaded at the end to fit the nut *N*, which is retained in position by the collar *M*. The nut is moved by means of the knurled collar *K*, and graduations on this collar in conjunction with a zero line on the face of the collar

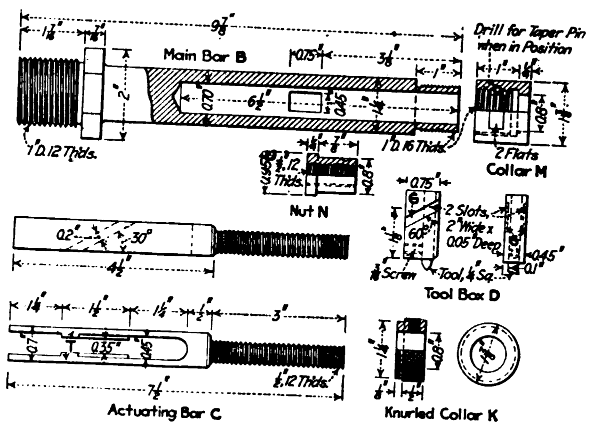

FIG. 2. DETAILS OF BORING DETAILS

M form a ready means by which the cut can be accurately gaged. In other words, the adjustment of the cut is micrometric.

For repetition work, such as threading or recessing to a given depth, a stop can be arranged by putting two locknuts on the threaded end of the actuating rod *C*. These will limit the travel of the rod inward to a definite point, and as a result, the depth of the cut will be fixed. When locknuts are used as stops, the tool should be in the opposite side of the tool box from that shown in Fig. 1. Dimensioned details of this bar are given in Fig. 2, each detail bearing the same letter as in the description.

A bar designed for recessing under the drilling machine and used through a bushing in a drilling jig is shown in Fig. 3. Obviously it would be equally useful in a boring machine where an outer support was necessary, if it was made longer. In use, this bar came into operation for putting in a recess after a hole was drilled, and it was followed by a reamer that completed the job.

While this bar is in principle similar to that shown in Fig. 1, it differs from it, inasmuch as the cut is put on from the opposite end. Here *A* is the main bar and *B* is the actuating bar that moves the tool box. The bar *B* is moved by means of the nut *N*, which is knurled on its outer diameter. This nut engages with a left-hand thread on the outside of the main bar *A*, and by means of a groove *G* it moves the pin *P* along a slot in the main bar. As the pin *P* is driven into the actuating

bar, it follows that when the nut N moves, the tool moves also. It will be readily seen that when the bar revolves in the drilling machine, if the nut N is held by the operator and prevented from turning, then the screw, being left-handed, will carry the actuating bar downward, thus putting on a regular feed to the recessing tool as long as the nut is prevented from turning. By fastening

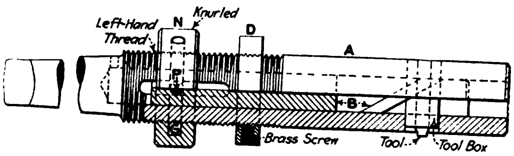

FIG. 3. RECESSING BAR FOR DRILLING MACHINE

the collar D at some definite point it follows that the recess can be gaged as to depth to close limits, if desired, because the nut, striking the locking collar D, will slip through the operator's fingers, thus stopping the feed. By reversing the drilling machine and again gripping the nut the tool is withdrawn from the recess.

A bar designed for threading work on a boring machine that was not fitted with a lead screw is shown in Fig. 4. Here the principle used for moving the chaser is similar to that of previous examples. The main bar A was threaded on one end to act as a guide screw when running in a thread bush. The inclined plane for moving the chaser was cut on one side of bar B and acted directly on the chaser.

This bar B is moved by means of the sleeve C, which is free to rotate between the two collars D and E. The inside of sleeve C is threaded and engages with nut N, the inner bore of which is a sliding fit on the main bar A.

The nut N is connected to the actuating bar B by means of the pin P. This pin works along a slot in the main bar and thus prevents nut N from turning.

Consequently, when the sleeve C is turned, the nut N and the bar B are moved longitudinally according to the direction in which the sleeve C is turned. The collar D being graduated and the sleeve C having a zero line, it follows that any desired cut can be had with exactness. When this bar is used on a boring machine, the machine is disconnected from the feed gear, thus leaving the longitudinal control of the bar to the guide screw.

In the illustration this bar is shown as it was designed, with the guide screw integral with the bar, suitable for

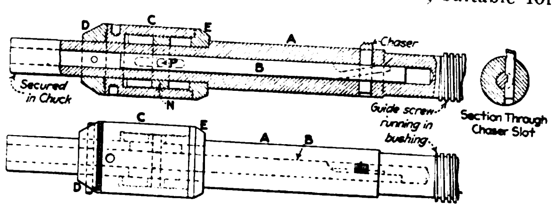

FIG. 4. THREADING BAR FOR BORING MACHINE

chasing a double thread in brass. For general purposes the guide screw would be made as a sleeve, in which case the bar would be adaptable for any pitch of screw.

When cutting an internal thread up to a shoulder, it is imperative that either the bar shall stop revolving at a given position or that the tool shall be rapidly withdrawn. Stopping a boring machine almost instantaneously, at a given position, is not easy. Accordingly, if the tool can be quickly withdrawn, it is undoubtedly the safer method. Apart from this, the quick withdrawal of the tool saves time.

A bar that will give this quick withdrawal is shown in Fig. 5. The main portion of the bar A fits into the spindle of the boring machine or is attached to the lathe spindle. It is bored to take the actuating bar B and is also counterbored and threaded at C to take a supplementary bar. These supplementary bars can be made either as shown in Fig. 6 for small work, in which case the actuating bar B engages directly with the tool, or as shown in Fig. 4, where the actuating bar is divided so that two inclined planes P engage with the tool box T. With regard to the type shown in Fig. 6 the writer has made such a bar to work in a 1-in. hole. It is this adaptability in conjunction with the quick withdrawal that makes this type of bar, Fig. 5, so useful.

Referring again to Fig. 5, D is a sleeve that fits on the main bar A, being free to move longitudinally between the solid collar E and the adjusting nut F. This sleeve D is coupled to the actuating bar B by means of the

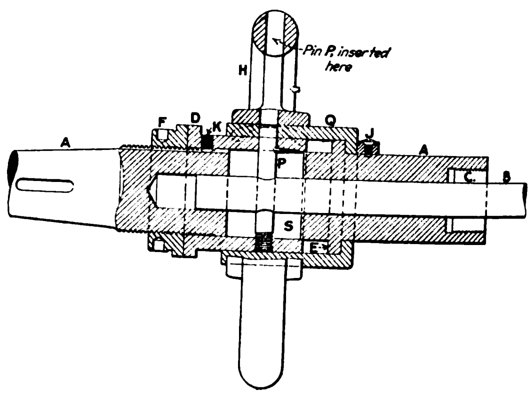

FIG. 5. QUICK-REVERSAL BAR

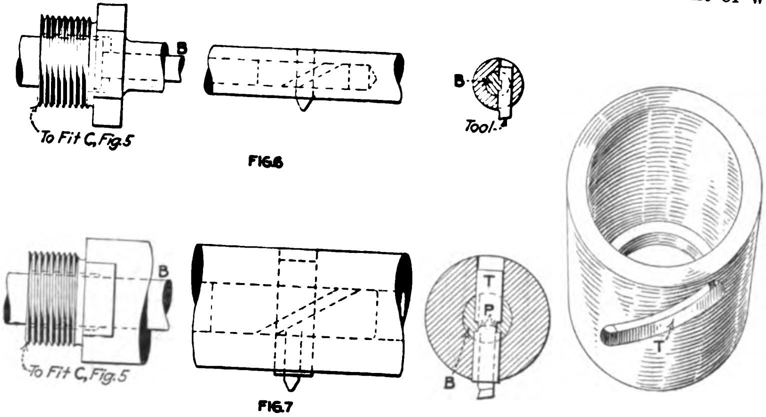
pin P. This pin is allowed longitudinal movement within the limits of the slot S in the bar A. The pin P is screwed into one side of the sleeve D and projects on the other side so as to engage in a spiral slot formed in the quick-return sleeve Q. Keyed to the outside of sleeve Q is the small handwheel H, and both are prevented by collars E and J from moving in a longitudinal direction.

The sleeve Q is shown again for clearness in Fig. 8, and T is the spiral slot into which pin P of Fig. 5 projects. The smaller the angle this spiral slot makes with the axis of the bar the more rapid the withdrawal of the tool, but for easy action it should be about 45 deg.

It will be clear that if the handwheel is prevented from rotating while the bar still revolves, then the tool actuating the bar B will be forced forward—by the pin P working in the spiral slot of the bushing Q—and the threading tool will thus be rapidly withdrawn. The boring machine is reversed and the bar run back to the starting point. The machine is then stopped and another cut is put on as follows:

The handwheel is turned in the direction of the machine rotation until the sleeve D strikes the adjusting collar F. This collar is screwed on to bar A and is graduated on the periphery. The sleeve D has a zero line to coincide with these graduations, and consequently we can

advance the tool by any desired amount. The inclined plane on the actuating bar is 1 in 4, and the adjusting collar *F* is threaded 5 threads per inch and divided on the outside into 50 graduations. Moving the collar through one of these graduations will advance the tool 0.001 in., equal to 0.002 in. in diameter of work. After the collar *F* is moved—toward the boring-machine spindle



FIGS. 6 TO 8. DETAILS OF SUPPLEMENTARY BARS

to advance the cut—the sleeve *D* should be moved up to it by the handwheel and the machine started to take another cut.

Although it takes some time to describe the operation of putting on a cut, it is in reality particularly rapid. As designed, there is no fear of accident, for should the handwheel be accidentally touched while the bar is revolving, it will only withdraw the cut. To prevent a too easy withdrawal—such as might be due, for instance, to the inertia of the handwheel in starting up the bar—a brass screw *K*, working in a flat-bottom groove, gives a ready and adjustable means of applying a retarding force.

I have no knowledge as to who originated the idea of a quick withdrawal, as described, but I am prepared to

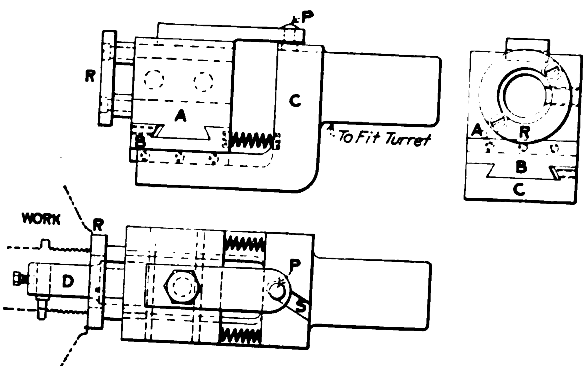


FIG. 9. RECESSING TOOL FOR AUTOMATICS

give the credit to one of the late foremen at the Woolwich arsenal, where a number of variations from the one described have been in use for probably more than 20 years. It is a good idea, whoever originated it, and capable of many adaptations. It is particularly useful on ordnance work, where cheap production is so seldom studied.

An interesting variation will be found in the next example—a recessing tool used on the automatics for fuse parts—shown in Fig. 9. This consists of a small compound slide *A* and *B* mounted on the stem *C*, which is turned to fit the turret of the machine.

The tool bar *D* is secured into the cross-slide *A*, on the front of which is fastened a hardened rubbing ring. Mounted on top of slide *A* is a bar carrying the stud *P*. This stud engages with an inclined slot *S* cut into the stem *C*. The action of this recessing tool is as follows:

When the turret moves forward, the ring *R* comes into contact with the face of the work, thus preventing the slides from moving forward; the relative movement between the slide *B* and the stem *C* is such that the slide *A* and the tool are forced toward the work by means of the pin *P* working in the slot *S*. When the recess is complete, the backward motion of the turret allows the springs to return the slides to their starting point, thus withdrawing the tool. The tool, although faulty in design, did well on small work. Proportionality in design may be all right in some cases, but it failed here when we attempted to make a similar tool for a larger job. The trouble was that the slides jammed. Undoubtedly, this was due to the fact that the inclined plane was too far away from the slide carrying the tool. With a light cut—that is, for a narrow recess—this never gave trouble; but with a wider recessing tool, things happened. However, we got over this trouble as follows:

The bar carrying the stud *P* (a roller in the larger tool) was fastened to the top of the stem *C*, and the inclined slot (into which *P* engaged) was cut into the top of the cross-slide *A*. By this means heavy cuts were taken without any tendency of the slides to bind.

For heavy recessing work, the type of bar shown in Fig. 10 has much to recommend it for all cases to which it can be applied. Here the bar *A* is slotted at the end, and the inclined plane *P* is formed on one side of the slot. This plane engages directly with the recessing tool that is carried in the supporting bushing *B*. The distance from the tool to the flange on bushing *B* governs the position of the recess in the work. To take the pressure of the cut, a driving key *K* is let in and secured to the bushing *B*, passing through a slot in the bar *A*. At the end of this bar a collar *C* ties the open ends together and incidentally acts as a stop against which the spiral spring pushes the bushing *B* when the tool is withdrawn by the turret.

In action the turret moves forward, taking the hardened bushing *B* into the already bored hole until the flange of the bushing *B* meets the work. As the turret still goes forward, the tool is forced into the work and the recess is formed. The strip *S* on the bushing *B* may be at any convenient position and acts as a pilot while the tool is cutting. When the turret recedes, the spring keeps the bushing *B* pressed against the work until the tool is withdrawn. For the sake of clearness, bar *A* and key *K* are shown again in Fig. 11. We have used this type on several occasions and have always found it both

cheap and efficient. The illustration shows it in the turret of a Potter & Johnston automatic.

There is one other example that should be shown, both because it is interesting and also because the type possesses infinite possibilities. It is particularly applicable to tools for turning or boring tapers from the turret of the larger type of automatic lathe. The one shown in Fig. 12 is one of several I have made for this class of work. As shown, it is adapted to the 7-A Potter & Johnston lathe for turning the clutch portion of a petrol-motor flywheel.

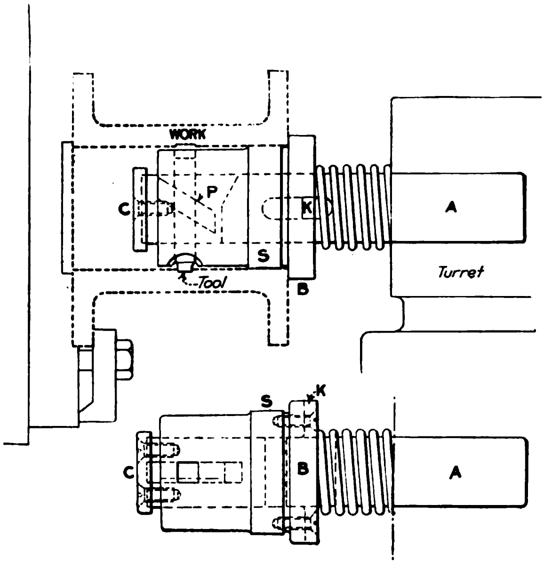

FIG. 10. BAR FOR HEAVY RECESSING WORK

It consists, in the main, of a steel casting *A* that is turned at one end to fit into one of the turret tool blocks of the machine. The other end of the casting *A* forms a pair of guides on which the sliding tool holder *B* works. The sliding tool holder is controlled by means of a hardened roller *R* working along the slot *S* of the rectangular control bar *D*. This control bar works along a groove machined in the main casting *A*, being retained in position by the rod *E* and the plate *P*. Attached to the end of the control bar *D* is the hardened pusher ring *H*, which is bored out to slide freely on the pilot bar *G*.

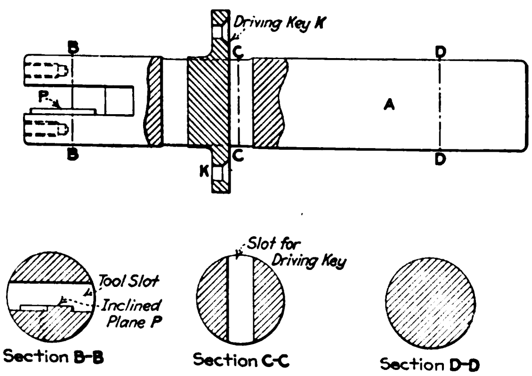

FIG. 11. DETAILS OF HEAVY RECESSING TOOL

A spiral spring on the pilot bar exerts a pressure between the turret and the pusher ring *H*. In the illustration the tool is shown just about to start cutting, and it will be obvious that as the turret moves forward, carrying the tool, the pusher ring *H*, being in contact with the pilot bushing of the machine, cannot move. Consequently, the control bar *D* also remains stationary; and as the tool is fed forward by the turret, it is also pulled downward by means of the roller *R* and the slot *S*.

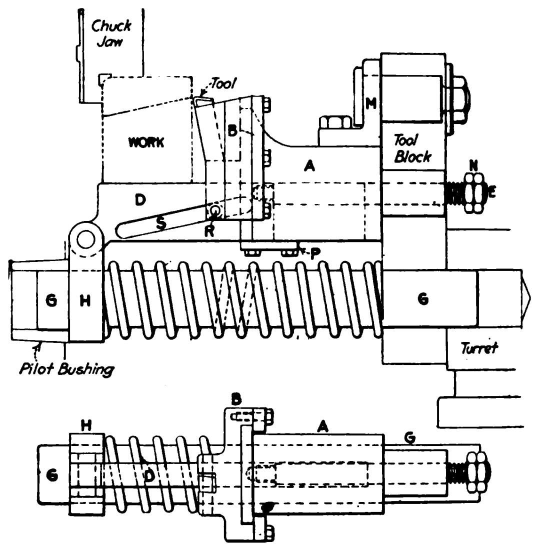

FIG. 12. BAR FOR BORING TAPER PLUGS

When the turret recedes, the spring keeps the ring *R* in contact with the pilot bushing until the locknuts *N* come into contact with the stem of the bar. This limits the outward stroke of the control bar. The bracket *M* was bolted to the main bar *A* and also to the turret tool block, thus materially helping to stiffen the bar in action. This bracket could of course be made integral with bar *A*, but in this case it was made separate, for simplicity.

College Military Training

Identical bills have been introduced into the United States Senate and House of Representatives providing for the extension of the military training now given in land-grant colleges and some other civil educational institutions and for the establishment of military instruction in such additional institutions as elect to come under the provisions of the bills. The prime object of the proposed legislation is that of building up a reserve of trained officers available for officering volunteer forces in case of war. The plan of the proposed legislation will accomplish this object at a minimum cost to the nation and will, at the same time, provide an element of discipline and training of great value in civil life.

The members of the committees of the five engineering societies who have prepared these bills earnestly request that the members of the various national engineering societies send personal letters or telegrams to their individual senators and representatives worded somewhat as follows: "I urgently request you to support and vote for the plan covered by Bill S-3946, introduced by Senator Pomerene, and H. R. 10845, introduced by Representative Gard, providing for the extension of military training in civil educational institutions."

Increases and Decreases of Machine Tool Exports

BY LUDWIG W. SCHMIDT

SYNOPSIS—A study of the percentage increases and decreases of machine-tool exports from the United States, Germany and England for the normal years 1910 to 1913. The American showing is quite satisfactory, giving many striking increases and only a few decreases.

Generally speaking, the machine-tool builder rather follows than leads the industrial development of his market. Machine tools are constructed according to the needs of the user, and constructive energy finds its greatest incentive from the progress made in other industries dependent upon the use of metal-working machines. This at least is the case in countries where competition exists and where, consequently, industrial production is forced to keep going ahead or perish. It is therefore no surprise that the American machine-tool industry has made rapid progress, having as its immediate customers industries well known for their progressiveness.

It is a generally recognized fact that American machine-tool makers have been able to build certain classes of machine tools superior to those of the same class made in Europe. This superiority is shown mainly in machines built for turning out large quantities of a certain article with a minimum of manual labor. It is further claimed for the American machine that it will do more exact work than the competing European machine and that it will be as a rule of greater durability. It is not my intention to inquire into the rights or wrongs of such contentions, which are of a purely technical character, but rather to study their economic effects.

Quantity Production Dominant

Quantity production is now recognized practically everywhere. Germany has made enormous progress. It has been taken up in England and France, and only the less industrial districts in Europe are still confining themselves to the older methods. It has been reserved to thé American constructor to build many of the leading machine tools necessary for such a development; and it is an astonishing fact that, notwithstanding the great progress machine-tool construction has made elsewhere, this country has still kept abreast in many ways.

One reason for this may be found in the general national American trend toward the new, which during some period of the American economic life suddenly evidenced itself strongly among machinery users. The rapidly changing demand, the lack and expensiveness of labor and the general high pressure under which American industries are carried on may have added as well to this development, which has ultimately brought American machine-tool builders to the top of their profession.

Foreign visitors, well connected with the machine-building industry in the old world, have frequently pointed out the general uniformity of equipment in the modern American machine shops. There is a tendency to use only the most recent machine tools. Even in small repairing plants one notices an abundance of modern machines, which astonishes the foreign visitor who knows how primitively similar places are furnished in other countries. This desire of the American machine user to have always the most modern and, as he hopes, also the most efficient machines of course brings the American machine-tool builder a very large number of customers. Consequently, he builds his machines in correspondingly large quantities.

We have therefore in the United States a highly developed machine industry, worked on a very efficient basis by the latest machinery, supported by a machine-tool industry that will readily take up every hint coming from the market. This condition, while tuning up the machine-tool industry to a high pitch of efficiency and constructive ability, has also limited it to a certain grade of machines—a limitation that, however, has produced many of the best and most suitable machine tools. The same system has slowly crowded out minor grades of machine tools, for which little or no demand has been left. The building of such machines, therefore, has in general become unprofitable as far as the American market is concerned.

Designing for Special Markets

While machinery construction in this country has been developed according to the conditions in the home market, in other countries, especially England and Germany, a new competition has grown up. European machine-tool constructors began to strike out in a different direction. Machine tools are constructed in large numbers to meet a demand for a machine of lesser efficiency than that required by the American user, but also cheaper in price. Those machines are selling well in their own markets and have found an active support in others. American constructors will do well to watch this movement, so as not to be overtaken by it if it should become predominant. The fact is that, while American machine-tool constructors have limited their designs to certain well-defined fields, the European industries are frquently building machines that are more suitable for foreign trade than are the American.

It must not be forgotten, however, that the market has changed as well during the last few years. The American machine-tool industry may not have reached all the markets possible, but the progress made during recent years in all the countries which are able to buy in large quantities is quite satisfactory.

Comparative Statistics of American Trade

After we have heard a good deal in the press and elsewhere about the inefficiency of American export methods, as well as about the unsuitability of the goods exported by this country (wherefore, as a rule, the example of England or Germany is held up before our eyes), the result of the following inquiry may be something like a shock to many. To prevent any possibility of using periods of unusual economic activity in this case, the figures of 1914 and later are excluded from the statistics and only

those relating to 1910 to 1913 are taken. They show that in 16 of the leading markets the American machine-tool imports have increased more rapidly than those of England or Germany. To take at first the European field, figures are given for Belgium, France, Germany, Great Britain and Russia.

TABLE 1. EXPORTS OF MACHINE TOOLS FROM THE UNITED STATES, GERMANY AND ENGLAND

	United States	Germany	England
To Belgium			
Exported during 1910	$162,529	$898,000	$112,945
Exported during 1913	$786,679	$1,650,000	$160,640
Total, 1910–13	$1,992,906	$4,450,750	$570,475
Difference, 1910 and 1913	+$624,150	+$742,000	+$47,695
Percentage of difference	+384.02	+82.83	+42.21
Sold during 1914	$552,531	....	$86,865
To France			
Exported during 1910	$691,480	$1,452,000	$363,030
Exported during 1913	$1,936,908	$3,131,500	$710,635
Total, 1910–13	$4,859,109	$8,814,500	$1,778,895
Difference, 1910 and 1913	$1,245,428	+$1,679,500	$+347,605
Percentage of difference	+180.11	+115.66	+95.75
Sold during 1914	$1,771,525	....	$464,855
To Germany			
Exported during 1910	$1,804,682	....	$117,355
Exported during 1913	$3,175,188	....	$229,990
Total, 1910–13	$10,456,966	....	$718,780
Difference, 1910 and 1913	+$1,370,506	....	+$112,635
Percentage of difference	+75.95	....	+95.97
Sold during 1914	$2,167,240	....	$91,450
To Great Britain			
Exported during 1910	$1,362,965	$623,250	
Exported during 1913	$3,417,655	$1,450,000	
Total, 1910–13	$9,766,417	$3,597,000	
Difference, 1910 and 1913	+$2,054,690	+$826,750	
Percentage of difference	+150.75	+132.65	
Sold during 1914	$3,178,630	....	
To Russia			
Exported 1910	$234,776	$1,687,000	$135,380
Exported during 1913	$1,088,751	$3,874,000	$425,105
Total, 1910–13	$2,260,609	$9,717,750	$1,128,510
Difference, 1910 and 1913	+$853,975	+$2,187,000	+$289,825
Percentage of difference	+363.73	+120.64	+214.82
Sold during 1914	$1,333,644	....	$1,364,085

The American figures for 1914 relate to the 12 mos. from July 1, 1913, to June 30, 1914; those for England and Germany relate always to the calendar year.

These figures, Table 1, show, as might well be expected, an enormous superiority in the total imports of German machine tools in three of the markets, while in the case of England the American machine-tool industry has the advantage. Except in these three instances, it appears that the American machine-tool industry has every reason to be satisfied with the progress made. To take the case of Belgium, the actual difference in the imports of the years 1910 and 1913 shows that the imports from the United States increased by $624,150. During the same years import from Germany increased by $742,000, while England was very much left behind, with an increase of only $47,695. Looking at the percentage increase, it appears that America takes first place with 384 per cent., followed by Germany with 82 per cent. and by England with an increase of 42 per cent. Taking France, Germany leads in the increase of value, but again it will be noticed that the American exports increased 180 per cent. against the 115 per cent. of the German and the 95.75 per cent. of the English.

In Germany, England has made a more rapid percentage progress. Both the total value of the import and the figures of the actual increase during the years in question compare, however, very badly with the American sales. Germany sells considerably less metal-working machinery to England than does the United States. The small difference in the percentage increase shows that that country was a very active competitor before the war. It would be impossible to predict how the conditions will be after the conclusion of peace.

An interesting problem is offered by Russia. Russia is generally considered one of the less developed industrial markets, consequently having only a medium demand for American machine tools. This was certainly the case until about 1912, from which time a rapid increase in the demand set in. Germany still dominated the Russian market at the end of 1913. The percentage increases against the year 1910, however, are in favor, not only of the United States, but of England as well. The figures are an increase of 363 per cent. in American, 129 per cent. in German and 214 per cent. in English machine-tool sales.

As in former studies of the same character the statistical facts are not taken from the import figures of the countries in question, but from the export statistics prepared by the Governments of the United States, Germany and England, representing probably the most reliable facts in each case.

Exports to Continental North America

Turning to our neighboring markets, the figures for which are given in Table 2, we find that the American machine-tool industry is supreme, holding by far the biggest part of the business. This is especially the case in Canada, where American machine tools show an increase of 593 per cent. against the 120 per cent. of the German imports and 49 per cent. of the English imports. The full significance of those figures becomes only apparent if one sees that during the four years in question the United States exported $4,790,895 worth of metal-working machines, while the English exports, the nearest, were only $415,585. In Cuba the situation is much in favor of this country, while in Mexico, Germany, as well as the United States, has to resign itself to an unavoidable loss that may hold on until political unrest ceases in that unfortunate country.

The markets across the Pacific may become some of the best buyers for the American-made machines in the near future, and they certainly deserve close attention. We have in Australia and Tasmania good and progressive buyers of such machinery, who until recently have favored very much the English style of machine. For some time, however, a decided leaning toward American-made machine tools has taken place, and the increase in favor of this country has been 193 per cent. against 77 per cent. in the English and only 59 per cent. in the German imports. The first two figures are especially interesting, as they indicate an energetic progress that is shown later in 1914 by the fact that American machine-tool sales in Australia nearly trebled the sales of English machine tools, which were formerly larger than those of American origin. In New Zealand a progress of 262 per cent. in favor of American machines was made, while

TABLE 2. EXPORTS OF MACHINE TOOLS FROM THE UNITED STATES, GERMANY AND ENGLAND

	United States	Germany	England
To Canada			
Exported during 1910	$336,172	$10,750	$82,820

Sold during 1914	$74,706	....	....

the English machines are showing a clean loss of 29 per cent.

In China, on the other hand, this country seems to be on the losing side, as it has lost 49 per cent. of its machine-tool trade since 1910 while, of course, an increase has taken place during 1914 and 1915, which is far surpassing that loss. The enormous activities of the English special agents in India have brought about a correspondingly large increase in the English exports of metal-working machines to that country. In fact, England showed an increase of 109 per cent. against a loss of 55 per cent. on the German and 4 per cent. on the American side. In the Japanese machine business Germany has been favored, increasing her sales at the rate of 316 per cent. against the 37 per cent. of the American sales and 54 per cent. of the English imports of machine tools.

Sold during 1914.........	$1,316,952	....	$137,065

It remains to review the position in the South American market as represented by the three A-B-C republics (see Table 4). In Argentina the machine-tool business of all three countries—United States, England and Germany—has declined. In Brazil the United States has shown the large increase of 1,615 per cent., while Germany shows an increase of 111 per cent. and England of 72 per cent. The American exports to Chile increased 49 per cent., the German 91 per cent. and the English 99 per cent. In Argentina and Brazil, Germany was the biggest seller, while England takes that place in Chile. This country, however, is pressing very hard now for second, or even first, place.

The most easy way of explaining the small sales of American metal-working machines in those countries where progress was slow or where a reduction took place is that of blaming the sales methods of the American manufacturer. The real reason, however, is that of respective industrial development. It is quite obvious that an industrial community like England or Germany will offer a better demand for high-grade machines than countries with a less developed industry. While in most of the leading European countries all signs are pointing in the direction of quantity manufacture, organized on the lines of the United States, there are still many countries relying on Europe or the United States for all those goods which have to be turned out by highly organized industrial effort and making at home only such goods as can be easily produced with the sort of labor obtainable. It seems to be waste of time and money for those countries to buy machines preëminently made for quantity production—a case of firing a 42-cm. gun at a sparrow, the object being not worth the charge, however efficient this method of destroying the bird might be.

Most of the repair shops in those markets are small, they have to do cheap work where labor does not count, and their overhead expenses naturally must be kept low. Also, they must not use complicated machines that cannot be repaired on the spot. So they buy from those markets still able to supply such machines or specializing for the needs of that class of buyers. England, Germany and Belgium found it a very profitable business to cater to such markets, while the American business in that direction is less successful, as shown by the figures given. Today the war has brought about an entirely new situation. For a time at least, German, English, Belgian and French machine-tool competition has gone out of the market and this country has become the largest machine-tool supplier of the world. It is well worth while to view the future possibilities of the American machine-tool industry in this new light.

Leaving the fighting nations out of consideration, it appears that many of the neutral countries in Europe—as Holland, Sweden, Norway and, of late Switzerland—have become considerable buyers of American-made metal-working machines. They all bought formerly from their European neighbors. They will now become more intimately acquainted with American machines than they were before, and the question arises, Will they in the future prefer the American machines or will they return to those supplied by European makers?

Undoubtedly, the European influence will again be larger than the American when peace is restored. But something of the experience of the present year will remain, and the American machines sold in so large numbers will act as powerful advertisers in every direction. So there will be a larger demand for American machines, and European manufacturers will be compelled to follow that demand by increasing their own output in modern machines. Lack of labor and more expensive labor in Europe undoubtedly will add as well to that development. We shall find after some years about the same conditions in the European machine-tool industry that are governing the industry in this country.

TABLE 4. EXPORTS OF MACHINE TOOLS FROM THE UNITED STATES, GERMANY AND ENGLAND

	United States	Germany	England
To Argentina			
Exported during 1910.....	$237,123	$494,750	$198,610

Sold during 1914.........	$85,168	....	$38,170

European construction methods will be more like the American. European machines will be more expensive, and it will be less profitable to build the cheaper and simple types, owing to a decrease in the purely European demand. The ultimate outcome of this condition will be a general raising of the standard of machine-tool construction and demand all over the world. In the end,

TABLE 5. PERCENTAGE INCREASE IN THE SALE OF MACHINE TOOLS DURING THE PERIOD 1910-13

* Decrease.

it must make the American machine-tool manufacturer more of a competitor in those markets where he has been more or less excluded until now, owing to the rather low standard of the demand.

The following statistics, given to round up the scope of the present inquiry, show that in eight of the analyzed countries the imports of American machine tools have progressed over 150 per cent. and that the total percentage

Total exports to previously named markets during 1910-13.......		$40,452,817		$31,287,000		$12,422,245

increase in those markets has been the largest of all the three countries whose export was investigated. Germany's increase is strongest between the figures from 50 to 150 per cent., while England shows an increase above 100 per cent. in two cases only. An average increase of 243.36 per cent. against 79.50 per cent. of the German increase and 69.20 per cent. of the English is a figure to be satisfied with (see Table 5).

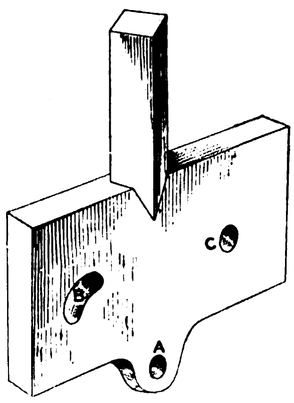
However, it must not be forgotten that, while the progress certainly has been very good, Germany has remained a competitor of very great importance and will surely show her strength again after the war.

The figures given in Table 6 relate preëminently to countries in which American machine-tool makers have shown special interest. It is therefore not surprising that the position of the American machine-tool sales should be so exceptionally good. The total exports of the United States, England and Germany to these countries during the years 1910 to 1913 were valued at $84,162,062. The United States supplied 48.06, Germany 37.17 and England 14.77 per cent. It will be interesting to see what the position of each of those countries is at the end of 1917.

Improved Type of Flask Pin

By A. E. Holaday.

Flask makers have been using an ear with three common countersink holes for wood screws. I noticed that a large amount of time was lost trying to get the pin to line up. To overcome this trouble, the pin is made as follows:



IMPROVED TYPE OF FLASK PIN

A common stove bolt is placed in the lower hole *A*. The long hole *B* is an arc, and the second stove bolt is placed in the center of this hole, to line up the pin. Then the last bolt is placed in the hole *C*, with the result that a perfectly lined-up pin is produced with little lost labor in assembling.

The job when completed is as good in every respect as that which is fastened with wood screws and the chances for readjustment when necessary are 100 per cent. better.

Taper-Shank Drills

By Robert J. Spence

Take a glance over the drill rack in any shop and notice the number of $\frac{9}{16}$- and $\frac{7}{8}$-in. drills with broken tangs. The reason for this lies in the fact that the shank sizes of drills do not change from one number to the next larger number of taper shank soon enough.

Take the Morse standard, for instance. The No. 1 taper on the shank does not change over to No. 2 until $^{37}/_{64}$ in. is reached. This leaves too weak a tang for the $\frac{9}{16}$-in. drill. The change of taper should take place at $\frac{1}{2}$ in. A greater weakness yet occurs in the $\frac{7}{8}$-in. and $\frac{15}{16}$-in. drills. Here, the tang is much too weak. The change from the No. 2 taper to the No. 3 taper should take place at $\frac{3}{4}$ in. diameter. The No. 4 taper should start at 1 in. instead of at $1^{17}/_{64}$.

A tang $\frac{1}{4}$ in. thick on a No. 2 taper for a $\frac{15}{16}$-in. drill is out of all proportion to the stresses to which such a drill is ordinarily subjected. It takes but a glance at a drill rack to prove that this assertion is correct. Any tool, such as a drill, should have a large margin of safety

with the ordinary machine-shop usage in view. The laboratory test should have second consideration.

Of course, it would add to the cost of the drill, especially at the present high price of tool and high-speed steels, by reason of the larger diameter of stock required for the shank; but the loss in cost would be greatly offset in the smaller number of mutilated drills.

Yet I presume it would be just as difficult to have manufacturers of drills adopt these changes as it would be to have them all adopt a single standard taper on all tapered machine parts. Both the tang and the taper are established things that will always remain with us against all argument, no matter how sound, like the French heel and the buttons on the sleeves of men's coats.

Argentine Manufacturing Shop

SPECIAL CORRESPONDENCE

For the accompanying illustrations and for the information in regard to the shop shown, thanks are due R. S. Rushton, manager of the Sociedad Anonima Fundicion y Talleres "La Union," Buenos Aires, Argentina. This is a good-sized shop, totaling about 31,000 sq.ft. and manufacturing a large line of both brass and iron goods, such as pumps, pipe fittings, hose couplings, bells, boat trimmings and such plumbers' supplies as valves, compression cocks and flush-tank fittings. This large variety of work in different lines demands a varied equipment as well as adaptability in both men and management.

FIG. 1. THE IRON FOUNDRY WITH ITS 8,500 SQ.FT. OF FLOOR SPACE

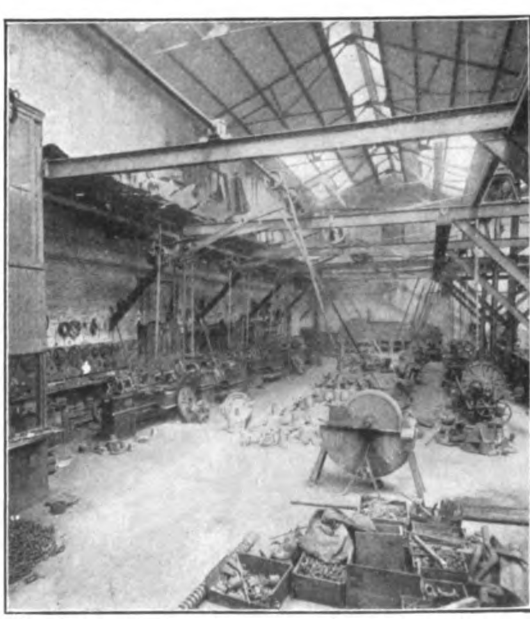


FIG. 2. THE IRON TURNING SHOP

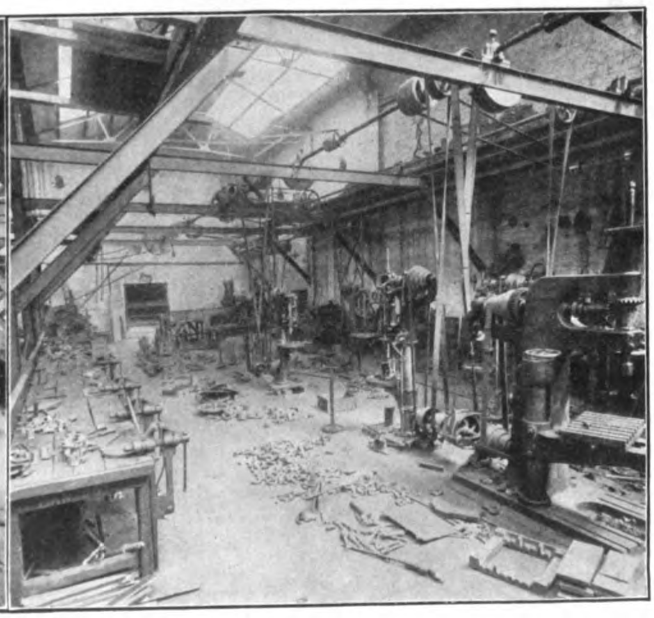

FIG. 3. IRON FITTING AND ERECTING

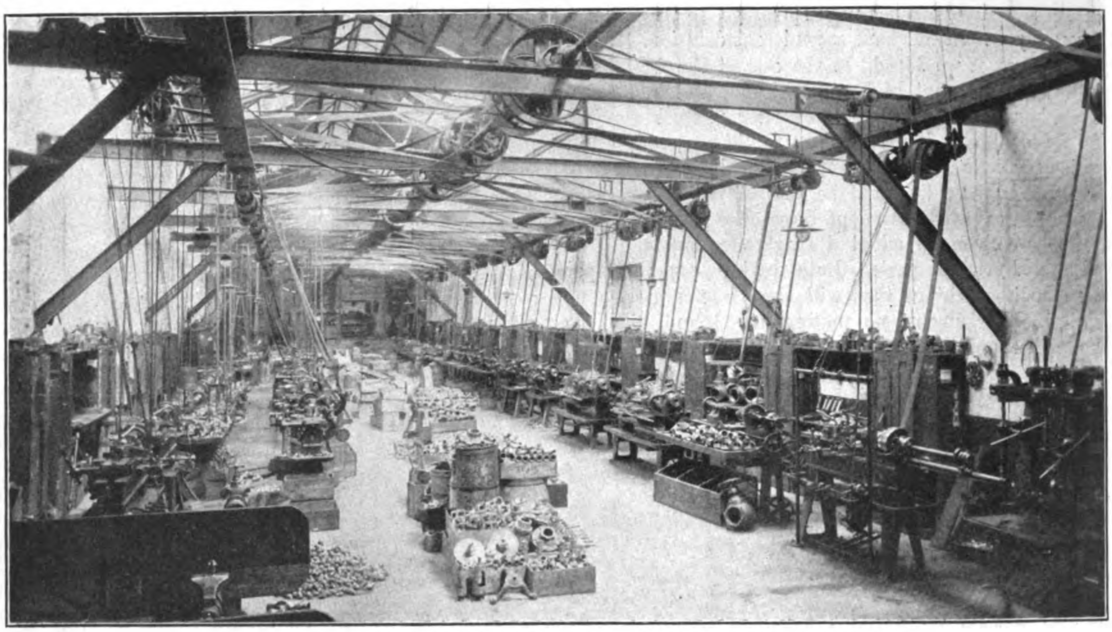

FIG. 4. THE BRASS TURNING SHOP; ITS EQUIPMENT AND PRODUCT

The iron foundry, shown in Fig. 1, contains about 8,500 sq.ft. The illustration gives a good idea of the building construction and shows the crane equipment and the businesslike lining-up of snap flasks on the floor.

There are two brass foundries, with a total of 9,400 sq.ft., equipped with crude-oil furnaces. From 4 to 5 tons of brass per day is cast.

The iron turning and fitting shops are shown in Figs. 2 and 3. They also total 9,000 sq.ft. These views show the monitor roof and the construction of the countershaft supports and also give an idea as to the variety of work turned out. Wooden and sheet-steel pulleys are used.

The brass shop, used for the manufacture of the firm's standard line, is shown in Fig. 4. It contains 4,000 sq.ft. The standard brass-shop equipment of turret lathes seems to have been followed. The parts shown, among them being the large globe valve at the right, give a good idea of the variety of work done.

Some conception of the toolroom can be gained from Fig. 5, the conditions making it necessary for the company to make practically all its own tools. As will be seen, the tool equipment is good; and a little study shows some of the dies, reamers and special tools made for the particular class of work on which this shop specializes.

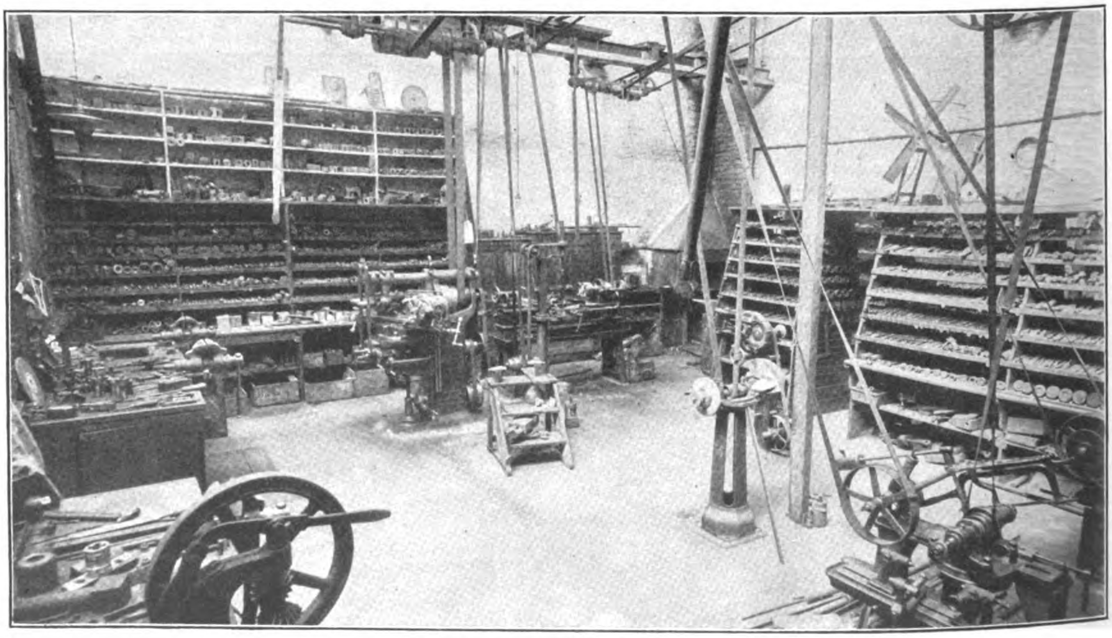

FIG. 5. TOOL-MAKING AND TOOL STORAGE ROOM

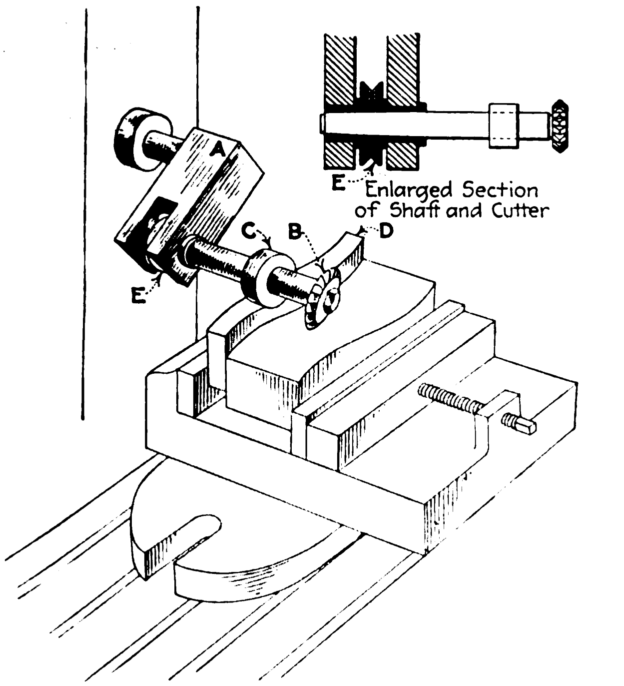
Letters from Practical Men

Neat Milling Attachment

The attachment shown in the illustration was used by a model maker in order to knurl the curved surface of a block. The device consists of a block *A*, having one hole to fit loosely on the mandrel of a miller and another hole to take a bushing with the cutter *B*. On the straight part of the cutter shank is a roll or bushing *C*, having a sliding fit. This roll rests on top of the



NEAT MILLING ATTACHMENT

guide cam *D*, which has the exact form of the work. By lowering the cam the depth of the cut is altered.

To drive the cutter, a dental electric motor was used, the belt running over the small pulley *E*; the table was fed by hand. WILLIAM SCHULTHEIS.

New Haven, Conn.

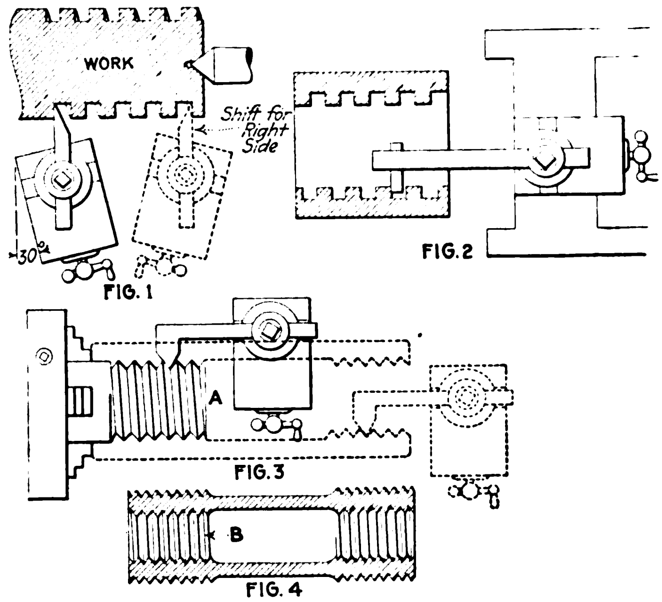
Cutting Square Threads

Cutting square threads on an engine lathe is sometimes very annoying, especially when it comes to the finishing cuts. This work is even more vexing on square-threaded taps, if the steel is hard from any cause. The following methods have been used in our shop and leave nothing to be desired for both external and internal single and multiple threads.

The thread is rough-turned to 0.010 in. of finish width with a square-nosed tool. The compound rest is then set at an angle of 30 deg. for external threading and at 90 deg. for internal threading. To finish-turn, two side tools are required, set at 90 deg. with the axis of the work. The kind of material governs the grinding of these tools.

Figs. 1 and 2 show the finishing of external and internal threads. The internal threading tool is held in an Armstrong boring bar. It will be seen that the width of the thread does not depend on an accurate width of the finishing tool.

Sometimes threads must be of continuous lead, both externally and internally, which is accomplished as fol-



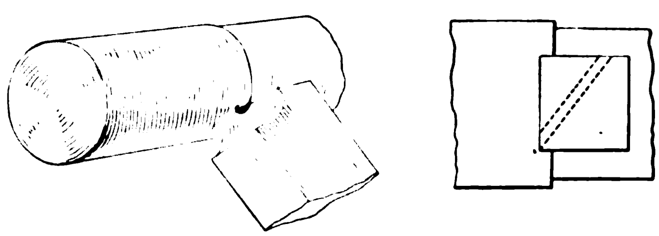
CUTTING SQUARE THREADS

lows: A piece is chucked and threaded, as at *A*, Fig. 3. The piece to be threaded has previously been bored to size and one end threaded, as at *B*, Fig. 4. It is then screwed on the chucking piece. The method of setting the tool correctly to obtain a continuous lead is shown by Fig. 3. Fig. 4 shows a sleeve made in this way for an inventor. It had four sleeves telescoping each other.

Titusville, Penn. G. STROM.

Finish-Turning Tool for Steel

The lathe tool shown in the illustration operates satisfactorily for finish-turning steel, especially if the piece is long and comparatively slender or if it is of unusually hard material. It is almost impossible for this tool to



A FINISH-TURNING TOOL FOR STEEL

chatter, providing too heavy a cut is not taken. With a fine feed, the finish can scarcely be distinguished from a ground surface; and as the thrust of the cut is almost negligible, the diameter varies but slightly from end to center on a long shaft.

The tool resembles closely a finished-planing tool, except that the chip is curled ahead of the tool. For this reason it is not advisable to work close to a shoulder, unless the tool is set well above center, as shown. Where the shoulder is filleted, as on crankshafts and similar work, this feature is not objectionable.

The angle of the cutting edge varies from 28 to 40 deg. from the perpendicular, depending on the material—the harder the material the smaller the angle. The rake should be about 15 deg. and the clearance about 2 deg. each way, giving a slight drag for polishing, if desired.

Charles City, Iowa. H. E. McCray.

Clamping Devices for Jigs

Clamping devices that have been used successfully in connection with drill jigs are here shown.

Fig. 1 illustrates a form of jig that allows the drilling to be done from the bottom side. In this figure, *A* is the jig base and *B* the leaf. The work is placed on a plate *C* and is located between two buttons *D* on each side of the work and against the button *E*. On the block *B* is mounted a stud *F*, in which swings a lever *G* hinged on

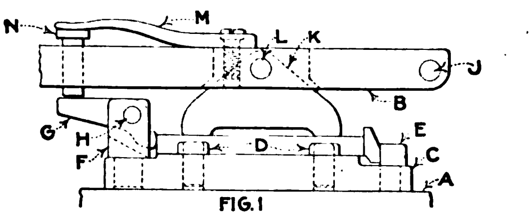


FIG. 1

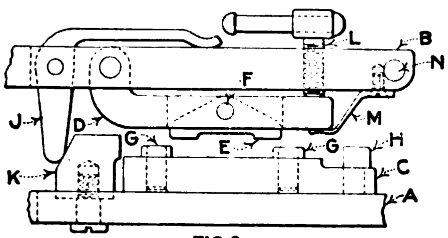

FIG. 2

CLAMPING DEVICES FOR JIGS

a pin *H*. The leaf is hinged on the pin *J* through the base casting and carries a swivel clamp *K* swinging on the pin *L*. A spring *M*, pressure from which is brought to bear upon a pin *N*, is attached to the leaf by two screws. As the leaf is brought down over the work, the pin strikes on the lever *G*, which in turn forces the work against the button *E*. By further pressure the swivel clamp *K* is brought up to the work and holds it securely by means of a cam handle.

This clamping device is of no use when it is desired to drill from both sides or perhaps to drill from one side and ream from the other. The reason is that the thickness of the work must have some limits. If the jig is made up to drill holes square with the work for maximum thickness, it will not drill a hole square if the piece is of minimum thickness. Therefore, all drilling must be done from the bottom or through the base.

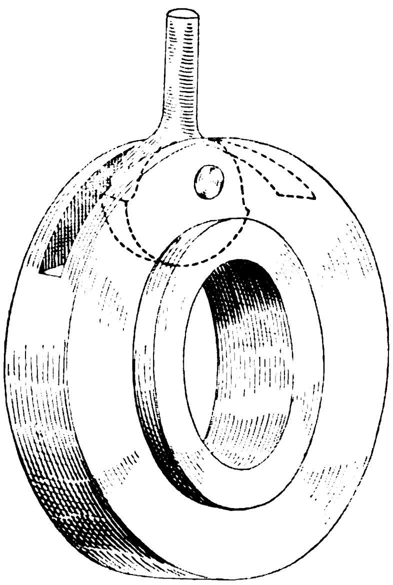
When it is desirable to drill and ream from different sides, the device shown in Fig. 2 should be used. The base is *A* and the leaf *B*; the locating block is *C*. In the leaf is hung a clamping arm *D*, in which is swung a swivel clamp *E* on the pin *F*. T[illegible]ork is located between the studs *G* and against t[illegible] before. The pressure of the work against the end locator *H* in this case comes from a spring finger *J* pushing against a sliding block *K*. In the base is milled a slot, into which fits a tongue on the bottom of *K*. As this slot is about $\frac{3}{16}$ in. narrower than the wide part of *K*, the tongue prevents the block from turning, and the screw prevents it from coming out.

The leaf is set parallel to the base, and the work is clamped by the screw *L*. In order that the clamping arm may not swing out into the operator's way when he is putting the work into, or taking it out of, the jig, a spring *M* is provided, which holds the arm against the screw. This spring should be very light, offering practically no resistance to the binding screw *L*.

Providence, R. I. M. W. Wright.

Quick-Acting Grinding Dog

Herewith is shown a very practical dog which may be used either for grinding or turning, but more particularly for grinding. The locking cam may be of any de-



A QUICK-ACTING GRINDING DOG

sired rise; but about 0.08 in. constant rise per revolution is satisfactory for ordinary use.

The dog is slipped on the work hub first and when the driver engages the stem of the cam the cam tightens. The heavier the cut the tighter it grips. One cam may be interchanged with several different sizes of collars. For rapid production where a dog is to be used this is a winner.

Harold E. Greene.

Ilion, N. Y.

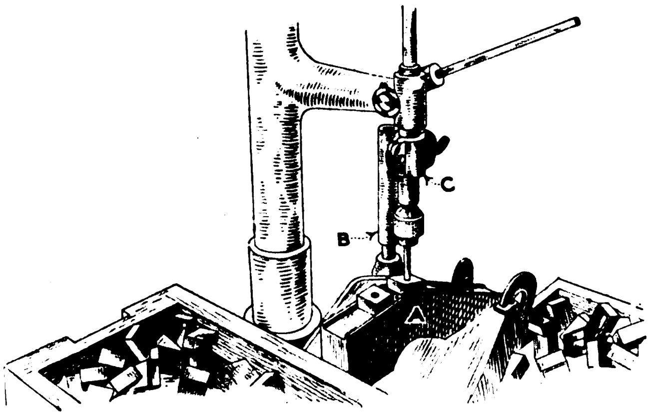
Simplifying Drilling Operations

A large quantity of cast-iron blocks were to have a $\frac{3}{16}$-in. hole drilled in their centers. These blocks were $1\frac{1}{4}$ in. square and were made hollow; that is, they had four sides and one end, all of about $\frac{5}{32}$ in. thickness. It will be gathered from this that the operation time must be principally consumed in clamping, centering, loading and unloading.

A fixture to simplify the operation and reduce the time to nearly all drilling was designed as shown at *A*. A base was made with raised sides, in which to lay the

blocks and by means of which to slide them under the drill. The sides kept the block from turning, and sloped down on one end so that the drilled block when pushed by the block entering would slide down and fall into boxes. Fully half of the handling and the necessity for holding the blocks while drilling were thus taken care of.

An arrangement *B* clamped to the spindle sleeve served to center the blocks under the drill. Inside a piece of steel



SIMPLIFYING A DRILL OPERATION

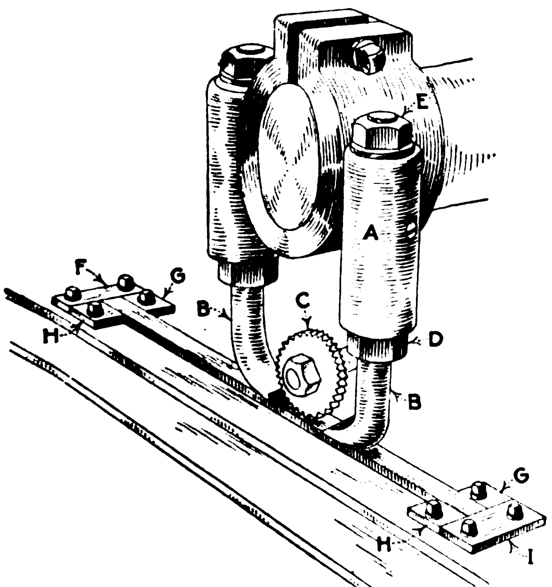
tubing a rod is fitted to travel up and down, but is prevented from turning by keys and is normally held down by a spring, also in the tube. The tube is held in a split casting socket *C* that is clamped to the sleeve. The rod carries the casting that centers the block. This casting is hollow and has four hardened ribs on the inside, the ribs tapering at an angle of 45 deg., so that a block is pushed to their center as the foot is brought down. This foot can go no farther, but holds the block while the drill is fed through.

The outfit was cheap to make and the results could hardly be bettered by an automatic device.

Middletown, N. Y. DONALD A. HAMPSON.

Attachment for Milling Flat Stock Without Clamping

A somewhat difficult thing to do on a miller is to grip thin, flat stock securely and quickly for surface milling. If gripped in a vise, the chances are it will



MILLING FLAT STOCK WITHOUT CLAMPING

buckle; if held by wedges, considerable time is lost in setting up. The illustration shows a simple attachment that fits on the supporting arm of the miller and holds the work down, at the same time supporting it close up to the cut.

This device consists of a bracket *A*, which fits the supporting arm, two rods *B* curved at the lower end to go under the cutter *C*, and the nuts *D* and *E* for adjusting the rods for various thicknesses of stock or different diameters of cutter.

The work is set on the machine table, located against the stop *F* between the blocks *G*, *H* and *I* for location and to take the thrust of the cut. The table containing the work is fed under the cutter in the usual manner. As it passes under the curved rods, they are adjusted to hold the work down in place, while allowing the work to slide under them.

With this arrangement it is unnecessary to clamp the work down, as one rod bears on the size before milling and the other on the thickness as milled, the stock machined being cold-rolled, running close to standard dimensions.

It is advisable on this class of work to keep the cutter flooded with oil or soda water. It washes the chips away, and there is no tendency for them to catch under the curved rods. M. HENDRICK.

Pawtucket, R. I.

Trying Out Inventions and a Bit of History

In conversation with an inventor the question of getting original ideas tried out was raised. The inventor said that when the proprietor of a plant is an inventor

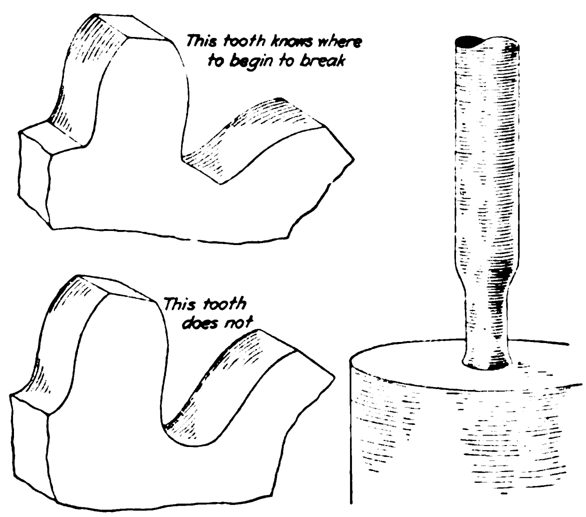


Fig. 1 Fig. 2

POINTS ON WEAR OF STEEL

he can do all the experimenting he wants to. This remark called to mind my brother, William A. Sweet, who did enough original work to have made him a big man. only the people in the steel business would not allow themselves to profit by his discoveries.

He told the mining engineers at their meeting in Pittsburgh, in the seventies, that steel rolled at a low heat during the last passes was very much tougher than if finished hot. Twenty-five years later an engineer claimed he had made this discovery and advocated that railroad rails be so finished.

My brother found that the teeth of his roll pinions were breaking beyond endurance, and he overcame this by cutting out the stock at the roots of the teeth, as shown at *A*, Fig. 1. He did practically the same thing with the piston rods of his steam hammers, which were all made as they are now—just a straight rod put in the hammer head by a taper fit. What he did was the sensible thing to do. He turned the rods down, as shown by Fig. 2, and that ended the trouble. He was the first to make a successful semiautomatic stoker by forcing the coal into the fire by a plunger above the bottom and below the top of the fire. Furnaces of this kind have been in use for years. The plungers are worked by hand, and the men do not like them.

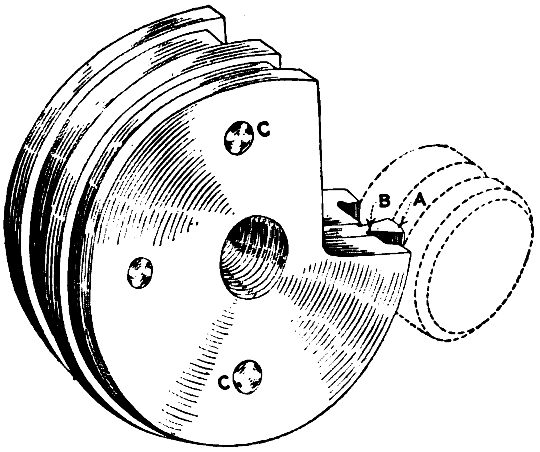
The change in the gear teeth was a wonderful improvement; but no one will accept it, and probably no one could sell a machine with gears so cut. Besides, it would call for several series of extensive tests to determine the strength of the new gear teeth. Yet one can only wonder how such tests can amount to anything when the strength of the standard test bars varies from perhaps 2,000 to 5,400 Johnson iron.

In the case of the piston rod the cause of the breaking is simple enough: The strain is centered on a line at the top of the hammer head and is excessive where the hammer does not hit exactly central. This repeating the strain centered on a single line breaks the rod in detail. It may be that the French scientist would explain it as the fatigue of the metal, while my brother would put it in plain English and say that it gets tired and lets go, which means exactly the same thing. If the engineer proposes to turn down the piston rods to save the breaking, the boss won't let him; and this comes back to the original claim that if the proprietor is the inventor he can get his ideas tried.

Syracuse, N. Y. JOHN E. SWEET.

Built-Up Circular Forming Tool

When making a forming tool, it is sometimes hard to grind the sides of the step *A*. This is especially difficult if it is necessary to provide a clearance angle, as at *B*. Since this step acts as a parting tool, it takes the brunt



A BUILT-UP CIRCULAR FORMING TOOL

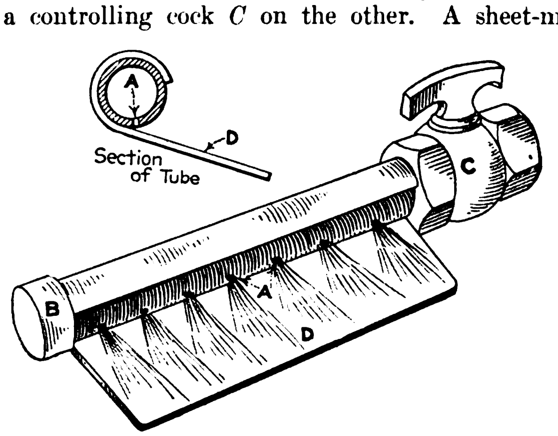
of the work and will wear much faster than the other steps. Furthermore, being very narrow, it is subject to breakage.

The forming tool shown is built up of three pieces, each hardened and ground, and the whole assembled together with rivets *C*. By grinding each part separately considerable accuracy can be obtained. If the step is a separate piece, it can be seen that trouble will be met in making the threads match after hardening; but if the rivet holes are drilled first and well doweled before tapping, everything will work all right. The threads should be cut a little full, so as to lap out after hardening. Of course, this tool has the drawback that it cannot be reground so many times as a solid tool, because of the rivets. WILLIAM BURR BENNETT.

Bridgeport, Conn.

Hacksaw Lubricator

The illustration shows a device for feeding lubricant to a hacksaw. It consists of a pipe, with several small holes *A* drilled in a line. There is a cap *B* on one end and a controlling cock *C* on the other. A sheet-metal



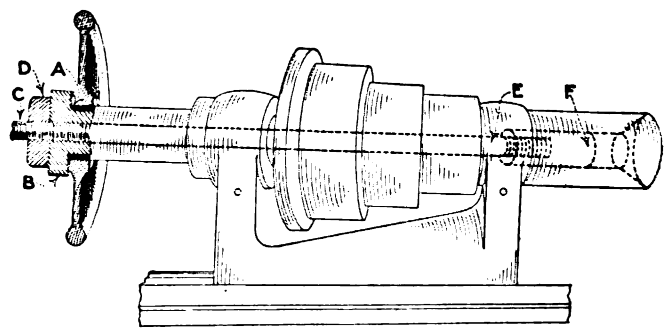
A HACKSAW LUBRICATOR

lip *D* is attached as shown and should be arranged so that the coolant flows off its edge in a thin flat stream and onto the saw blade. A little care by the operator in the adjustment of this lip will keep the blade well cooled.

Bridgeport, Conn. B. W. BURR.

Stop for Bench Lathe

The stop illustrated is convenient for use on bench lathes with the draw-in collet. It was designed to hold pieces which were drilled from each end. A thread was chased in the end of the tube at *A* and a plug *B* was tapped with a $\frac{5}{16}$x24 thread. On the stop a thread was cut on at *C*, which screws into the plug *B*. The thread



STOP FOR BENCH LATHE

is cut long to allow for adjustment, and is held in position with the nut *D*. The end *E* is tapped so that sockets of various diameters can be screwed on as shown at *F*.

By butting the end of the piece to be machined against the end of the stop at *F* and using the stop on the tailstock, accurate work is obtained, as the stop will keep the work from being drawn in. THOMAS B. BRACEY.

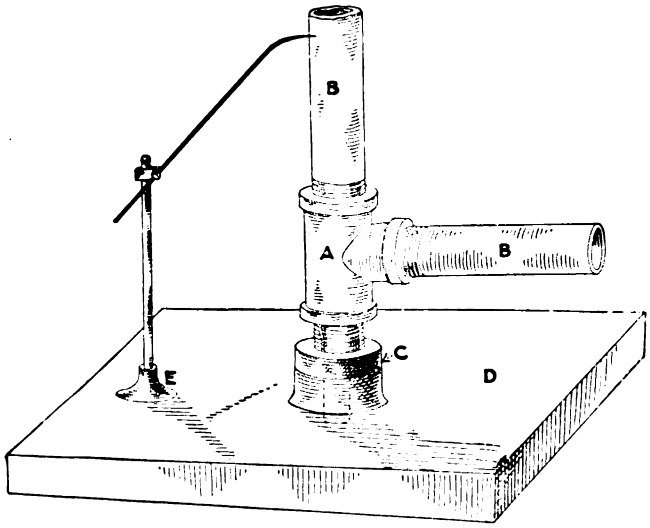
Wilmington, Del.

Discussion of Previous Question

Device for Testing Fittings

The device shown on page 164 brings to mind another that I have seen used for the same purpose. The illustration is almost self-explanatory. *A* is the fitting to be tested, *B* a standard test piece and *C* a special plug having a hub fitting into the base plate *D*, as shown, while *E* represents a surface gage.

In use, plug *C* is revolved 180 deg. The surface gage will show at once if the fitting is not tapped straight.



DEVICE FOR TESTING FITTINGS

To test for horizontal tapping, do not revolve, but use the gage near the fitting and at the end of the test piece. The different test pieces should have the threads marked for depth and act as thread gages.

Odd-angle or 45-deg. fittings cannot be gaged with this device, but screwed flanges can be tested to see that tapping is perpendicular to the flange. It was for this purpose that I first saw this contrivance in use.

Milwaukee, Wis. JOHN BAILEY.

The Suggestion System

At different times articles on the suggestion system have appeared in the *American Machinist*. Generally, the articles do not speak well of the plan. In the first year there is a large flow of ideas, gradually decreasing until only 20 or 30 per year are received.

Of course, a system of this description would not be thought of in connection with such big plants as Ford's and Studebaker's. These are up-to-the-minute shops; but what about the shop with a hundred men, which is being run in a go-as-you-please way? Just the same thing would happen here. The first year would bring in a hundred or more ideas, and then there would be a decrease. But I think this is just the reason why each shop should adopt the system. The operators are the men right in touch with the details of the work. If the manager and foremen would pull themselves together and decide to row in the same boat as the men in the shop, matters would be successful.

Now take the suggestion system when it gets to where only 20 or 30 ideas come in a year. The majority of these might come from one man. He loves his work, but likes it better if some of his suggestions are paid for. His ideas are carefully thought out. Is he not worth watching? He is not always going to be an operator. It would pay to run a suggestion scheme if the only result was the finding of such men. J. H. DAVIS.

Wembley, England.

Effect of Oil in Cutting Off

The article by W. G. Groocock on page 295 is in line with the experience of many who have had to do with broaching. Some time back, a broach that had been tested at the factory, giving satisfactory results, was complained of by the user. It acted as described by Mr. Groocock. A man from the broach makers found oil being used as a coolant. Upon his recommendation a change was made to "economy compound" in the proportions of five parts of water to one of compound and excellent results were obtained.

On another occasion a lot of tough low-carbon steel had to be threaded 8 threads per inch. The cut was very rough, the tool gouging in. Three men tried the job before it was turned over to the toolroom foreman, who experimented with all the lubricants that had been used in the lathe department, with no better result. Finally, he tried turpentine and white lead, which proved all that was needed. I. K. MACKENZIE.

South Acton, Mass.

Lack of Attention to Want Ads

The editorial on page 346, discussing certain phases of advertising for employees, deserves to be carefully pondered by every small-shop owner who, like myself, cannot afford a regular employment clerk and is therefore in the habit of leaving the job of finding new employees to someone in "the office" who has probably neither the training nor the patience to fit him for this task.

No matter how large the town, there is only a certain definite number of men available for work in a given shop, and no manufacturer can afford lightly to antagonize or discourage a single one of these prospective employees, lest he be the very man best fitted to fill some future vacancy.

When advertising for help, a manufacturer should bear in mind that he is really endeavoring to sell an opportunity to the man who best deserves it and should make his advertisement appeal to that man in terms that will make him covet the opportunity and set about securing it. "Men Wanted" will attract only the out-of-works, but "Opportunity for an ambitious man to work into a position of responsibility" will bring answers from the

best class of workmen—those who are always alert to better themselves and willing to give the best that is in them in the process. It need hardly be added that it is futile to "color" the position misleadingly; that will mean merely a disgruntled employee who will leave on the first payday. But write up honestly and convincingly the attractions of the place you have to offer, even if it takes a little time and thought to get the proper wording.

Having secured and read your answers, the usual process is to write to the two or three most promising applicants and throw the remaining letters in the waste-basket. "No time" or "Costs too much" to answer them all, you say. But the time and the money thus spent will yield big returns when help is scarce and you have to come out in the open and fight for the men you need. In such an event a reputation for decent and considerate treatment of help will be as bread cast upon the waters. An easy and inexpensive way of dealing with answers to ads is to have a number of stamped post cards printed with the following form:

Dear Sir—We have received and considered your reply to our recent "Help Wanted" ad and do not believe that your qualifications will enable you to fill this vacancy satisfactorily.

We have, however, filed your letter and will write you further when a suitable vacancy occurs.

Kindly call about o'clock next for an interview.

Thanking you for bringing your services to our attention, we are, very truly yours,

THE BLANK MANUFACTURING CO.

By crossing out the irrelevant lines this makes a suitable reply to the three classes of applicants—promising, unpromising and hold-overs—and requires in addition merely the writing of the name and address on the face side. In this way, at an expense of about $2 per hundred, many friends and advocates of the establishment are secured, and as many men are relieved of the uncertainty and suspense that always follow the sending of a letter seeking employment.

"Courtesy pays" is a slogan that applies as aptly to the relations between employer and employee as to those between dealer and customer.

New York City. W. J. SPIRO.

Miller Designer and Shop Superintendent

On page 10 E. P. Armstrong writes, "The scarcest men in the country today are men who are capable of satisfactorily filling the superintendent's position . . . because it is not altogether a question of skill in cutting iron and machinery, but of broad-sightedness, diplomacy and tact coupled with well-developed executive ability.

In a discussion of this subject recently with some friends it was pointed out that the foregoing is doubtless very true to some people's minds, but let us review the prospects facing aspirants for such positions—men who are fully qualified, possessing both mechanical skill and knowledge, with executive ability and tact acquired in positions that call for and train the holders in the broadest manner.

The most likely means of finding better opportunities are the advertisement columns of the *American Machinist*. Many hours are spent composing letters, setting forth, as if writing for the mechanical "Who's Who," all one's life history in answer to such inquiries as seem to offer steps in advancement. The result in far too many instances is not even an acknowledgment.

At times I have found it necessary to advertise for skilled help. I considered it a question of honor, if nothing more, to answer even the postal card of some poor fellow who had no more ability, or knew no better, than to state his experience in such a condensed form.

The alternative method for "upward and onward" candidates is to wait until chance positions come in their way through the tips or recommendations of friends. This procedure does not always result in the right man being fitted into exactly the right place.

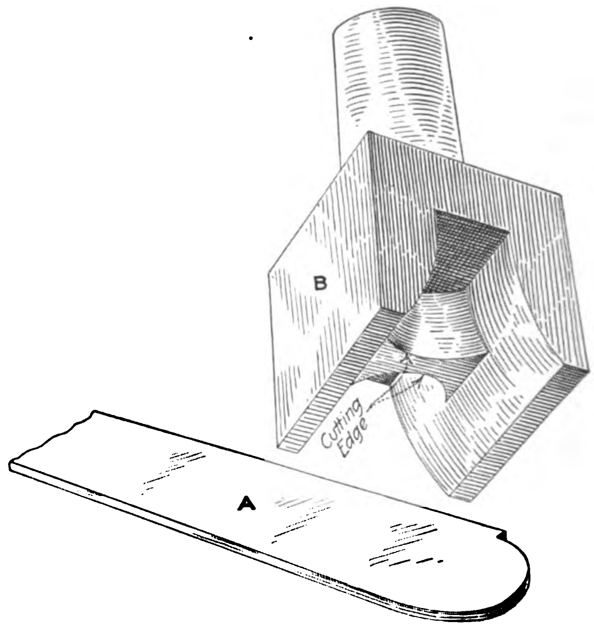
Is there not a need for a clearing house or exchange for men who have sufficient confidence in themselves to be willing to demonstrate their ability to fill better positions.

Middletown, Conn. J. A. ERITH.

Saving Costs in Shearing and Punching Flat Bars

The method of cutting off flat bars described by A. Patterson, in the *American Machinist*, Vol. 44, page 372, is very old. The trouble with the tools as he shows them is that all commercial flat-bar stock varies so much in width that it is impossible to center the stock properly and get a good-looking job. Anybody who tries this kind of tool will find that a big percentage of the work will look as illustrated at *A*.

To overcome this objection, I have used a punch, as shown, with very good results. The two tapered sides



STOCK-ALIGNING DIES

on this punch act as a guide for the stock and will naturally bring it central over the die every time, provided the distance between the prongs is made right. The two projections on the punch are backed up by the die and act as guides between the punch and the die, at the same time guiding the stock.

In making this punch, care must be taken in hardening, as it has a tendency to break at the sharp corner where the prongs leave the punch proper. If the prongs are made thick enough and ordinary care is taken in quenching, no difficulties will be experienced.

New York City. B. NAUCKHOFF.

Editorials

Take Warning!

The most dangerous and insidious of all attempts to foist the metric system on this country is now underway. Dr. Stratton, Director of the National Bureau of Standards, has prepared a "Report to the International High Commission Relative to the Use of the Metric System in Export Trade." This report has been prepared at the request of Secretary McAdoo for the International High Commission which convenes in Buenos Aires, Apr. 3, next, for which Secretary McAdoo is at this writing en route; and all signs point toward its use before the commission in order to commit our Government to the adoption of the system.

In this devious and roundabout way it is sought to undo the great work accomplished by manufacturing interests a dozen years ago in defeating the bill for the compulsory adoption of the metric system then before the House Committee on Coinage, Weights and Measures. It must be remembered that that work is now ancient history and practically forgotten in Washington. The personnel of Congress has largely changed, the administration has changed more than once, and meanwhile Dr. Stratton has been constantly on the ground and ceaselessly active in poisoning our public officials with his specious assumptions.

Let no one be deceived by the reference to export trade in the title, for most of the report is an argument for the general use of the system, and all know Dr. Stratton's aim to be the bringing about of such use. In the concluding paragraph we find, "A common system of weights and measures will also aid in realizing one of the aims of the High Commission in securing the unification of law and practice." The body is a commission on uniform law and the report can have no other use at Buenos Aires than to commit our Government to the adoption of the system.

The second paragraph opens as follows: "The following examples are given as a few typical of the large number of manufacturers who are already using the metric system, in some cases in both domestic and foreign trade." In this enumeration we find the following from our list of advertisers (we give the names as they appear in the report): Brown & Sharpe, Pratt & Whitney, the Standard Tool Co., Morse Twist Drill Co., L. S. Starrett Co. Some (we think all) of these companies will be recognized as unalterably opposed to the system; and they will certainly enjoy seeing their names thus lugged in to support the metric cause, as they will enjoy this piece of wisdom: "Some well-meaning men have urged that English measures are working well enough and a change would be all but impossible. Yet the very firms concerned are using the metric system for their own profit. No more could be asked."

The report is expressly announced as intended for wide circulation. It is a Senate document, which means that, to the resources of the Bureau of Standards, Dr. Stratton has now annexed the facilities of the Government Printing Office and, through the franking privilege, the use of the postal service in spreading his metric propaganda—and all without cost. It is the object of Dr. Stratton's life to force the metric system upon this country; and much as we condemn, we cannot but admire, his ingenuity in enlisting the Government departments in his service. It is plain that since the victory of a dozen years ago manufacturing interests have been asleep, and on them Dr. Stratton has stolen a march. Much as we deplore the re-introduction of a subject of which all—and none more than we—are heartily tired, it is plain that another and united effort must be made to nullify the activities of the most dangerous enemy of our industries which our country harbors.

The pamphlet is Senate Document No. 241 of the Sixty-fourth Congress, First Session. Every reader should write to the Government Printing Office at Washington for a copy. While of school-boy grade and unworthy of serious discussion, the pamphlet cannot fail to have large influence with the unthinking and uninformed, for whom, indeed, it is obviously intended. It is inconceivable that Dr. Stratton regards his arguments as of serious value.

Commercial Credits in South America

With the exception of Colombia and Venezuela, the common method of doing business in South American countries is on a credit basis. The two countries named have always been on a cash basis, for reasons that are perhaps not entirely complimentary. At the present time the length of credit is running from 60 to 120 days, although in the past much longer terms have often been extended.

The position of Ecuador is strong financially, and the best houses expect terms of from 60 to 90 days from the date of receipt of goods there. In Peru, Chile and Bolivia the conditions are very much the same. At one time German exporters used to give credit in these countries for long periods up to two years, and it is stated that there were heavy losses from this custom.

Up to the opening of the European War the business of Argentina had been very largely handled through Europe; thus commercial houses in that country were not well known in North America, and the little business that was conducted was very largely on a basis of cash against documents in Buenos Aires or New York. But this situation has now changed, and the average length of credit extended to Argentine buyers is from 90 to 120 days. The long-established well-known houses get this extension from the arrival of the goods in their home port.

The situation in Brazil is very similar to that now prevailing in Argentina, although before the opening of the war there had been a much greater flow of commodities from Brazil to North America and from the United States back than had prevailed with Argentina.

The South American inclination to be easy-going exhibits itself in the payment of these obligations, as in many other business relations. It is not at all unusual for customers to allow a draft to run over a few days, say three or four or five, before taking it up. But in the end they pay, which is the important consideration. Thus it is always wise for a North American exporter to allow a draft or note to run on a few days beyond the date of payment without entering a protest. As a simple rule, say, let such documents run for at least ten days before taking steps to collect. This is a wise policy, which in the long run works no serious hardship to the exporter. On the other hand, it is a course that tends to build up the all-important asset of good feeling.

There has been an erroneous opinion in the United States that South American accounts are apt to be bad. Southern credit has often been looked upon with suspicion. In the main this viewpoint is all wrong. There are as strong, well-established, reputable business houses in South America as can be found anywhere in the world.

In this connection the experience of a United States manufacturer during the year 1915 is of particular interest. During the year 1914 this firm exported about $8,000 worth of goods to Brazil. Owing to the cutting off of European supplies, this account jumped to $500,000 for the year 1915. (As a matter of interest, this concern is now doing about 65 per cent. of the business in its line in all Brazil.) During the year 1915, when this half-million dollars' worth of business was done, there was only one bad account—amounting to $146. And in that case the goods were not claimed at the custom house; thus the property was not lost. Where is there a half-million dollars' worth of business in the United States, divided up into a large number of small accounts, that can equal this record?

Still another Brazilian incident is instructive in this consideration of the reliability of South American business houses. Some six months ago the Brazilian congress passed a law requiring the execution of a written document with revenue stamps attached as an acceptance in the case of all credit sales. One house in Rio de Janeiro, doing business with 1,800 customers scattered throughout the length and breadth of Brazil, wrote to each one, pointing out this law and asking that it be conformed to in connection with its business. With hardly an exception the customers wrote back saying that they would not execute such documents and rather than do so would not accept any more goods. As a result the merchants got together and appealed to the Brazilian congress, which at first prorogued the law and finally annulled it.

The viewpoint of the customers was that this law was a reflection upon their honesty and business integrity. They thought that the merchants had inspired it and were prepared to fight.

At the present time the efforts of the banks are being directed toward cutting down long credits. A number of evils flow from them. They tend to foster spasmodic buying and even speculative buying. These facts are being pointed out to South American customers, with the hope of influencing them toward short credits or cash business. The practical advantages of short credits to the seller are easily pointed out. Frequent orders mean a steady flow of product. This tends to stabilize the working conditions in machinery-building shops.

Navy-Yard Preparedness

We are in the midst of a campaign for military preparedness—that is, an agitation looking toward the appropriation of large sums of money for the provision of ships, armies, artillery and munitions. Also there is likely to be a campaign for industrial preparedness. The *American Machinist* has already signified its approval of this project.

There is a little combination of these two ideas that could be put into operation right away. It would conduce to military preparedness and be an example of industrial preparedness; moreover, it would require no appropriations.

Under the Navy Department there are several industrial plants—the navy yards, including the gun factory at Washington; the powder factory, the torpedo factory and a number of magazines, or arsenals, at which powder and shell are stored and packed. A navy yard is not a park, where ships may tie while the officers and crews go ashore on liberty. It is a good-sized industrial plant, employing from 1,000 to 5,000 hands; and four or five of the navy yards are equipped for shipbuilding.

The *American Machinist* has taken occasion previously to dwell on the necessity of doing something toward the development and organization of these properties. They are not run economically, nor modern in equipment and methods. They should be models for the rest of us.

Not only should the economic wastes be eliminated; the military value of the properties should be recognized and developed. As at present organized, all the magazines, the torpedo factory, the powder factory and the gun factory are officered by line officers doing shore duty. Each navy yard is divided into two industrial divisions, and the line officers run one of these in each yard. This condition is subject to criticism, not alone because line officers—conscientious and hard working though they may be—are not experienced in this work, but principally because on the outbreak of hostilities it would be necessary to withdraw them from shore duty to officer naval vessels—necessary because the ships would require them. Incidentally, the navy is shorthanded as to officers even for a peace footing.

Upon removal of the line officers who chance to be in these industrial plants at the outbreak of hostilities it appears to be the plan to replace them with retired officers not suitable for sea service. This would be a military mistake, if not a calamity.

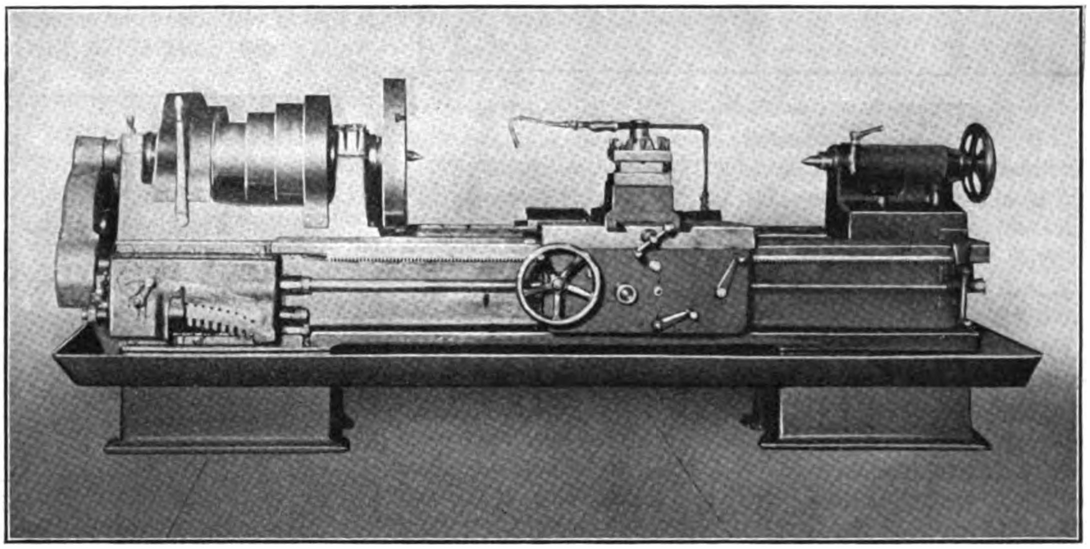
These Government plants are wanted for war-time purposes principally. At the outbreak of war they would go as quickly as possible on a 24-hr. basis. The navy yards in converting merchantmen and refitting men of war would have to do in a week what they now take six weeks or more to do. In order that these plants may fulfill their mission, in order that their military value may be maximum at the time of greatest need, they must at that time have well-oiled, smooth-running organizations in the hands of officers trained to run them and stay with them during the war. The present is the time to start to develop these organizations; and the work of development can be done without the appropriation of large sums of Government money.

The authority to issue an order involves the responsibility to see that it is properly executed.—H. L. Gantt.

Shop Equipment News

Quick-Change Double Back-Geared 24-In. Lathe

The Weir Frog Co., Cincinnati, Ohio, has taken over the drawings, patterns, templets and jigs for the Series D 24- and 26-in. lathes made by the Rahn-Larmon Co. Under this arrangement the latter company, no longer manufactures these sizes. The 24-in. size is here shown. A lathe built along similar lines has been previously described in these columns, but the present machine is equipped with quick-change gear box, oil pan, oil pump and cross-slide turret, which were not on the former machine of this size.



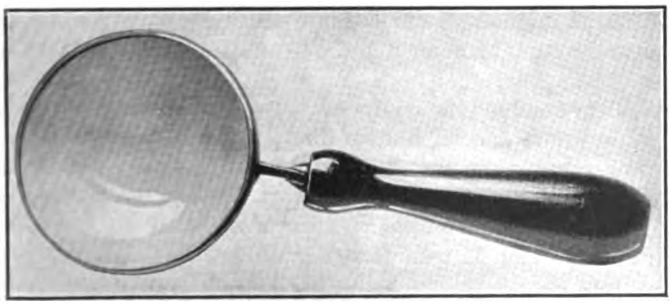
QUICK-CHANGE DOUBLE BACK-GEARED 24-IN. LATHE

Swing over V's, 25 in.; swing over carriage, $17\frac{1}{4}$ in.; front bearing, $4\frac{5}{8}$ in. in diameter by $7\frac{1}{4}$ in. long; back bearing, $3\frac{1}{8}$x5 in.; hole through spindle, $2\frac{1}{8}$ in.; tail-spindle diameter, $2\frac{7}{8}$ in.; traverse of tail spindle, $9\frac{3}{4}$ in.; cone diameters, 10, 13 and 16 in.; width of belt, 4 in.; ratio of first back gear, 4.75 to 1; ratio of second back gear, 12 to 1; cuts threads, 2 to 20 per in.; threads on lead screw, 4 per in.; range of feed, 0.01 to 0.27 in.; length of bed, 10 ft. 6 in. and longer; extreme length between centers, 5 ft.; weight, with 10-ft. bed, 5,600 lb.

The wings of the saddle are provided with the usual T-slots, their top surfaces being above the top of the cross-slide. By removing the turret tool post and cross-slide, work can be bolted direct to the top of the carriage, for boring, etc. All gears are protected by gear guards, which are readily removable. The lathe is furnished with taper attachment if desired.

Handy Magnifying Mirror

The form of magnifying mirror shown was designed primarily for tool makers' and machinists' use. In addition to its handiness for the close examination of various classes of machinists' work and toolroom operations it is calculated to afford relief from eye strain in connection with fine work. The mirror is of course adjustable.



HANDY MAGNIFYING GLASS
Diameter of mirror, $2\frac{3}{16}$ in.

Many applications for such a mirror will come to mind, as, for example, observing the points of cutting tools while in the machine, examining internal threaded and other work, setting dividers to scale lines, etc.

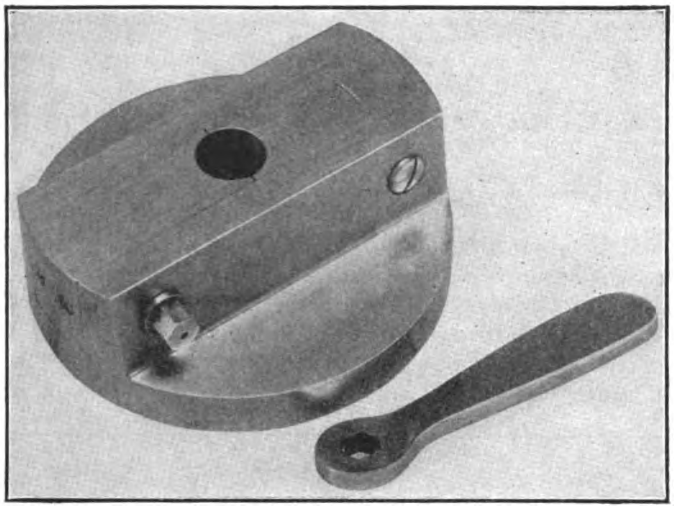
The convex mirror is of high magnifying power and is mounted in a white-metal die casting. Either metal or wooden handles may be obtained. The device is a recent product of the Pajaro Manufacturing Co., 1251 Brown's Ave., Erie, Penn.

Self-Centering Bushing Chuck

To provide adequate means of holding thin bushings for boring or internal grinding, the Rivett Lathe and Grinder Co., Brighton, Boston, Mass., has recently developed a self-centering chuck, one size of which is shown.

The chuck is designed to take a bushing of a given size and hold it on the outside in such a manner as to prevent distortion. The chuck has two jaws, the total travel of which is not over $\frac{1}{16}$ in. It is universal in action, both jaws moving simultaneously. The body of the chuck is made of cast iron. The two chuck jaws are of ample depth to afford sufficient bearing on the bushing to be held. The jaws slide in a slot cut through the body of the chuck. At right angles to the travel of the jaws are two spindles through which the movement of the jaws is secured. The spindles are connected by means of suitable links, and the jaws are operated through the eccentricity of the spindles.

It will be observed that all the moving parts are entirely inclosed and that the design has been made especially compact. The chuck may be used in any lathe or



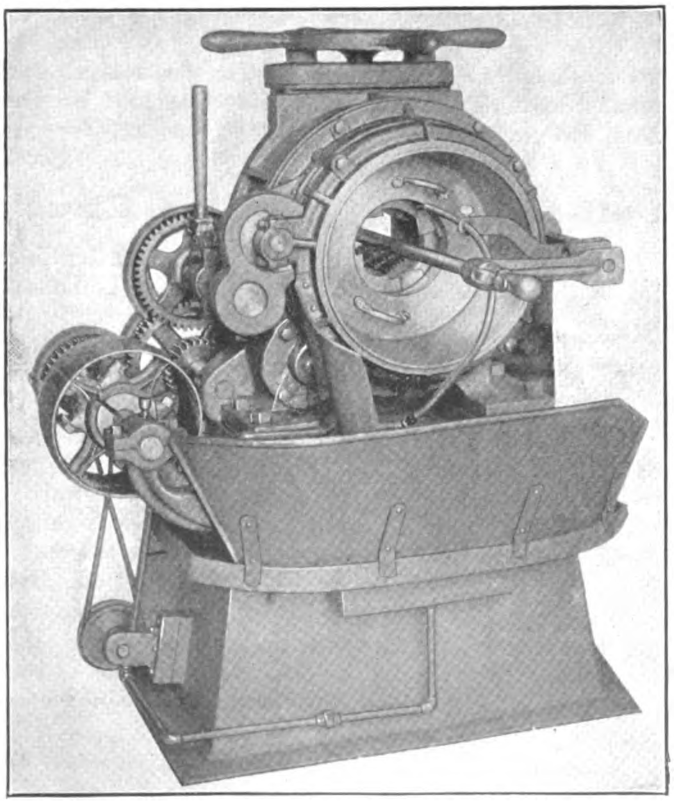
SELF-CENTERING BUSHING CHUCK

grinder and is mounted on a faceplate in the regular way. It is made in two sizes—for holding bushings up to $\frac{7}{8}$ in. and $2\frac{9}{16}$ in. in diameter.

Shell Cutting-Off Machine

The illustration shows an automatic cutting-off machine for cutting off the ragged ends of shrapnel and high-explosive shells. In this machine the Curtis & Curtis Co., 66 Garden St., Bridgeport, Conn., has adapted the principle followed in its line of pipe and threading machines—namely, turning the dies around the work instead of turning the work in the dies.

Four cutting-off tools are used, all cutting simultaneously under automatic control, and there is provided quick return for the cutting-off tools.



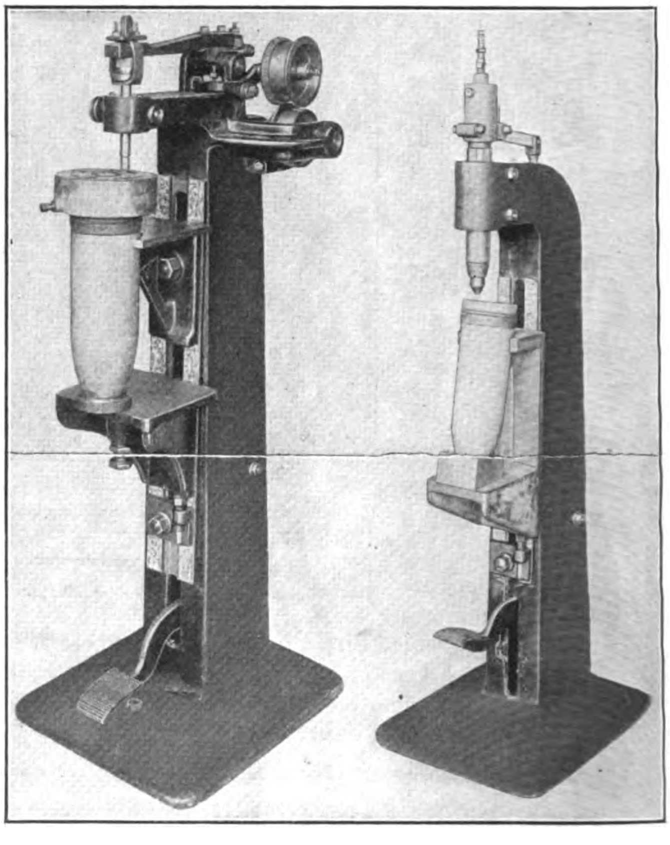
AUTOMATIC CUTTING-OFF MACHINE

The general construction of the machine is made apparent by the illustration. Aside from the insertion and removal of the work, the machine is entirely automatic. It may be arranged for direct-connected motor drive by installing a motor in the base and interposing a train of compound gears.

The machine is made in a number of sizes for shells ranging from 3 to 6 in. and with varying thicknesses of walls.

High-Speed Shell-Riveting and Marking Machines

The two machines shown were adapted by the Grant Manufacturing and Machine Co., Bridgeport, Conn., from its line of riveters, to be especially suitable for high-speed riveting and marking of high-explosive type of shells.



HIGH-SPEED SHELL-RIVETING AND MARKING MACHINES FOR HIGH-EXPLOSIVE SHELLS

Diameter of piston of riveting machine, $1\frac{1}{16}$ in.; length of stroke, 4 in.; speed, 1,000 blows per minute; air pressure per square inch, 80 to 100 lb.; weight, 300 lb.; speed of marking machine, 2,000 blows per minute; marking can be arranged for 18-lb., 4.5-in. and 60-lb. shells

The riveting machine, shown to the right, is of the pneumatic stationary type, designed for heading the base plugs in high-explosive shells fitted with plugs having an annular rim turned on the end of the shell for riveting over the plug.

The machine is equipped with a special supporting table, and a special fixture that fits the nose of the shell, thus supporting the shell in proper position under the riveting hammer to close the joint. Inasmuch as the riveter is of the stationary type and fitted with a foot treadle, which is used to bring the riveting hammer into action, the operator's hands are free to handle the shells.

After the shell is in position, the treadle is depressed, thus starting the machine; the shell is then rotated one

complete revolution by hand, and with the riveting hammer striking about 1,000 blows per minute the plug can be riveted perfectly tight into the shell in about 20 sec. This machine can be equipped for riveting various sizes of shells.

The machine shown to the left is an adaptation of the rotary vibrating shell-riveting machine made by the same company and especially fitted up for rapidly marking the bases of high-explosive shells.

The arrangement is such that the blow is brought to bear on each individual letter and figure successively and with uniform pressure. Adjustment is provided so that a shallow or deep impression can be obtained. In operation a marking chuck is fastened on the end of the shell by means of a thumb-screw. The shell is then placed on the ball-bearing revolving fixture, which fits the nose of the shell. The base of the shell is supported in a position that brings the vibrating hammer to the proper location to do the marking. The machine is then started and the shell rotated one complete revolution by hand. With the machine striking 2,000 blows per minute, the official marking is done in about 15 sec. The machine can be equipped for various-sized shells.

Worm Thread Miller

The latest model of worm thread miller built by the Newton Machine Tool Works, Philadelphia, Penn., is shown in the illustrations.

In operating, the turned worm blanks are forced on a mandrel inserted in a taper draw chuck in the hollow spindle, controlled by a lever. After this first clamping, the mandrel is not released until the worm is entirely completed, as the adjustment to, and division for, the successive leads is controlled by a tooth clutch connected to the indexing worm and wormwheel.

The gear box contains the required gear combinations through sliding sleeves controlled by latch levers. Six leads are covered without removal of gears, whether threads are right or left hand. The various pitches are obtained through change gears.

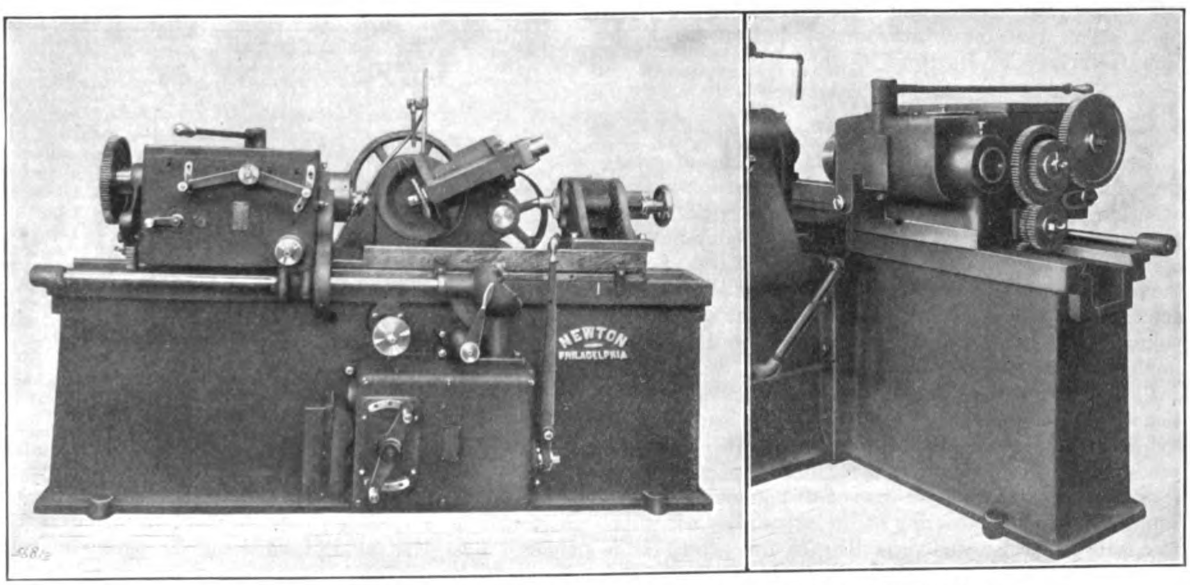
Motion is transmitted to the index box from a feed box, in which sufficient gears, mounted on sliding sleeves, controlled by levers, are included to give nine changes of feed without removal of the gears.

The feed is also carried through a box for connection with the rotating mechanism and then to gears for connection with the table feed screw. A lever controls the engagement of the feed clutch and another lever the reversing fast-power table clutch.

An eccentric clamp is controlled by a lever to lock the head securely in place after the cutter has been adjusted to the required depth through a screw equipped with a micrometer measuring collar.

All features are controlled from the front, with the one exception of the spindle-head rotating worm-shaft, which is fitted with an adjustable circular gage to give fractional degrees of angularity to the cutter spindle, within a maximum range of 40 deg. each side of the horizontal. Cutters are located with the axis by the use of spacing collars. A latch pin lever controls the clutch that gives suitable feeds and rotation for the left- and right-hand worms.

The drive is from a pulley through reduction gear, a spur gear through bevel gears and finally through hardened pinion and gear to the hardened helical gear made integral with the spindle, which has a taper bearing on each end. The thrust of the spindle is taken by an oil-immersed bearing of ample proportions for the purpose.



IMPROVED DESIGN OF WORM THREAD MILLER WITH CENTRALIZED CONTROL

Diameter of bore in spindle chuck, 3 in.; maximum distance between end of spindle and center, 24 in.; center of spindle to table, 8¼ in.; width of table, 14½ in.; base, over all, 8 ft. 3 in. by 4 ft. 6 in.

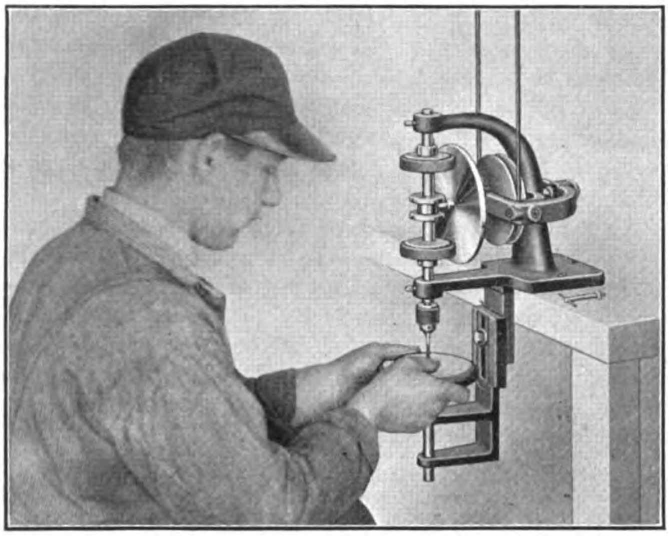
The base serves as a reservoir for the lubricant, which is delivered at the point of cutting by a pump and conductors.

It will be noted that control of all of the machine's motions is effected from the front with the exception of the spindle head rotating wormshaft. It will be understood that the work to be finished on this machine is in the form of hollow cylinders previously turned.

Sensitive Tapping Machine

The special feature of the tapping machine shown is the friction drive for both forward and reverse, making it sensitive to the touch of the operator and reducing the possibility of tap breakage.

The friction rolls are adjustable, simplifying the speed changes and at the same time permitting reversal at a higher speed than when driving forward. The friction-roll adjustment secures any speed from 225 to 600 r.p.m. This machine is a recent product of the Fenn Manufacturing Co., Hartford, Conn.



SENSITIVE TAPPING MACHINE

Capacity, $\frac{3}{16}$ in.; maximum distance from chuck to table, $3\frac{3}{8}$ in.; distance from upright to center of spindle, 3 in.; weight, with countershaft, 62 lb.

Coating for Blueprint Paper

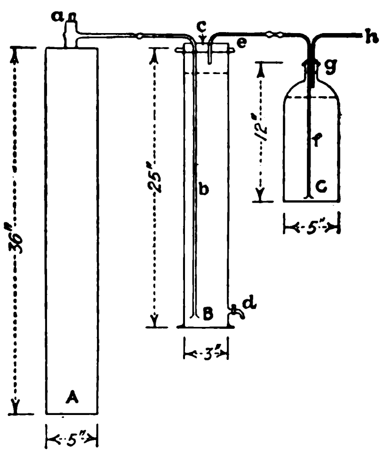
As a result of the great increase in the price of potassium ferricyanide, or red prussiate of potash, which is extensively used as a coating material for blueprint paper, an economical method of preparing the substance has been devised by the Department of Agriculture. Before the beginning of the war potassium ferricyanide could be obtained for 55c. a pound. It now sells for about $6 a pound, and moreover, it is exceedingly difficult to obtain in this country even at that price.

Potassium ferricyanide is produced by oxidizing a solution of potassium ferrocyanide with chlorine gas. At the same time a small amount of potassium chloride is produced. Investigations by the Bureau of Chemistry show, however, that the presence of this amount of potassium chloride in the coating of the paper does not interfere with the color and durability of the print. It is unnecessary, therefore, to separate the potassium chloride by crystallizing the potassium ferricyanide, provided that the latter is to be used on the spot and soon after it is prepared.

The apparatus devised by the Bureau of Chemistry for preparing in this way potassium ferricyanide solution is simple. The chief precaution to be taken in its operation is to see that the finished solution does not contain an excess of chlorine. At the prevailing prices of the materials potassium ferricyanide solution can be made by this process at the cost of approximately $2.80 per pound, calculated on the dry-salt basis. At the prices which prevailed before the war and which may be regarded as normal the cost would be approximately 35c. per pound.

Allowing for possible loss, 100 lb. of potassium ferrocyanide should yield about 75 lb. of potassium ferricyanide.

In the illustration is shown apparatus designed to produce 1 lb. of potassium ferricyanide from 1.33 lb. of potassium ferrocyanide. *A* is a cylinder containing chlorine; *B* is a glass cylinder 3 in. in diameter and 25 in. in height, capacity approximately ¾ gal., in which the solution of potassium ferrocyanide is placed. *C* is an ordinary acid bottle containing a solution of sodium hydroxide for absorbing any excess of chlorine that may be unabsorbed by the solution of potassium ferrocyanide. The glass cylinder *B* is fitted with a glass pet-cock *d* near the base for withdrawing a portion of the solution for testing completion of oxidation. At the top it is fitted with a 3-in. cork *c* sealed with paraffin and having two holes to accommodate the glass tubes *b* and *e*. One of these tubes *b* extends to the bottom of the cylinder and is blown at the end to distribute the gas. It is connected by a short piece of rubber tubing to the pipe attached to the chlorine cylinder. The other tube *e*, which does not touch the surface of the solution in cylinder *B*, is connected by a rubber tube to a glass tube *f* running to the bottom of the acid bottle and blown to distribute any gas that may not be absorbed in *B*. Bottle *C* is fitted at the top with a cork *g* sealed with paraffin and having two holes through which pass tubes. One of these tubes *f* runs to the bottom of the bottle; the other *h*, starting from above the liquid, is so connected as to carry unabsorbed chlorine out of doors. The chlorine gas is regulated by a valve *a* in the head of the chlorine cylinder. The glass tubing used should be ⅛ in. in inside diameter.



APPARATUS FOR THE PREPARATION OF POTASSIUM FERRICYANIDE

In operation it is only necessary to dissolve 1.33 lb. of potassium ferrocyanide in about 2½ qt. of distilled water and pour into cylinder *B*. Nearly fill bottle *C* with a 10 per cent. solution of causic soda. Connect the chlorine cylinder with tube *b* by means of a short piece of rubber tubing, tube *e* with tube *f*, and finally run a tube *h* from bottle *C* out of doors. Turn on the chlorine gas and allow it slowly to bubble through the solution of potassium ferrocyanide. Shut off the chlorine at intervals of a half-hour or so; and to aid the absorption of the gas, shake or agitate the container. Do not allow

the caustic soda solution to suck back when the gas is shut off. This can be prevented by breaking the connection between *B* and *C* immediately after shutting off the chlorine. Continue passing the chlorine into the potassium ferrocyanide solution for some time after the color has darkened considerably. After this, frequent tests are necessary to determine when the oxidation has been completed. To test for complete conversion to the ferricyanide, draw off a little of the solution through the pet-cock *d*, dilute with distilled water and test with a solution of ferric chloride. If a blue precipitate is formed, potassium ferrocyanide is still present and the process must be continued. If a brownish or amber-colored solution results, the oxidation is complete. After tests show the oxidation to be complete, turn off the chlorine gas, disconnect the chlorine cylinder and connect *b* with an air-pressure line. Bubble air through the solution until no odor of chlorine is noticeable. In case air pressure is not available and suction can be obtained, break the rubber connection between tubes *e* and *f* and connect *e* with the suction and draw air through the solution until it is free of chlorine.

Great care must be exercised that no chlorine escapes into the room and comes in contact with the flesh, as it is a powerful irritant and serious injury may result to the throat, nose, eyes and hands from exposure to the fumes or from contact with the liquid.

NEW PUBLICATIONS

AMERICAN MACHINIST GEAR BOOK—By Charles H. Logue. Revised edition, Reginald Trautschold, editor. Three hundred and forty 6x9-in. pages; 300 illustrations; indexed; cloth bound. Published by "American Machinist," McGraw-Hill Book Co., sole selling agents. Subscription price with the "American Machinist," $4.75; sale price, $2.50.

The first edition of this book was published some five years ago and met with a most gratifying success. It provided reliable, useful information on the subject of gearing. However, the last few years have added much to our knowledge of certain types of gears, making it advisable to revise a part of the original matter and to add some that is new. In doing this the original plan of the work has been followed, and much of the text remains intact. However, four sections have been entirely rewritten. These cover bevel, worm, helical and skew-bevel gears. In addition, the former section on gear-pattern work and molding has been omitted, and its place has been taken by a new section devoted to the costs of standard gears.

STEAM POWER—By W. E. Dalby. Seven hundred and sixty 6x9-in. pages; 258 illustrations; 35 tables; indexed; cloth bound. Longmans, Green & Co., New York City. Price, $6.

English technical books, particularly those relating to thermodynamics, have certain disadvantages when used by American readers. The most apparent is the system of units. Professor Dalby's massive volume, for instance, makes use of the pound-calorie rather than of the British thermal unit and consequently of the Centigrade rather than of the more familiar Fahrenheit temperature scale.

The book opens with an outline of the practical working of a steam plant, then goes on to explain how the power developed can be measured, and afterward considers practical and theoretical thermodynamics and dynamics of the plant.

The author has chosen to divide the heat-carrying media into three interacting circuits—the heating circuit, dealing with the transformation of the fuel into gas and the work done by the latter; the motive-power circuit, in which the steam gives up its energy; and finally the so-called cooling circuit, where the water is circulated through the condensing system. The first five chapters are devoted to the consideration of these three circuits.

Chapter I gives a general description of the duties of the boiler, reciprocating engine, condenser and auxiliary apparatus forming the power plant. It also explains the meaning of such terms as indicated and brake horsepower, as well as the principle and construction of apparatus used in their measurement. The reader is next given an elementary conception of the method of calculating thermal efficiency and is shown by carefully prepared flow diagrams the heat-energy conditions in various steam plants.

The second chapter deals with the steam boiler. The principal elements of the construction of several English boilers are described, as also are safety valves, gages and other very English mountings. Particularly clear and useful are the sections relating to fuels and to the theory of combustion.

The third chapter is a 75-page review of the laws of thermodynamics.

Chapter IV applies the theory to the performance of compound engines for both stationary and locomotive work, paying considerable attention to losses and to the means of reducing them. Concluding the part of the book concerned with heating, motive power and cooling circuits is a chapter on condensing apparatus, which seems all too short in view of the importance of the condenser and auxiliary apparatus in the operation of the modern power plant.

Chapters VI, VIII and IX relate chiefly to locomotive design and operation considered from a technical point of view.

Chapters VII and X deal with engine mechanism, the first explaining the method of calculating and graphically determining turning couples and giving the theory of flywheels and governors. The tenth chapter relates to steam distribution and therefore to valves and valve mechanisms. The rectangular-valve diagram is used to illustrate a number of practical problems. The Reuleaux, Bilgram and Zeuner diagrams are explained, as are also typical locomotive valves, link and reversing motions.

The last hundred pages (Chapters XI and XII) are devoted to the steam turbine. After starting with the theory of steam flow and of nozzles and applying the theory to the steam jet in the vacuum-brake ejector and the boiler injector, the reader is introduced gradually to the principles underlying impulse and reaction turbines and to the general design of such apparatus. The construction of the Zoelly, Sturtevant, De Laval, A. E. G. Parsons and Curtis turbines is described somewhat briefly, mainly as used for ship propulsion.

Professor Dalby's treatise should prove exceedingly valuable to students, to engineers and, in fact, to anyone desiring a thorough and authoritative exposition of the principles, both thermodynamic and dynamic, on which the design and operation of steam-power apparatus depend. Original authorities, such as Newton, Carnot, Clausius and Lord Kelvin, have been consulted, and even the most advanced theory presented is at all times closely linked with fundamental principles. The author has not been niggardly in giving his authorities. In fact, he goes farther, so that the references to articles dealing with particular phases of the subject are in themselves a useful part of the book. Another pleasing feature is that the illustrations, instead of being photographic reproductions, are nearly all line drawings carefully prepared to explain and to amplify the text.

PLANE GEOMETRY—By Claude Irwin Palmer and Daniel Pomeroy Taylor. Two hundred and seventy-seven 5x7½-in. pages; illustrated; indexed; cloth bound. Scott, Foresman & Co., New York City. Price, $1.

Reviewed by Walter B. Carver*

He who undertakes the thankless task of writing a textbook on geometry at this time finds himself between the devil and the deep sea. On the one hand are the centuries of Euclidean tradition, demanding an ostensibly logical deductive system. This tradition is given immediate and vital significance by the fact that the examinations which the student will be expected to pass are based upon it. On the other hand, there is the growing conviction that the student would acquire a better working knowledge of the truths of geometry and greater facility in the application of them if it were not necessary for him to devote so much of his time and energy to the proving of these truths. Moreover, it is generally conceded that many of the socalled proofs are so lacking in rigor as to be of very questionable value as a training in logic. Following the traditions, an author may produce a book that is distinguishable from its predecessors by means of the color of its binding. It will be made up largely of proofs of formal propositions, and many of these proofs will be unworthy of the name. If, on the other hand, the author be so courageous as to disregard the prescribed canons, he is quite likely to produce a book not usable as a text under present conditions.

The authors of the work under review have been notably successful in steering a careful course between these two disasters. The book impresses the reviewer as a conservative step in the right direction. In the editor's preface he suggests that the book should be gaged by "pedagogical rather than logical standards" and admits that at certain points "logic has been intentionally sacrificed to insight." It is then somewhat surprising to find the book distinctly su-

*Professor, Department of Mathematics, Cornell University.

perior to the average plane geometry in the rigor of its reasoning. The sacrifice of logic seems to consist largely of the omission of formal proofs in certain difficult cases. For instance, at the beginning of the chapter on areas there is an informal discussion, in which even the treatment of the incommensurable case is clearly suggested by a numerical illustration. Then we read, "From the foregoing considerations the truth of the following statement may be accepted: The area of a rectangle is equal to the product of its base and altitude." Perhaps this may be called a sacrifice of logic. But it is not faulty logic. There is no pretense that the theorem has been proved. Is this not the simple pedagogical and logical solution of our difficulty in elementary geometry?

The first obvious truths of the subject are presented in an informal way, appeal being made to the student's intuitions rather than to his reasoning powers. There are at the beginning no formal definitions or axioms; no pretense at proving anything. The first (very simple) proof occurs on page 39. The more important statements made in these earlier pages are proved later in the text. This method of procedure, admirable from a pedagogical point of view, is dangerous logically. It is easy to show, by a circular route of faultless reasoning, that if a statement is true it follows that it is true. One comes out by the same door where one went in. The two series of paragraphs—30, 32, 96, 97, 132, 133, 143 and 122, 123, 132, 133, 135—seem to furnish two examples of this kind of reasoning. It is only fair to add that the book is comparatively free from such defects.

The very difficult matter of measurement is well handled. The necessary assumptions are made explicitly, but in a natural form that makes them intuitively acceptable. There may be objections to defining the numerical measure of a quantity as "the number of times the quantity contains the unit of measure" and then following this by the assumption that "the numerical measure may be an integer, a fraction or an irrational number." Nevertheless, this treatment obviates many difficulties that are often less happily disposed of. It is to be regretted that the paragraphs on measurement in general (332-336) were not inserted before the paragraphs on angle measurement (304-305). The definite statements of paragraph 333 are tacitly assumed in paragraph 304.

The arrangement of the book is excellent. The subject is divided into five "chapters" (instead of "books"), and the usual order of the chapters on areas of polygons and similarity has been reversed. The material presented is more than sufficient to meet college-entrance requirements, and the arrangement is such that certain parts may be omitted when a short course is desired.

A review of the text would be incomplete without some mention of the exercises. They are numerous and varied and are well selected both for emphasizing and making clear the abstract truths of geometry and for connecting these truths with everyday experience. One is pleased to find a large number that involve the use of algebraic methods and numerical computations. There are a collection of formulas for reference and a good index.

The typographical work on the book is good; the figures are clean cut and accurate, and the general appearance is attractive.

INDUSTRIAL LEADERSHIP—By H. L. Gantt. One hundred and twenty-eight 5x7⅜-in. pages; 9 charts; cloth bound. Yale University Press, New Haven, Conn. Price, $1.

The five chapters of this book constitute the Page lectures for 1915, delivered before the senior class of the Sheffield Scientific School, Yale University. Presented now in permanent form, this book is one of the most important of recent works dealing with any phase of industrial management. In some quarters there is a feeling of uneasiness and dread of the coming period of industrial competition that must follow the great European War. In some minds there is a belief that the forces that can knit peoples together for physical warfare can also produce a superior industrial competition that will be very difficult to meet.

Mr. Gantt in his foreword admits that autocracy in the past has been able to organize a nation for both industrial and military efficiency in a manner superior to anything that has been accomplished by democracy. He then goes on to say: "If democracy is to compete successfully with autocracy in the long run, it must develop organizing and executive methods which shall be at least equal to those of the autocracy."

He believes that this can be done, however, and states the purpose of this series of lectures as follows: "In this course of lectures I have tried to set forth the principles on which I believe an industrial democracy can be based which will be even more effective than any system of industrialism which can be developed under autocracy." This conviction, expressed after mature reflection, should serve to encourage every weak-kneed American industrialist.

The titles of the five lectures, or chapters, are these: Industrial Leadership; Training Workmen; Principles of Task Work; Results of Task Work; Production and Sales.

The first naturally receives the most attention by the reviewer, for Mr. Gantt's method of training workmen and developing task work is well known and its results generally recognized. At the outset we are invited to ponder on the fact that our industrialism is so modern that its greatest problems have hardly been clearly grasped, even by those who have given them most study. Then a brief sketch of the usual conditions that have prevailed in industrial plants leads us to accept as truth: "Both employer and employee thus put a premium on inefficiency."

But the experience of the last ten years has tended to change this, and it is now becoming recognized among the most progressive manufacturers of the day that "the ratio between the wages paid and the work done is more important than the absolute amount of wages paid, and that the absolute amount of work done is more important than either." And the most important principle that is today working for the success of industrial organization is, "The authority to issue an order involves the responsibility to see that it is properly executed."

From this brief outline of industry as it was and as it is trending, Mr. Gantt invites us to consider the importance of leadership in war as the starting point of emphasizing the importance of leadership in industry. He quotes this well-known passage from Napoleon: "In war, men are nothing; it is the man who is everything. The general is the head, the whole of any army. It was not the Roman army that conquered Gaul, but Cæsar; it was not the Carthaginian army that made Rome tremble at her gates, but Hannibal; it was not the Macedonian army that reached the Indus, but Alexander; it was not the French army that carried the war to the Weser and the Inn, but Turenne; it was not the Prussian army which for seven years defended Prussia against the three greatest powers of Europe, but Frederick the Great."

The historian who gives the above quotation stated that Napoleon merely reiterated a truth confirmed by the spirit of successive ages—that a wise direction is of more avail than overwhelming numbers, sound strategy than the most perfect armament. Mr. Gantt paraphrases this conclusion for industrial conditions as follows: "A wise policy is of more avail than a large plant; good management, than perfect equipment."

The remaining pages of the first chapter amplify and expand this idea, carrying the conviction that industrial leadership is not a haphazard growth, not the chance positioning of some man or small group of men. On the contrary, it is an avocation for which men should be especially selected and trained to make them industrial leaders of the quality that the future will need, if American industries are to hold their present position in world-wide affairs.

The second chapter of the book outlines Mr. Gantt's principles and methods for training workmen, which have been associated with his name for a number of years. The third chapter outlines the principles of task work, and the fourth gives the result of this work in several industries. The examples are striking and are presented by means of the colored graphical charts that Mr. Gantt has used in his previous writings.

The fifth chapter, devoted to production and sales, follows very closely the argument of a professional paper contributed by Mr. Gantt at the Buffalo meeting of the American Society of Mechanical Engineers in May of last year. Early in the chapter he invites us to consider this fact: "If we produce an article for which there is a large demand, and sell it for a price that most people can afford to pay, the cost of selling that article in large quantities will be extremely small." Then after holding up the production and sale of the Ford automobile as an example, he writes: "This seem to dispute the theory held by so many business men, that a high selling price is necessary to large profits."

The final pages of the book are devoted to a brief discussion of the problem of expense apportionment and of the newer theory advanced by Mr. Gantt himself: "The output of the factory should not bear the total expense of the factory, but only that portion of the expense needed to produce it."

Every man who wishes to keep in touch with the newer theories and developments of the best thought on industrial management will be compelled to read this book.

Cutting Downward in the Lathe—The captions for the two illustrations accompanying the discussion of downward cutting in the lathe, which appeared on page 518, were erroneously transposed. The upward and downward cutting actions were made clear by the illustrations, and therefore the transposition of the captions was no doubt obvious.

Metal Trades Branches

At the annual meeting of the Cincinnati branch of the National Metal Trades Association, held on Mar. 2, the following officers were elected for the ensuing year: August H. Tuechter, president; J. B. Doan, vice-president; John A. Le Blond, secretary; J. W. Manley, business secretary; William Emmes, treasurer. Murray Shipley, E. A. Muller and C. H. Fox constitute the executive committee.

The Cleveland branch, the annual meeting of which convened on the same date, elected the following officers: Christian Girl, president; Franklin Schneider, vice-president; J. D. Cox, Jr., treasurer. A. W. Foote, N. S. Calhoun, J. H. Francis and Henry Souther were elected the Board of Directors.

OBITUARY

Eugene E. Garvin, vice-president of the Garvin Machine Co., New York City, which was founded by his father, the late Hugh R. Garvin, died at his home in Englewood, N. J., Mar. 20. Mr. Garvin was born in Hartford, Conn., 58 years ago, and had been connected with the above concern during his entire business career, for the past twelve years as vice-president.

John Watson, proprietor of the plant of John Watson & Sons Co., Trenton, N. J., and a veteran machinist, died at his home in that city on March 15. Mr. Watson was 80 years old and had the distinction of building the first automobile in his section of the country. He was a prolific inventor, particularly in the field of pottery machinery. During the Civil War Mr. Watson was superintendent of the old Trenton Arms and Ordnance Works at which plant many guns were manufactured for the Union Army.

William H. Dayton, master mechanic of the Excelsior Needle Co., Torrington, Conn., died suddenly of heart failure on Mar. 6. Mr. Dayton was born in Torrington, then known as Wolcottville, Oct. 28, 1840, the son of Arvid Dayton, a builder of melodeons and organs, from whom no doubt he inherited his mechanical genius. He was first employed in his father's shop, but joined the newly organized Excelsior Needle Co. in 1866, remaining in its employ until his death. His many inventions concerned the machinery used in the product of the Excelsior Needle Co.—sewing-machine and knitting-machine needles, bicycle spokes, nipples and pedals. Mr. Dayton was also the inventor of the swaging machine which bears his name. Mr. Dayton is survived by a son, James M. Dayton, and three grandchildren.

PERSONALS

Clarence G. Arvidson has been promoted to the position of foreman of the experimental department of the Stenotype Co., Indianapolis, Ind.

Fred C. Meyer is now assistant superintendent of the Stenotype Co., Indianapolis, Ind., having recently been promoted to the position.

A. R. Murray has resigned from the designing department of the Cincinnati Shaper Co. to become general manager of R. A. Jones & Co., Covington, Ky.

Clifford N. Lockwood has become treasurer and general manager of the Vulcan Process Co., Minneapolis, Minn., succeeding L. E. Jordan, who has disposed of his interests in the firm.

Dewitt Tappan, for eleven years with the Watervliet Arsenal, has resigned from the position of planning-room foreman to enter the employ of the Veeder Manufacturing Co., Hartford, Conn., as assistant superintendent.

F. D. Walden, formerly of the Heald Machine Co., Worcester, Mass., has taken a position with the Davis Machine Tool Co., Rochester, N. Y., as manager in charge of operation. Peter Plantinga has been placed in charge of the mechanical engineering department.

George M. Basford, for several years assistant to the president of the American Locomotive Co., and more recently chief engineer of the railroad department of Joseph T. Ryerson & Son, has been elected president of the recently organized Locomotive Feed Water Heater Co., 30 Church St., New York City.

INQUIRY FOR MACHINERY

Machine wanted for branching artificial flowers used for decorative purposes. Address, Information Department, "American Machinist."

TRADE CATALOGS

Cowan Truck Co., Holyoke, Mass. Catalog. Transveyors. Illustrated, 8x10½ in.

C. F. Roper & Co., Hopedale, Mass. Circular. Gear circulating pumps. Illustrated.

Charles Eisler, 43 Dodd St., Bloomfield, N. J., Circular A. Turret heads for bench and engine lathes. Illustrated.

Spray Engineering Co., 93 Federal St., Boston, Mass. Bulletin No. 210. Coating Explosive Shells. Illustrated, 12 pp., 6x9 in.

The Greaves-Klusman Tool Co., Cincinnati, Ohio. Pamphlet. "G-K Betterments." Engine lathes. Illustrated, 20 pp., 8½x11 in.

Bay State Saw and Tool Mfg. Co., 30 Whittier St., Boston, Mass. Catalog. "Tiger" hack saw blades. Illustrated, 8 pp., 3½x6 in.

The Chisholm-Moore Mfg. Co., Cleveland, Ohio. Catalog No. 24. Third Edition. Cyclone chain hoists. Illustrated, 96 pp., 6x9 in.

Rome Brass and Copper Co., Rome, N. Y. Loose Leaf Catalog. Brass and copper sheet, rods, tubes, wire, etc. Illustrated, 5x7 in.

The Curtis & Curtis Co., 66 Garden St., Bridgeport, Conn. Catalog No. 14. Pipe cutting and threading machinery. Illustrated, 32 pp., 7½x10 in. Circular. Automatic cutting-off machine for pipe, shrapnel, etc. Illustrated.

U. T. Hungerford Brass and Copper Co., Hungerford Building, New York. Catalog. Brass, copper, bronze, yellow metal, in sheets, tubes, wire rods, rolls, etc., extruded metals, brass fittings, hardware, roofing materials, etc. Illustrated, 404 pp., 6x9 in.

FORTHCOMING MEETINGS

American Society of Mechanical Engineers. Spring meeting, April 11-14, New Orleans, La., Calvin W. Rice, secretary, 29 West 39th St., New York, N. Y.

National Metal Trades Association. Annual meeting, Apr. 27-28, New York, N. Y., Hotel Astor. H. D. Sayre, secretary, Peoples Gas Building, Chicago, Ill.

American Society for Testing Materials. Annual meeting June 27 to July 1, 1916, Hotel Traymore, Atlantic City, N. J. Edgar Warburg, secretary, University of Pennsylvania, Philadelphia, Penn.

American Society of Mechanical Engineers. Monthly meeting first Tuesday. Calvin W. Rice, secretary, 29 West Thirty-ninth St., New York City.

Boston Branch National Metal Trades Association. Monthly meeting on first Wednesday of each month, Young's Hotel. W. W. Poole, secretary, 40 Central St., Boston, Mass.

Providence Association of Mechanical Engineers. Monthly meeting fourth Wednesday each month. J. A. Brooks, secretary, Brown University, Providence, R. I.

New England Foundrymen's Association. Regular meeting second Wednesday of each month. Exchange Club, Boston, Mass. Fred F. Stockwell, 205 Broadway, Cambridgeport, Mass.

Engineers' Society of Western Pennsylvania. Monthly meeting third Tuesday; section meeting, first Tuesday. Elmer K. Hiles, secretary, Oliver Building, Pittsburgh, Penn.

Rochester Society of Technical Draftsmen. Monthly meeting, last Thursday. O. L. Angevine, Jr., secretary, 857 Genesee St., Rochester, N. Y.

Superintendents' and Foremen's Club of Cleveland. Monthly meeting third Saturday. Philip Frankel, secretary, 310 New England Building, Cleveland, Ohio.

Western Society of Engineers, Chicago, Ill. Regular meeting first Wednesday evening of each month, excepting July and August. J. H. Warder, secretary, 1735 Monadnock Block, Chicago, Ill.

Philadelphia Foundrymen's Association. Meetings first Wednesday of each month. Manufacturers' Club, Philadelphia, Penn. Howard Evans, secretary, Pier 45 North, Philadelphia, Penn.

Technical League of America. Regular meeting second Friday of each month. Oscar S. Teale, secretary, 35 Broadway, New York, N. Y.

Prices--Materials and Supplies

IRON AND STEEL

Pig Iron—Quotations were current as follows at the points indicated:

	Mar. 24, 1916	One Month Ago	One Year Ago
No. 2 Southern foundry, Birmingham	$15.00	$15.00	$9.25

R. J. Cunningham will establish a 2-story factory on West 77th St., Cleveland, Ohio, for the manufacture of automobile bodies, etc.

The contract has been awarded for the construction of a 1-story factory at 2698 East 79th St., Cleveland, Ohio, for the Electric Controller and Manufacturing Co. Estimated cost, $30,000.

The Ford-Clark Co. has purchased the plant of the Aetna Rubber Co. at 3125 Perkins Ave., Cleveland, Ohio, and will enlarge and equip it for the manufacture of automobile accessories.

The contract has been awarded for the construction of a 1-story, 80x116-ft. addition to the plant of the J. Roamer Heating Co., 735 St. Clair Ave., Cleveland, Ohio.

John Kellar, care of the Chamber of Commerce, Columbus, Ohio, plans to construct a plant for the manufacture of mechanical tools.

The City Machine and Tool Works has purchased a site at East 3d and June St., Dayton ,Ohio, and plans to build a factory. Estimated cost, $30,000.

The Marting Iron and Steel Co. has purchased a site on South 3d St., Ironton, Ohio, and plans to build a factory.

Plans are being prepared by William Loomis, Arch., 501 Canal St., Logan, Ohio, for the construction of a 2-story garage at Logan for the Main Motor Car Co. Estimated cost, $10,000.

Bids will soon be received for the construction of a garage at Miamisburg, Ohio, for D. A. Stump. Estimated cost, $15,000.

The W. H. Huber Co. plans to build a 40x80-ft. aluminum foundry at New Berlin, Ohio.

The Binnell Automobile Co. has taken over the plant of the Binnel Buggy Co. at Sidney, Ohio, and will improve it for the manufacture of automobiles.

Bids will soon be received for the construction of a garage on Market St., Warren, Ohio, for James A. Gargill, 7 Electric Bldg., Warren. Estimated cost, $10,000.

The contract has been awarded for the construction of an addition to the plant of the National Malleable Casting Co., 546 Holmes Ave., Indianapolis, Ind. Estimated cost, $20,000. Noted Mar. 16.

Plans are being prepared by George W. Graves, Arch., for the construction of a 2-story,60x300-ft. factory on Kercheval Ave., Detroit, Mich., for the Bour-Davis Motor Car Co. Estimated cost, $150,000. C. J. Bour is Pres. Noted Mar. 9.

The contract has been awarded for the construction of a 2-story, 96x204-ft. factory at Detroit, Mich., for the Briggs Manufacturing Co., manufacturer of auto trimmings. Estimated cost, $75,000.

The Grand Rapids Salvage Co. has leased a building at Grand Rapids, Mich., and will remodel it for a machine shop and for the manufacture of baling machines.

The Metal Office Furniture Co. has awarded the contract for the construction of a 96x125-ft. addition to its plant at Grand Rapids, Mich. Estimated cost, $10,000.

Plans are being prepared for the construction of a 2-story, 55x100-ft. factory at Scribner Ave. and Blumrich St., Grand Rapids, Mich., for the Glendon A. Richards Co., manufacturer of sheet metal and roofing.

The Ford Motor Co., Detroit, Mich., has awarded the contract for the construction of an addition to its plant at Highland Park, Mich. Estimated cost, $800,000. Noted Mar. 9.

We have been advised that the contract has been awarded for the construction of a foundry at Lansing, Mich., for the Novo Engine Co. Noted Mar. 9.

F. B. Hart will build a garage at Union City, Mich.

S. M. Hastings, 336 West Madison St., Chicago, Ill., has awarded the contract for the construction of a 1-story garage at 4069 Broadway, Chicago. Estimated cost, $13,000.

The contract has been awarded for the construction of a forge and axle plant at 21st St. and Brady Ave., East St. Louis, Ill., for the Bytanic Metal Co.

The Cadillac Co. has awarded the contract for the construction of a 2-story, 100x150-ft. garage, sales and service station on Main St., Peoria, Ill. Estimated cost, $35,000.

The contract has been awarded for the construction of a factory at Springfield, Ill., for the Sangamo Electric Co., manufacturer of electric meters. Estimated cost, $100,000. Noted Mar. 23.

Work will soon be started on the construction of an addition to the plant of the Gardner Machine Co. at Beloit, Wis. The company is in the market for engine, boilers and electric generator. Estimated cost, $35,000. L. Waldo Thompson is Secy. Noted Mar. 16.

The Obenberger Drop Forge Co. is constructing a 1-story, 75x75-ft. forge shop on Packard Ave., Cudahy, Wis.

Plans are being prepared for the construction of a factory at Janesville, Wis., for the Janesville Tractor and Engine Co. Estimated cost, $12,000.

The Peter Pirsch & Co., manufacturer of fire apparatus, plans to construct an addition to its plant on Market St., Kenosha, Wis.

Plans are being prepared for the construction of a 1-story, 75x200-ft. addition to the plant of the Kohler Co., manufacturer of enameled plumbing ware, at Kohler, Wis. Noted Mar. 23.

The Chalmers Motor Co., Jefferson St. and New Belt Line, Detroit, Mich., plans to construct a 4-story, 60x400-ft. plant with a 40x60-ft. wing at La Crosse, Wis. Estimated cost, $150,000.

The Pawling & Harnishchfeger Co., manufacturer of cranes and hoists, has awarded the contract for the construction of a 2-story addition to its pattern shop at Milwaukee, Wis. Noted Mar. 23.

We have been advised that work will soon be started on the construction of a 2-story, 140x200-ft. plant for the Wisconsin Iron and Wire Works, 186 East Water St., Milwaukee, Wis. Estimated cost, $20,000. George H. Norris is Pres. Noted Mar. 16.

We have been advised that work will soon be started on the construction of a 3-story, 83x150-ft. addition to the plant of the Automatic Cradle Manufacturing Co. at Stevens Point, Wis. The company is in the market for a full line of woodworking machinery and 2 elevators. Estimated cost, $35,000. Noted Mar. 16.

WEST OF THE MISSISSIPPI

Plans are being prepared by C. B. Zalesky, Arch., 601 Security Bank Bldg., Cedar Rapids, for 2 garages at Cedar Rapids, Iowa. Estimated cost, $88,000 and $16,000.

Thorstenson Bros., Plentywood, Mont., plan to construct a commercial garage and repair shop at Plentywood.

The Mississippi Valley Iron Co., recently incorporated with $5,000,000 capital stock, will construct a plant at Carondelet, Mo. Estimated cost, $500,000.

The Bichler Manufacturing Co., St. Louis, Mo., recently incorporated with capital stock of $17,000, will equip a machine shop at St. Louis. Nicholas Bichler and Frederick Shamrod, St. Louis, are interested.

The contract has been awarded for the construction of a garage at St. Louis, Mo., for the Easton Taylor Trust Co., 4474 Eastern Ave., St. Louis. Estimated cost, $75,000.

The plant of the Kraushaar Brass Manufacturing Co., St. Louis, Mo., recently destroyed by fire will be rebuilt and new equipment installed.

The Platifrice Chemical Co,. St. Louis, Mo., recently incorporated with $25,000 capital stock, plans to equip a plant for the manufacture of dentral machinery and fixtures. Wesley A. Chamberlain is interested.

The St. Louis Frog and Switch Co., St. Louis, Mo., is building a manganese foundry. Estimated cost, $30,000.

The National Enameling and Stamping Co., St. Louis, Mo., will construct a steel plant. Estimated cost, $200,000.

We have been informed that the Wagner Electric Manufacturing Co., St. Louis, Mo., is building 2 new additions to its plant on Plymouth Ave. W. A. Layman is Pres. Noted Feb. 3.

Roy Haskett and Guy Mace plan to construct a 50x200-ft. garage on St. Louis St., Springfield, Mo.

The Texas Motor Co., Texarkana, Ark., recently incorporated, will establish a garage and machine shop. J. K. Waddy and B. W. Anthony are interested.

The K. A. Auto Supply Co., San Angelo, Tex., has awarded the contract for the construction of a 1-story, 50x150-ft. garage. Estimated cost, $13,500.

The contract has been awarded for the construction of a garage at Oklahoma, Okla., for the Paige Motor Co. Estimated cost, $10,000.

The Willys-Knight Overland Co., Toledo, Ohio, plans to establish a distributing plant at Denver, Colo.

WESTERN STATES

The Gerlinger Motor Car Co. plans to construct an assembling plant at Centralia, Wash.

R. Becker, Portland, Ore., will construct a 2-story, 50x60-ft. garage at Corbett, Ore.

The Electric Foundry Co. will rebuild its plant at Portland, Ore., which was recently destroyed by fire.

Plans have been prepared by A. C. Meyer for the construction of a 50x105-ft. garage at Derby and McClellan St., Portland, Ore.

The contract has been awarded for the construction of a 1-story, 100x175-ft. garage at Colorado St. and El Molino Ave., Pasadena, Calif., for C. Y. Knight. Estimated cost, $17,780.

The contract has been awarded for the construction of a 1-story, 100x175-ft. garage, salesroom and service station at Pasadena, Calif., for the Willys-Overland Co., Toledo, Ohio. Estimated cost, $17,580. Noted Mar. 2.

Plans are being prepared for the construction of an electrical repair plant on 8th St., San Diego, Calif., for the Auto Electrical Equipment Co., National City.

H. M. Mickish plans to construct a garage and machine shop at 2d and C St., San Diego, Calif. Estimated cost, $10,000.

The Hecht Investment Co. has awarded the contract for the construction of a garage on Post St, San Francisco, Calif. Estimated cost, $30,000.

W. T. Steele and O. F. Brigham plans to build a garage and machine shop at Saticoy, Calif.

CANADA

The Joliette Steel Co., Ltd., is constructing an addition to its plant at Joliette, Que., and will be in the market for machinery.

Fire recently damaged the plant of the Canadian Metal Manufacturing Co., Ltd., St. James and Richmond St., Montreal, Que. Loss, $15,000.

Joseph Gertler, 676 Drolet St., Montreal, Que., plans to construct an addition to its foundry at Montreal.

The Regal Motor Co. plans to construct a factory at Berlin, Ont.

The London Foundry Co., Ltd., will construct an addition to its plant at London, Ont. Estimated cost, $10,000. E. Grobb is Mgr.

Plans are being prepared for the construction of an addition to the plant of the Crow Auto Co., Mt. Brydges, Ont. New machinery will be installed. Estimated cost, $25,000.

Fire recently damaged the foundry of the Ottawa Steel and Iron Works, 137 Broad St., Ottawa, Ont. Loss, $3,500.

Fire, Mar. 14, destroyed the plant of the Renfrew Machinery Co. at Renfrew, Ont. Loss, $100,000.

The contract has been awarded for the construction of an addition to the plant of the Sheet Metal Products Co. of Canada, Ltd., at 199 River St., Toronto, Ont. Estimated cost, $20,000. Noted Mar. 9.

GENERAL MANUFACTURING

NEW ENGLAND STATES

The Willard H. Griffen Shoe Co. has awarded the contract for the construction of a 4-story, 45x150-ft. factory at Manchester, N. H. Estimated cost, $35,000. Noted Mar. 2.

The Harris, Emery Co. operating the Dustin Island Woolen Mills plans to build a weave shed at Penacook, N. H.

The contract has been awarded for the construction of a factory at Portsmouth, N. H., for the Morely Button Manufacturing Co. Noted Mar. 23.

The Foster Spinning Co. has awarded the contract for the construction of a mill at Fall River, Mass. Francis A. Foster, Boston, is interested.

Fire, Mar. 15 destroyed the factory at Fall River, Mass., of Smoss Bros., manufacturer of rope. Loss, $30,000.

The contract has been awarded for the construction of an addition to the factory of the Momomet Mills Co. at New Bedford, Mass. Estimated cost, $575,000. Noted Mar. 16.

The Otter River Yarn Co. has purchased the plant of the Turner Mills at Otter River, Mass., and will equip it for the manufacture of yarn.

The Ideal Coated Paper Co., Brookfield, Mass., plans to construct a 1-story, 100x300-ft. factory at Ware. Estimated cost, $50,000.

The Warren Cotton Mills has awarded the contract for the construction of a 2-story, 26x125-ft. dye house at Warren, Mass. Estimated cost, $20,000.

MIDDLE ATLANTIC STATES

Plans have been prepared for an addition to the plant of the Schoellkopf Aniline and Chemical Works, Inc., Abbott Rd., Buffalo, N. Y. Estimated cost, $16,000.

The Du Pont Fabrikoid Co., Wilmington, Del., plans to construct an addition to its plant at Newburgh, N. Y.

The American Sugar Refining Co., New York, N. Y. (Borough of Brooklyn), plans to construct an addition in connection with the Havemeyer Plant on Kent Ave. Estimated cost, $1,000,000.

Plans are being prepared by Benjamin Driesler, Arch., 153 Remsen St., New York, N. Y. (Borough of Brooklyn), for 1-story, 75x140-ft. building on Ditmas Ave. for William Beckers Aniline and Chemical Co., Brooklyn. Estimated cost, $12,000.

The contract has been awarded for the construction of a factory for the National Sugar Refining Co., Dock St., New York, N. Y. (Borough of Queens).

The contract has been awarded for the construction of several additions to the plant of the Butterworth-Judson Co., Ave. R, Newark, N. J., manufacturer of chemicals. Noted Jan. 6.

The Seton Leather Co., Newark, N. J., will construct 2 additions to its plant on Verona Ave. Estimated cost, $25,-000.

L. H. Gilmer Co., Philadelphia, Penn., will build a 3-story belting factory. Harry C. Eisenbise is Engr.

The Mifflin Chemical Co., Philadelphia, Penn., will build five 2-story buildings.

The C. C. Young Dye Works, 324 Federal St., N. S., Pittsburgh, Penn., has awarded the contract for constructing an addition to its plant. Estimated cost, $6,000.

Plans are being prepared for a 3-story plant for Wilson Chemical Co., Tyrone, Penn. George C. Wilson is Pres.

E. Sutro & Son Co., Elkton, Md., plans to build additions to its plant or install new machinery for the manufacture of hosiery.

SOUTHERN STATES

The Maxwell Hosiery Mills, Suffolk, Va., plans to enlarge its plant.

Plans have been prepared for a plant at Benwod, W. Va., for the Gasoline-Oil Supply Co.

Liledoun Manufacturing Co., Taylorsville, N. C., manufacturer of knitting yarns, will enlarge its plant. J. A. Miller, Jr., is Pres.

The Southern Aseptic Fiber Co., Columbia, S. C., recently incorporated with $50,000 capital stock, will construct three 2-story factory buildings for the manufacture of absorbent cotton, etc.

The Clark Pratt Cotton Mills, recently incorporated with a capital stock of $100,000 will make extensive improvements to its plant at Prattville, Ala.

J. M. Hays & Co., Memphis, Tenn., will organize a company to construct a cotton compress and warehouse. Estimated cost, $250,000.

MIDDLE WEST

The McGraw Tire and Rubber Co. plans to construct additions to its plant at East Palestine, Ohio.

The contract has been awarded for the construction of a factory at Niles, Ohio, for the Grasselli Chemical Co., Arcade Bldg., Cleveland, Ohio. Noted Feb. 10.

The Standard Oilcloth Co. has increased its capital stock from $7,000,000 to $9,000,000, and plans to enlarge its plant at Youngstown, Ohio.

Ernest G. Reece is forming a company to build a canning plant at Waldron, Ind.

The Holland Canning Co. will build an addition to its plant at Grand Rapids, Mich.

The National Photo Paper Co., recently incorporated, plans to construct a factory at Grand Rapids, Mich., in the spring.

The Edwards & Chamberlin Hardware Co. plans to construct an addition to its plant on East Main St., Kalamazoo, Mich. A. K. Edwards is Pres. and Gen. Mgr.

The Carrom-Archarena Co., manufacturer of games, etc., plans to build a factory at Ludington, Mich.

Plans are being prepared for the construction of an addition to the plant of the Manistee Manufacturing Co., manufacturer of furniture, at Manistee, Mich. Noted Mar. 16.

The Wolverine Paper Co. has awarded the contract for the construction of an addition to its plant at Otsego, Mich.

The contract has been awarded for the construction of a 4-story factory at 3522 Iron St., Chicago, Ill., for the Central Bag Manufacturing Co. Estimated cost, $125,000. Noted Dec. 23.

WEST OF THE MISSISSIPPI

The Lake City Button Co., Lake City, Minn., plans to enlarge its plant.

Press reports state that the Heil Packing Co., St. Louis, Mo., plans to construct an addition to its plant. Estimated cost, $40,000.

The Independent Tire Co., St. Louis, Mo., plans to equip a plant for the manufacture of tires and tubes for automobiles. William Chorlis, 3150 Locust St., St. Louis, Mo., is interested.

The Linde Air Products Co., 30 East 42d St., New York, N. Y., has awarded the contract for the construction of a plant at Harwood and Gould St., Dallas, Tex. Estimated cost, $30,000.

Taylor Bros., Denton, Tex., plan to construct a cotton gin. Estimated cost, $10,000.

Edgar Van Slyke and associates, Gainesville, Tex., plan to construct a woolen mill at Gainesville.

Press reports state that the W. E. Smith Manufacturing Co., manufacturer of waterproof roofing, etc., Cleveland, Ohio, plans to construct a branch plant at San Antonio, Tex.

The Sealy Oil Mill and Manufacturing Co., Sealy, Tex., has increased its capital stock from $40,000 to $50,000 and will improve its cotton-seed oil mill.

The Mohawk Refining Co., Oklahoma, Okla., plans to rebuild its oil refinery at Ringling, Okla.

The J. S. Cosden Co., Tulsa, Okla., plans to construct an addition to its oil refinery.

The National Plaster Co., Dayton, N. M., plans to enlarge its plant and also install new machinery.

WESTERN STATES

The Boise Valley Packing Co. plans to construct an addition to its plant at Tagle, Idaho.

The Amalgamated Sugar Co. plans to enlarge its plant at Ogden, Utah. Estimated cost, $150,000. J. F. Ellis is Supt.

The Ogden Packing and Provision Co. plans an expenditure of $300,000 for improving its packing plant on 24th St., Ogden, Utah.

J. A. Gumm and associates plan to construct a canning plant at Benson, Ariz.

The National Infusorial Earth Co., Ellensburg, Wash., is in the market for crushing and drying machinery.

The Ferndale Canning Co. plans to construct a plant at Ferndale, Wash.

The Pacific Sea Food Co., La Conner, Wash., will rebuild its cannery recently destroyed by fire with a loss of $15,000.

The Walla Walla Pickling Works contemplates enlarging its canning plant at Walla Walla, Wash.

A. F. Adams and W. A. Schaffner is constructing a 1-story, 26x60-ft. fruit processing factory at Hood River, Ore.

The Lakeview Oil Co., No. 2 Maricopa, Calif., plans to construct a treating plant on South Midway property.

CANADA

Work will soon be started on the construction of a plant at Drummondville, Que., for the Aetna Chemical Co. of Canada, Ltd. Estimated cost, $300,000.

Work will soon be started on the construction of an addition to the plant of the McLagan Furniture Manufacturing Co., Ltd., 93 Trinity St., Stratford, Ont. Noted Mar. 16.

The Jeffries Furniture Co. will rebuild its plant at Welland, Ont., which was recently destroyed by fire with a loss of $4,800.

The Union Carbide Co., Ltd., will build an addition to its drum shop at Welland, Ont. Estimated cost, $20,000.

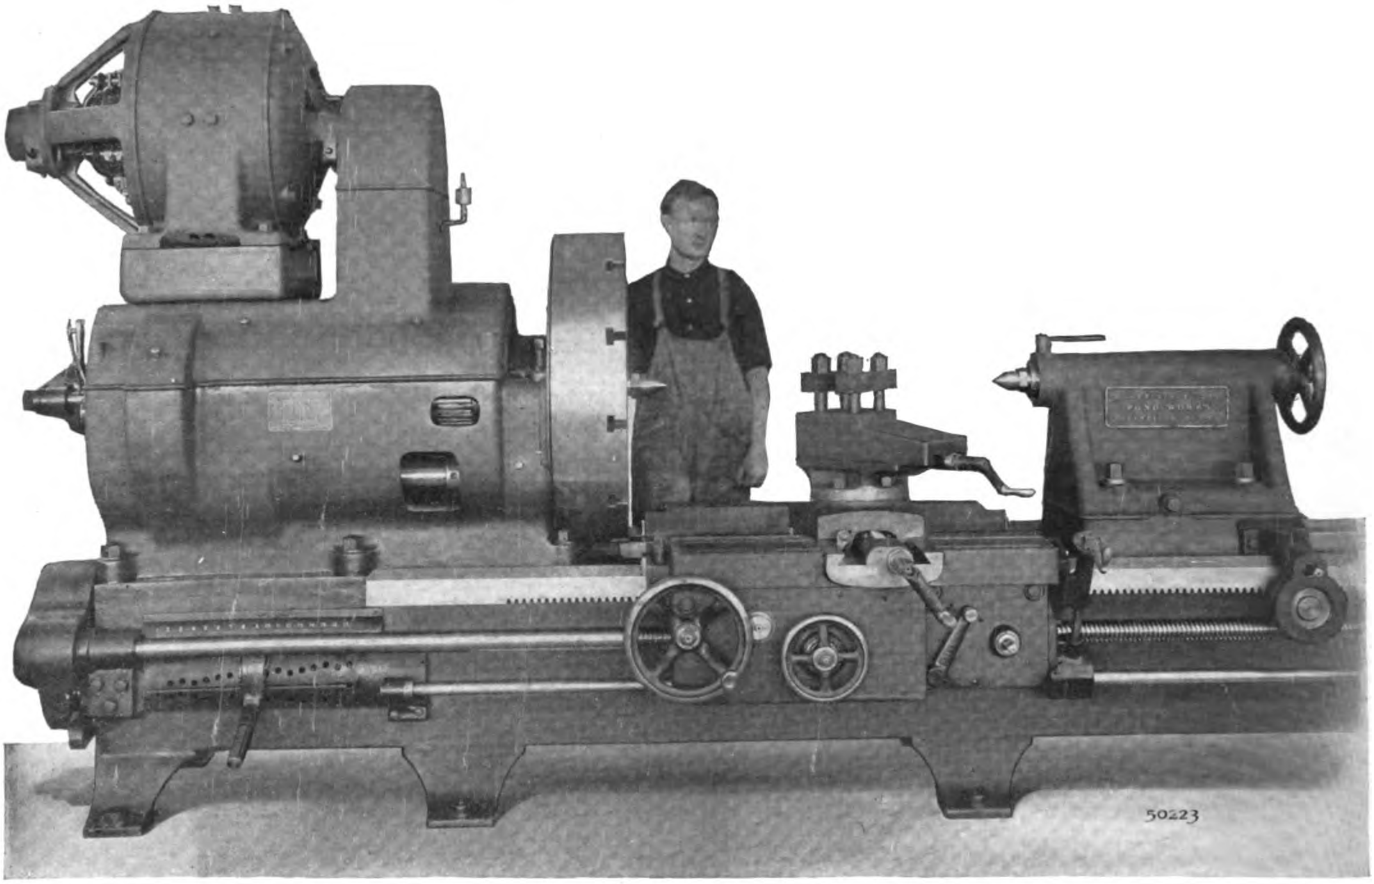
For Short Delivery

We Offer a Number of Our Standard



36-In. Heavy Lathes

Especially Well Adapted for Heavy Shells

Driven by 15-hp. Variable Speed Motor. Equipped With Quick Change Feed Gears. Bed Length to Suit Requirements.

The back gears and triple gears are conveniently located at the front, and for heavy cutting give a powerful *positive* drive through sliding gears. No friction clutches are employed.

Pond Lathes possess all features required for efficient maximum output, without sacrificing simplicity of design. The weight is ample and carefully distributed, as our long experience has taught to be essential. The spindle bearings are large and bronze lined. The carriage has an exceptionally large bearing on the bed.

Have you one of our catalogs, "Heavy Lathes?" If not, drop us a line

By simply tightening up the small hand-wheel in the proper direction, the cross or longitudinal feeds are thrown in and only one can be in operation at a time. The feeds can be reversed at the carriage. The feed and screw-cutting mechanisms are interlocking so that both cannot be engaged at the same time.

On motor-driven lathes the speed may be varied through a wide range by the handle on the right side of the carriage. Thus the operator does not have to leave his work and is more apt to use the proper speed for his job.

As the tool does not overhang the bed the full driving power can be used in turning work of the maximum swing.

Specifications, Delivery, Prices, Etc., Furnished Promptly on Request.

Under-Advertising of the Steel Business

By George H. Jones,
Vice-President and General Manager of Sales, Inland Steel Company, Chicago

ENGLAND has raised the greater part of an army of four millions by advertising, using newspapers, bill-boards, omnibuses and other methods. This was considered the most effective way and its application is almost universal.

This is an object lesson to the iron and steel manufacturers who have been in the habit of saying about advertising, "When the demand for our products is good there is no need for it, and when the demand is poor there is no use of it."

The steel manufacturers can pave the way to make depressions less severe by stimulating a demand for the products of the steel mills. The way many of us advertise is to place what amounts to a business card in a trade paper and let it go at that. It will do once in a while to call attention to a full list of our products, but it possesses little sales value. We want our advertisements to be read. We must, therefore, give truthful information of value to a prospective customer, and whenever possible the matter should be well illustrated. One product only should be treated in one advertisement. Sizes, quality, capacity and other special advantages we have to offer should be stated and enlarged upon. We should answer the readers' questions before they are asked.

About six years ago five men in the south each put up $260 into a fund to advertise red gum in an architectural journal, after dint of much hard work on the part of a representative of that journal.

Though they were men of wealth, this $260 came hard because they really did not believe that anything would come of it.

But the result of that $1.300 venture was the sale of red gum aggregating $350,000 with three successive $2. jumps in price per 1,000 feet in a single year. This campaign has continued year after year, as high as $40,000 a year being spent in it. The result is the widespread use of red gum wood for fancy interior finish—a wood that had previously been in the railroad tie class.

This campaign started the Southern Cypress Association into action, and their annual advertising expenditure far exceeds that of the Red Gum Association.

Let us acknowledge that, as a class, the steel industries of the country are the most clumsily and inadequately advertised of all our industries.

I almost feel safe in saying that more advertising money has been spent in *tooth paste* than all of us combined have expended in all of our products.

And our total expenditure would look like small change beside the bank roll expended annually by the chewing - gum profession, the soap artists or the baking powder family.

Yet steel products as a group are just as susceptible to the power of publicity as any of these; because just as universal in consumption and vastly more important to the public welfare.

Extracted from an Address before the American Iron and Steel Institute.

Motorcycle Frame and Tube Work

By Ethan Viall

SYNOPSIS—Many of the bending, pinning, brazing and other fixtures used in the construction of a well-known model of motorcycle frame are here shown. The bending fixtures are hand-operated, but so constructed as to produce commercially accurate work as speedily as the operator can handle it. Attention is called to the taper-pin clamping method frequently employed.

The frame of a modern motorcycle is a rather complicated assemblage of specially shaped or bent tubing so designed and joined as to hold up under the weight it is to carry and to stand the shocks and vibration of service. Though the general outlines of the various makes are nearly the same, each maker has his own particular and distinctive type of frame construction. Naturally, the size and shape of a motorcycle frame are largely governed by the kind of motor used. The Henderson Motorcycle Co., Detroit, Mich., uses a 12-hp. four-cylinder motor in its machines. These machines have a 58-in. wheelbase and weigh close to 300 lb., so that especial care and skill must be employed in the design and construction of a frame that will give satisfactory service.

A Henderson motorcycle practically completed is shown on an assembling stand in Fig. 1. This view will give the reader a good idea of the position of the motor, the shape of the frame and other details needed to follow the mechanical descriptions of this article. Incidentally, attention is called to the assembling stands, one of which appears more in detail in Fig. 2. A small bench is set under the machine between the standards. It holds all the parts that go to make up a motorcycle. Along the sides of the bench are pockets for holding the various bolts, nuts, screws and other small parts. These benches are filled from stock for each machine and save the assemblers considerable time.

No attempt will be made to show other than the principal operations in the making of a frame, and for several reasons they will not be given in the order of shop procedure. The first fixture illustrated is in Fig. 3 and is the one used to hold the frame while brazing the various joints. The type of gas torch employed is shown at *A*. It will be readily seen that the construction of the frame does not lend itself to the dip-brazing process. A few of the frame parts are brazed on before being placed in the frame assembly, but the main joints are brazed here.

The two lower tubes of the frame rest in pillow blocks formed to receive and hold them correctly. The clamping blocks are locked down by taper pins *B* and *C*, which

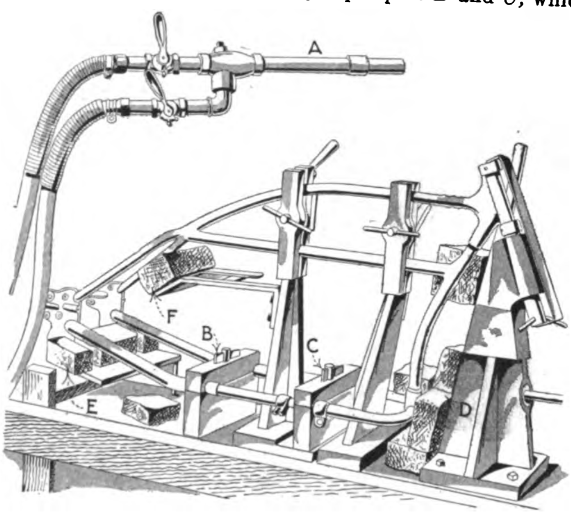

FIG. 3. FRAME-BRAZING FIXTURE

are run through slots in the holding pins. Vertical standards hold the upper tubes of the frame and head. Firebrick are placed on special holding brackets at *D*, *E* and *F*, to back up the flame in heating the parts. Another view of this same fixture may be seen in Fig. 5. For some of the upper joints firebrick are placed at *G* on a stand *H*, which can be moved back out of the way when inserting or removing a frame from the fixture or when brazing other joints. The heavy pin used to line up and hold the head is shown at *I*. The clamping

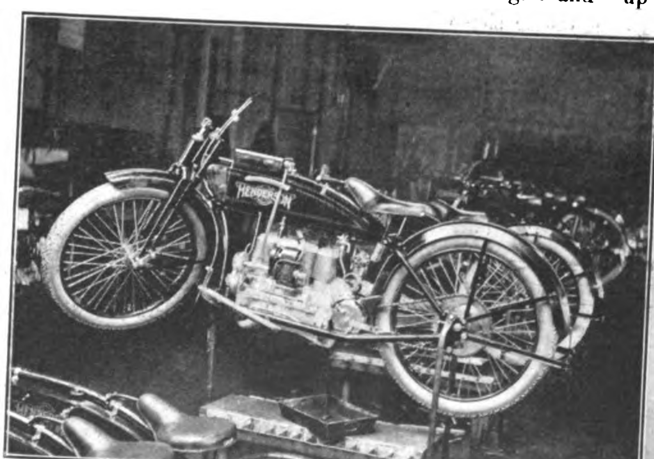

FIG. 1. MOTORCYCLE ON ASSEMBLING STAND

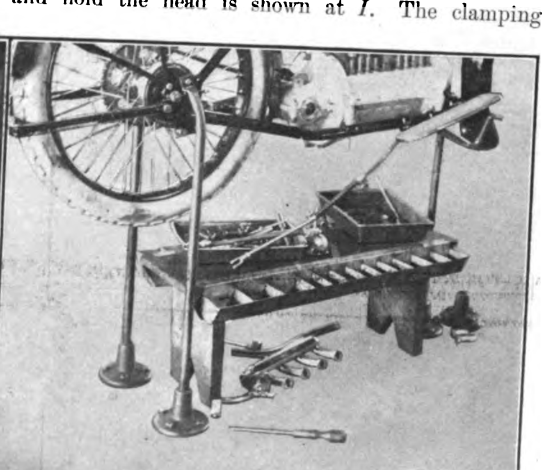

FIG. 2. ASSEMBLING STAND AND PARTS HOLDER

blocks J have convenient handles K. When in place they are locked by slotted pins that go through holes in the uprights, into which taper pins such as L are thrust and tapped in with a hammer.

After a frame has been brazed and filed, some of the small holes are drilled. The frame is held on pillow block similar to those in the brazing fixture, Fig. 4. The same method of clamping down by taper pins is employed also, as indicated at A. A drill jig or templet for the saddle bracket holes is shown clamped to the frame at B. Pins set into the templet give the correct position on the frame fork and upper tube. The holes are drilled with the air drill C.

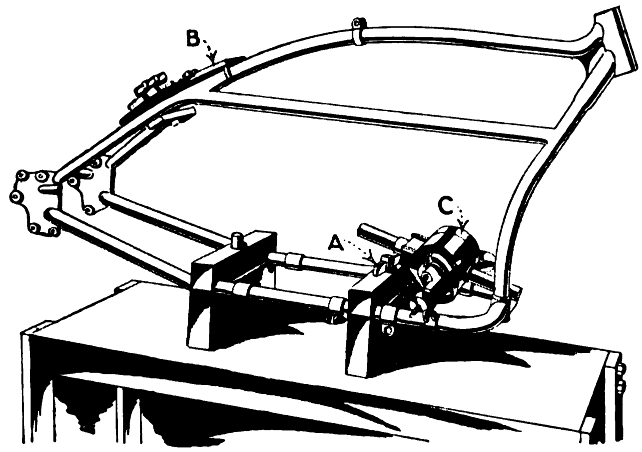

FIG. 4. HOLDING FIXTURE FOR SMALL DRILLING

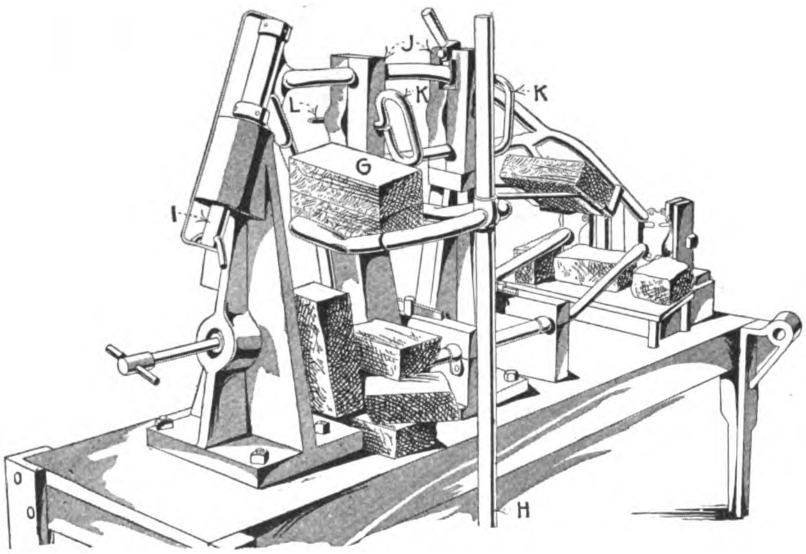

FIG. 5. ANOTHER VIEW OF BRAZING FIXTURE

Most of the bending on the main frame tubes is done with the device illustrated in Fig. 6. This consists of several lever-operated sets of forming jaws carried on a vertical plate. This plate is mounted on a heavy base fitted with small truck wheels, so as to be easily moved to advantageous positions near the heating furnaces or run out of the way when not in use. One of the side tubes for the lower frame fork is shown in the jaws at A. The heated tube is thrust in between the jaws against a stop, and a firm downward pressure on the lever quickly gives the desired bend. After the main bend is made, a slight side bend is given the tube. This is done by holding down on the lever, taking the outer end of the tube and forcing it over by hand, using the gage C to indicate the amount of the bend. As these fork sides are made right and left, the gage has two wings on it so as to be available for either side.

Previous to the bending, these side tubes have some of the brackets and joints braced on them, which is done in a special holding fixture. One of the tubes with the brackets braced in place is shown at D. Another set of forming jaws is seen at E. On the opposite side of the plate are two more forming-jaw sets, as in Fig. 7.

Where the bending angle of a tube is not great, no filling is needed; but where the bend is as sharp as that shown on the end of the fork side, the tube is filled with sand previous to heating. This bend is made in the fixture illustrated in Fig. 8. The tube is heated about where the bend is to be and is then thrust down so that the end rests on the stop A. The clamp is next tightened by turning the screw B. The tube is then pulled over into the forming groove by hand. There is naturally a little spring in the tube, so that it will not fit down snugly into the channel by merely pulling on the outer end. This difficulty is remedied by placing a swage a few inches back of the bend and driving down with a hammer until the tube rests in the channel, as shown. Two of the tubes in the front forks are flattened on the lower ends and these ends given a rather sharp bend. The first flattening of the ends is done in the die in Fig. 9. One of the tubes with the

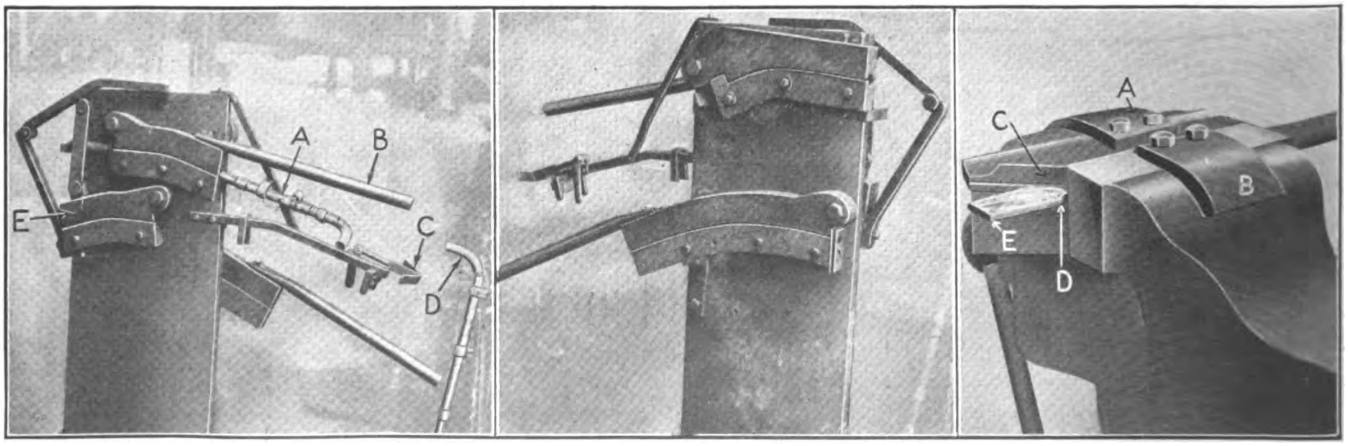

FIG. 6. TUBE-BENDING DEVICE FIG. 7. OPPOSITE VIEW OF BENDER FIG. 10. BENDING DIE IN VISE

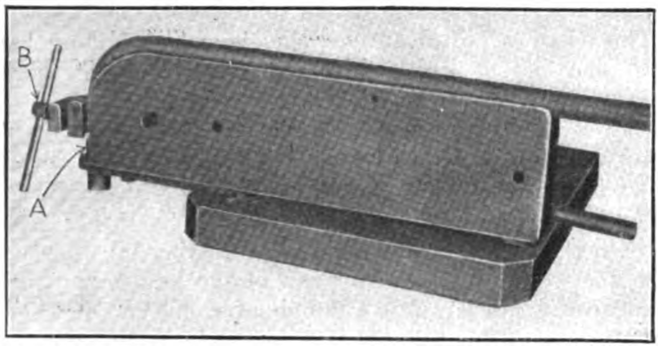

FIG. 8. ANOTHER TUBE BENDER

end flattened is shown at *A*. Before a tube is placed in the die, the mandrel *B* is thrust into it and the cross-handle butted against a forked stop. The use of this mandrel prevents the tubing being crushed or flattened back of the desired point and gives a nicely rounded shoulder. One of the tubes with a flattened and bent end may be seen at *C*. This bend is obtained in the device shown in Fig. 10.

It consists of two formed jaws set into an ordinary vise. Hooked straps *A* and *B* bolted to the jaws hold

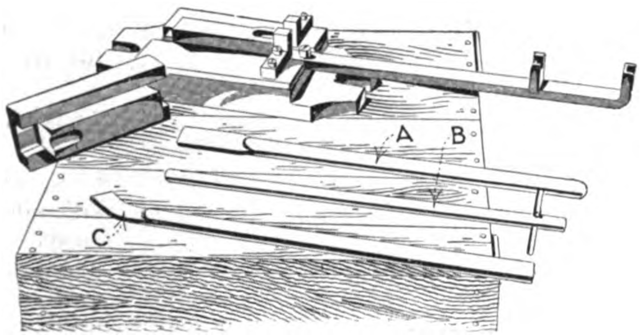

FIG. 9. FLATTENING DIES AND MANDREL

them to the vise jaws. The parts of the false jaws that close in on each other are grooved to receive the round part of the tube. The outer end of the jaw *C* is beveled to the angle of the bend and grooved to receive the flattened part of the tube. The flat part is notched in at *D* with a round file and then heated. It is then placed in these jaws and the end *E* pounded into the groove with a hammer. Afterward the uneven edge on the notched side is trimmed off in a heavy-duty shear.

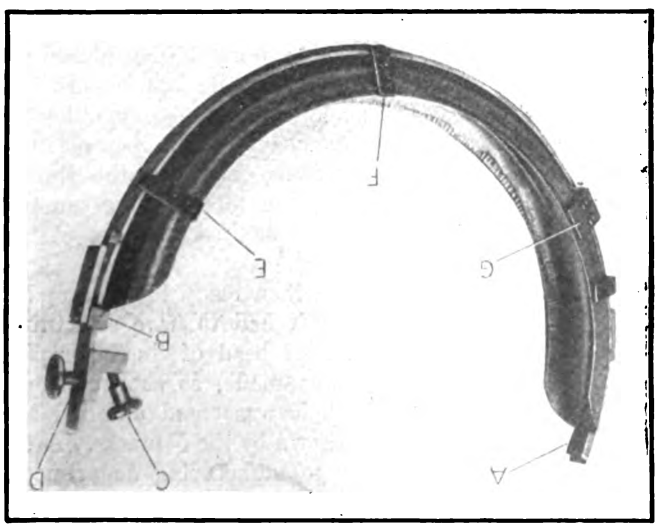

FIG. 11. REAR-GUARD DRILLING JIG

After being shaped, rear mud guards are drilled for the attaching rivets, in the jig shown in Fig. 11. The end of the guard to be drilled is butted up under the block *A*. Then the slide *B* is run down so as to clamp the other end. This slide is held in place and locked by

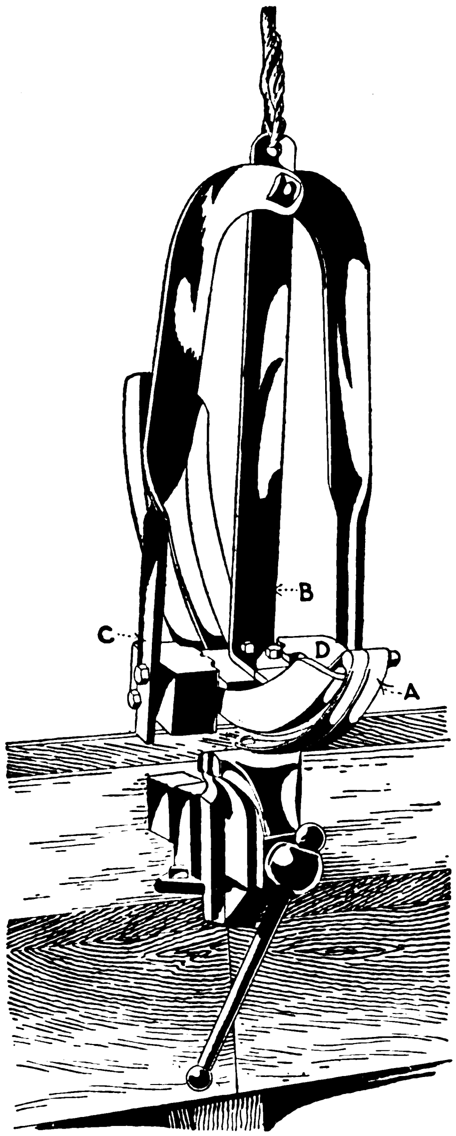

FIG. 12. FRONT-GUARD SWAGING DIE

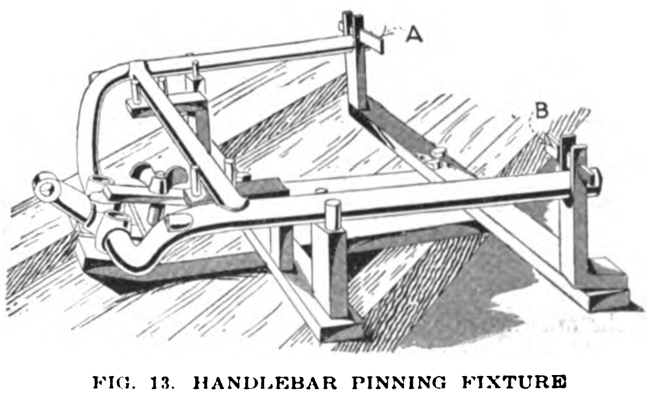

FIG. 13. HANDLEBAR PINNING FIXTURE

the handscrew *C*, which is carried in an adjustable block *D*, to accommodate different lengths of guards. The drill bushings are carried in small brackets riveted to the body of the jig at *E*, *F* and *G*.

Front mud guards are swaged in the device in Fig. 12, to give front-fork clearance. A center piece is clamped

in a bench vise. This center piece has a loop arrangement *A*, into which the guard may be thrust to a stop. An inside forming swage is fastened to the upper end of the loop and is also carried by bar *B*. With the guard in place, the two outer swages *C* and *D* are rammed against it, which bends the thin metal to the inner swage. The entire device is counterbalanced. When not in use, it may be removed from the vise and held suspended against the wall, from where it can be easily set into the vise at any time.

A handle-bar truing and pinning jig is shown in Fig. 13. It holds the various brackets and fittings in place, as well as the crossbrace. The taper-pin clamps are used in this jig also, as seen at *A* and *B*.

Drilling Two Half-Holes in a Time-Fuse Ring

By D. Baker

The illustrations show a jig for drilling two half-holes in a time-fuse ring, these holes being shown at *B*, Fig. 1. At first glance it seems a simple operation, but because of the fact that there were large limits on the preceding operations, it was found to be a difficult matter to locate these rings in proper relation to the drill bushings.

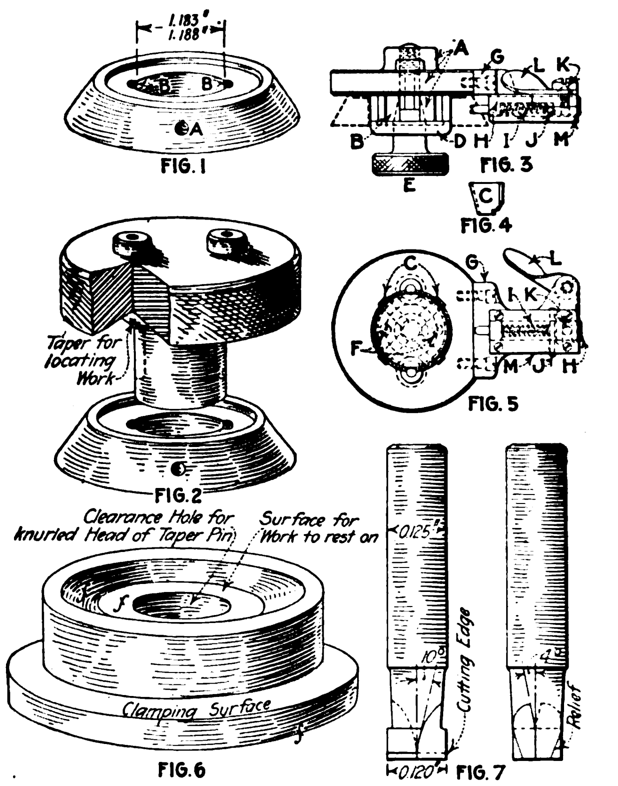
We could not locate from the tapered part outside of the ring, because it was finished in a separate operation from the bore and could not be depended upon to run true with it. We first tried locating from the inside. However, the plug that located the work had to be made to the low limit of the ring, which was 0.005 in. smaller than the high limit. In working on the larger rings, the drills, operating as they were on only half-holes, crowded the work to one side, so that when it was taken out of the jig it would not go on the gages, the holes being too close together.

To overcome this difficulty, we next made a jig with a locating plug having, as shown by Fig. 2, a short, stiff, tapered portion. This tapered part was depended upon to locate the work central. This plan might have been all right, had not the bore been previously burred, or chamfered, with a hand tool that left it irregular and so threw it off center.

To construct a jig that was both rapid and accurate, the following design was gotten up: Referring to the drawing, *A*, Fig. 3, is the body of the jig, which was made of machine steel. *B* is a part of the body that was turned about 0.003 in. smaller than the low limit of the bore of the rings. In this part four slots were milled, into which the four hardened blades *C* were inserted, and held from falling out by the cap *D*. These blades were made, as shown by Fig. 4, with a stiff taper on the inside. *E* is a hardened and ground taper pin, threaded at one end and having a large knurled head at the other. On each end of the taper is a part of the pin which is ground straight. One end has a bearing in the jig body; and the other has a bearing in the cap *D*, which is also hardened and is held central by a shoulder turned on the body, as shown. It is kept in place by the two screws *F*, Fig. 5.

Attached to the jig body is a device for locating the ring in relation to the hole *A*, Fig. 1. It consists of a machine-steel body *G*, which is fastened to the jig proper with two fillister-head screws and dowels, not shown. This piece is milled out to take the square sliding bar *H*, one end of which is turned round and acts as a locating pin, as shown. The bar has several thousandths play vertically, to allow for various thicknesses of rings, but does not permit any rotary movement. It is slotted out to take the coil spring *I*, one end of which rests on the pin *J*, driven through the body. This spring gives the needed tension for holding the locating pin in place in the work. In the outer end of the locating-pin bar is driven a pin *K*. *L* is a thumb lever, one end of which engages with this pin. *M* is a thin plate, fastened to the body with screws, as shown, for holding the locating-pin bar in place.

To operate this jig, it is first picked up in the left hand, with the thumb on the thumb lever, which holds



DRILLING HALF HOLES IN TIME-FUSE RING

the locating pin out of engagement with the work. Then with the right hand, the taper pin *E* is screwed out, releasing the blades *C* and letting them fall back a few thousandths into the body. The work is then picked up and placed on the jig, passing over the knurled head of the taper pin, which is made small enough to allow it to pass freely. It is then turned to the proper position for the entering of the locating pin, and the thumb lever is released, after which the taper pin is screwed tight, forcing the blades *C* out against the bore of the ring, bringing it exactly central.

The jig, with work in it, is then ready to place under the multiple drill head. As it had to have something to stand on besides the knurled head of the taper pin, a simple cast-iron fixture was made, as shown clearly in Fig. 6. The clearance hole was cored out and the casting finished only where shown by the *F* marks. After turning the jig over to the manufacturing department, we began to have difficulties in getting cutters to stand up to the work. We tried out all kinds of cutters and

drills without much success. If they were the least bit dull, they would crowd over against the bushing, which was meant to be a support for them, so hard that they soon lost their size, besides wearing out the half-bushings.

The final development, which is proving a success, was to make the bushings so that they acted as guides only and did not extend down into the work. Then we made up cutters from Novo high-speed drill rod, Fig. 7. It will be noticed that the drill rod is 0.125 in. in diameter. The cutting end only is ground down to 0.120 in. after hardening, and the side relief is ground on, free hand. The end is relieved by resting the cutters in a V-block, which is set up in front of a grinding wheel in such a way that the center of the V comes on a line with the edge of the wheel.

This arrangement enables the operator to grind one cutting edge, then revolve the cutter in the V and grind the other, regulating the amount of clearance given by setting the V-block either higher or lower.

The cutters made in this way are practically end mills and act as such. If for any reason they are crowded to one side when being fed into the work, they will on the return feed have a tendency to clear themselves and thus leave a clean, true hole.

Milling cuts run exactly to center, but are given 10 deg. angle one way and 4 deg. the other, to strengthen the cutter back of the cutting edge. When grinding, if the center gets too thick, it is stoned up again.

These jigs in the hands of a skilled operator have a capacity of over 200 pieces per hr., two half-holes to the piece, while the cutters have done over 500 pieces without regrinding.

Piston Jigs and Tools

By E. V. Allen

Two wrist-pin hole jigs are shown in Fig. 1. They are used in the shop of the Caille Perfection Motor Co., Detroit, Mich., for work on the pistons of portable boat motors. The one at the left has a piston in place ready to drill and ream. The one at the right is shown empty. In putting a piston into one of these jigs, it is inserted with the center hole of the closed end over the point of the screw *A*. The locating plug *B* is then inserted through the large bushing in the opposite end. This plug is located correctly in the bushing by the key *C*, which fits snugly in a keyway. The formed end of the plug butts under and against the wristpin bosses inside the piston and lines them up so that a drill run through the guide bushings will make a hole through the center of the bosses. A final tightening of the screw *A* completes the setting of the work.

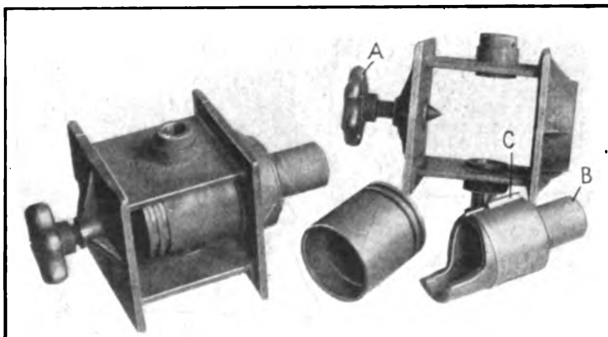


FIG. 1. PISTON DRILLING AND REAMING JIGS

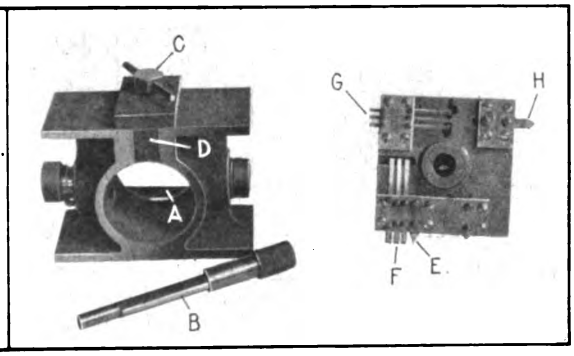

FIG. 2. REAMING JIG AND SPECIAL TURRET

Though the holes are drilled and reamed in the type of jig just shown, they are finish-reamed in the jig seen at the left in Fig. 2. The piston is put into this jig and butted against the stop *A*. The wristpin hole is then lined up approximately with the guide bushings. The ground setting plug *B* is next run through the bushings and wristpin hole, lining them up as closely as possible. The piston is locked in place by turning the screw *C*, which operates the clamp slide *D*. In order to facilitate the lining up of the wristpin hole with the bushings, where the wristpin hole may be slightly out of line, the plug *B* is considerably flattened where it goes through the piston. Two edges of it, however, are ground to size, so that by turning the plug the hole may be lined up as nearly as possible. A hand reamer is then run through and the hole accurately lined up and sized.

At the right is a turret used on the cross-slide of a lathe for grooving and chamfering pistons. The chamfering tool is shown at *E*, the rough-grooving tools are seen at *F* and the groove-finishing tools at *G*. A turning tool is carried at *H*.

A Simple Method of Preventing Injury to Charts

By E. J. Gibson

Authors of some of the latest reference books, being awake to the need of presenting data in the most convenient form, have prepared elaborate charts to meet this demand. Unfortunately, constant use will in time deface some of the graduations, and the surface of the chart is impaired while the rest of the book is in good condition. Particularly is this true in cases which require the use of dividers to obtain the desired information.

It has been found that this trouble is avoided by inserting in the book, next to the page containing the chart, a piece of tracing cloth the size of the page. The tracing cloth is pasted along the inner edge, so that it virtually becomes one of the leaves of the book. When the chart is in use, it can always be covered with the tracing cloth, through which every detail can easily be seen.

In addition to the preservation noted the dull side of the tracing cloth is handy for making reference notes.

Tools for Machining Details for a Press Feeder

By Robert Mawson

SYNOPSIS—In this article are shown some of the small tools—jigs—used in machining the details on a printing press. In most cases the drilling operations follow the milling, and the casting rests on finished pads in the jigs. The tools are designed with quick-acting locating and holding devices, such as V-blocks and pin-headed screws. Where covers are used on the jigs, they are fitted with open-sided washers which, swinging under shoulders on the locating pins, are quickly located and hold the cover in the correct position.

On page 58 was shown and described the two-sheet rotary printing press manufactured by the United Printing Machinery Co., Woonsocket, R. I. Various machining operations and the tools used are illustrated on pages 56, 138, 232, 318, 458 and 492. Herewith are shown four other details and the jigs used in machining them. This article, as well as the former articles, illustrates examples of high-grade small-tool construction where the production is comparatively small.

In the jig used when drilling the cut-out ratchet holder the tool has been designed with two screws set at an angle of 45 deg. which are used as locating surfaces for the boss on the casting. As the castings are liable to vary owing to foundry conditions the screws are made adjustable to take care of such variations. The tool used for machining the conveyor drive clutch lever is made with tool steel spacing block against which the arms of the casting are placed. This affords not only a locating means but also supports the ends of the arms against the machining stresses.

The boss on the casting rests on pins which place the surface at the correct height for the hob to be drilled and reamed through the boss. The single arm of the piece is placed in a cut-out recess in the jig.

The conveyor drive gear yoke is drilled after being completely milled. To locate the casting properly in the jig a finished steel block is used which fits between machined surfaces on the two internal bosses.

The jig, Fig. 6, is of the open type, the casting being located by a V-block on the other three tools. After the piece is in position covers are dropped down.

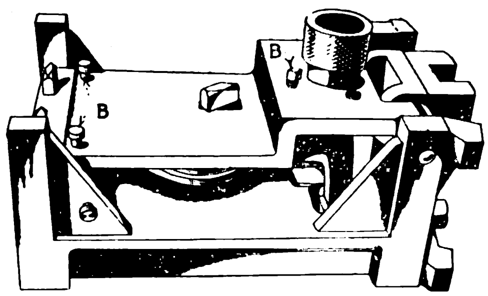

FIG. 2

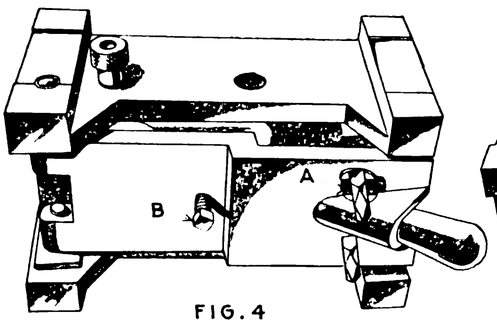

FIG. 4

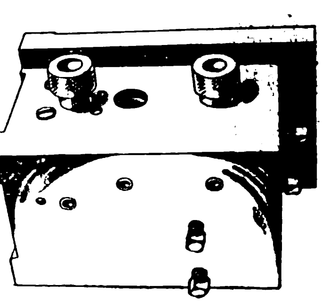

FIG. 6

DRILLING JIGS USED IN MACHINING PRINTING-PRESS FEEDER DETAILS, WITH WORK SHOWN IN POSITION

FIGS. 2 AND 2-A

Operations—Drilling and reaming cut-out ratchet holder, Fig. 1. The milled casting is located against two adjustable screws placed to form a V. It is forced against these with the pin-headed screw. The clamps are then tightened onto the part to hold it securely. The cover is afterward dropped over the pig, located by two pins and held down with the three screws B.

Holes Machined—One $1\frac{31}{64}$-in. drilled and reamed to $1\frac{1}{2}$ in., one $\frac{1}{4}$-in. drilled, one $\frac{13}{32}$-in. drilled and $\frac{3}{4}$-in. spot-faced, and three $\frac{17}{64}$-in. drilled.

FIGS. 4 AND 4-A

Operations—Drilling and reaming conveyor-drive clutch lever, Fig. 3. The rough casting is located against pins, being forced against them with knurled-head screws. The cover is then dropped down, being held with the thumb-screws A. The screw B is then tightened onto the piece to hold it securely.

Holes Machined—One $\frac{47}{64}$-in. drilled and reamed $\frac{3}{4}$ in., one $\frac{19}{64}$-in. drilled and reamed to $\frac{5}{16}$ in., and one $\frac{3}{16}$-in. drilled.

FIGS. 6 AND 6-A

Operations—Drilling and reaming bracket support for sheave wheels, Fig. 5. The milled casting is located against a machined block, being forced back with a setscrew inside the jig body. The cover is then dropped down and held with the thumb-screws. A setscrew tightened on the piece holds it securely.

Holes Machined—Three $\frac{31}{64}$-in. drilled and reamed $\frac{1}{2}$ in. and two drilled to suit a No. 20-18 thread.

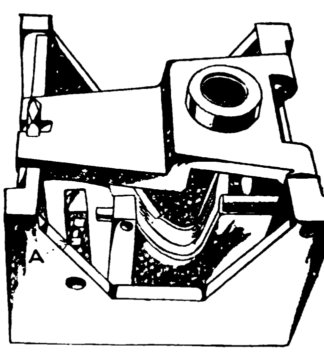

FIG. 8. JIG FOR DRILLING AND REAMING CONVEYOR-DRIVE GEAR YOKE

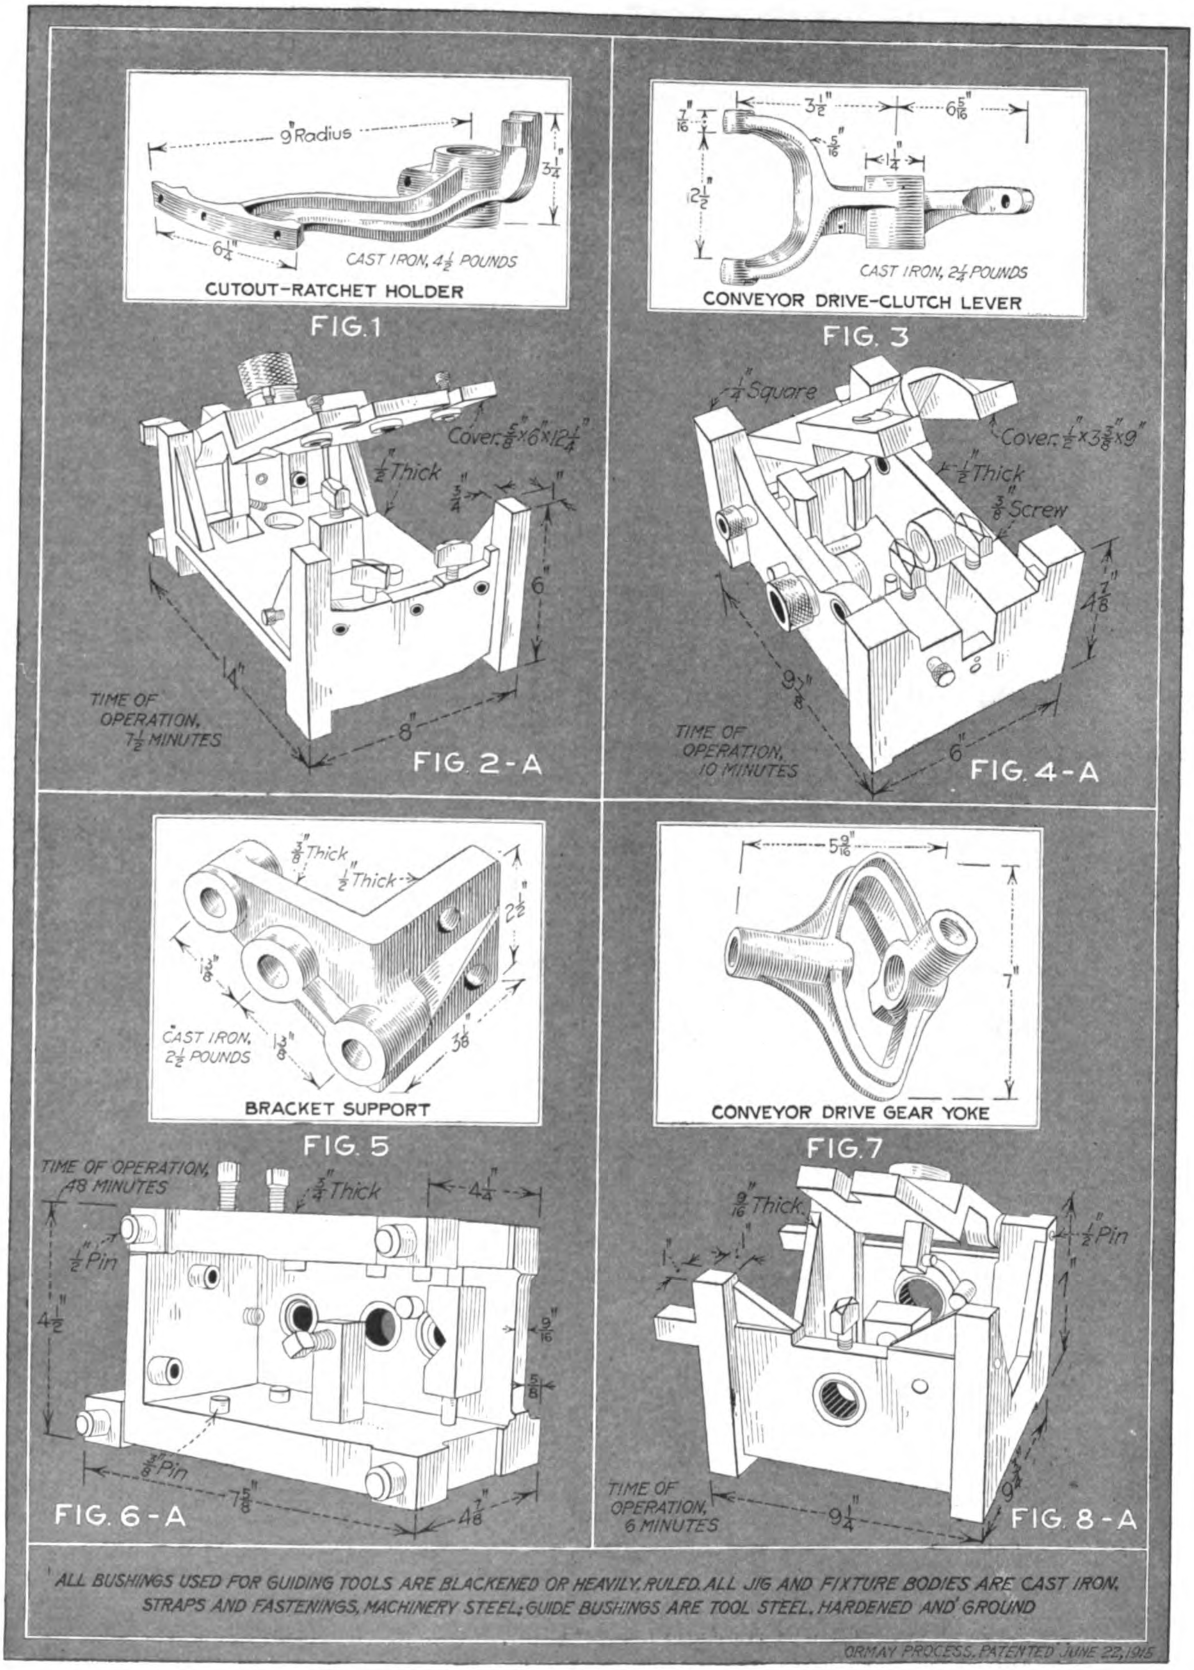
FIGS. 8 AND 8-A

Operations—Drilling and reaming conveyor-drive gear yoke, Fig. 7. The milled casting is located in the jig by a machined steel strip which fits into a finished slot. It is forced back and held in position with the setscrew A and one at the end. The cover is then swung down and fastened with the thumb-screw as shown.

Holes Machined—One $\frac{47}{64}$-in. drilled and reamed $\frac{3}{4}$ in., one $1\frac{23}{64}$-in. drilled and reamed $1\frac{3}{8}$ in., one $\frac{55}{64}$-in. drilled and reamed $\frac{7}{8}$ in.



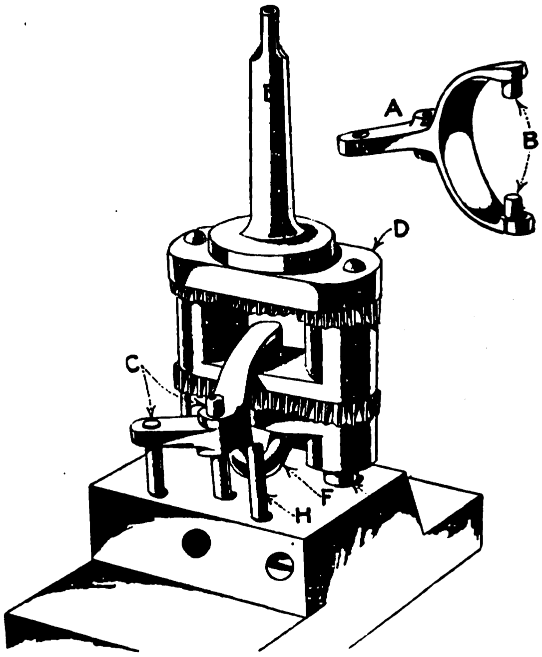
DETAILS OF DRILLING JIGS USED IN MACHINING PRINTING-PRESS FEEDER PARTS

Machining Pins Inside a Fork

By E. A. Thanton

An ingenious method of machining pins on the inside of a small brass fork is here shown. This process is employed in the shop of the Caille Perfection Motor Co., Detroit, Mich. One of the finished forks, shown at *A*, will give a good idea of the work, which is indicated by the arrows at *B*.

Two holes are first drilled in the fork in a drilling jig. These holes are used both to hold and to locate



MACHINING PIN INSIDE A FORK

by, as will be seen where a fork is shown set over the pins *C*. The pins on the inside of the fork are machined by a hollow mill carried in the frame *D*. The taper shank *E* fits the drilling-machine spindle, and the hollow mill at *F* is driven through the gears shown.

The frame carrying the gears and the milling cutter is made to slide on two posts set into the base, like that of a subpress. One of these posts is partly shown at *G*. In putting a fork into the fixture the frame is raised on the posts and the fork is put into approximate position; then frame and fork are lowered until the fork is held securely on the locating pins *C* and the lower part of the fork rests on the bedplate. The milling cutter can now be used to finish the fork pin. For the pin on the other side of the fork the piece has to be turned over and the outer hole set over pin *H*.

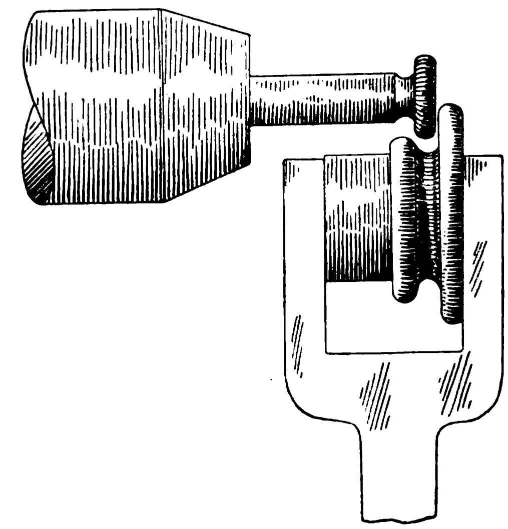
Method of Knurling Brass Cup

By W. R. Armstrong

Two or three years ago the firm I was with needed a large number of brass cups.

The method of production was to blank and draw the cup from 0.25-in. thick brass and redraw to $\frac{13}{32}$ in. in diameter by ½ in. long. Blanking the cup was done at 85 per min. and the redraw at 80 per min. on a table-feed press.

Beading the end and knurling form the interesting part. This work was done in an ordinary speed lathe at the rate of 10,000 to 12,000 pieces in 10 hr. The apparatus consisted of an arbor shaped as the piece required and small enough in diameter to let the cup be taken off after knurling, and a knurl or roll, with a flange as shown, held in the tool post of a lever-feed slide on the lathe.



METHOD OF KNURLING BRASS CUP

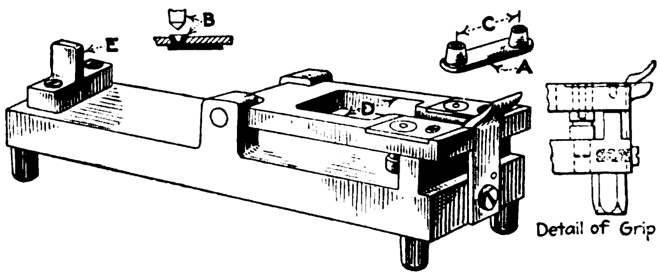
At first, trouble arose in getting cups to come round and at the some time getting production enough per day. At my suggestion the arbor was knurled on the bead. No further trouble developed, and production almost doubled—to the quantity mentioned. As I remember, these cups were annealed lightly before knurling. The lathe was run at 900 or 1,000 r.p.m.

An Interesting Drill Jig

By Harold E. Greene

The accompanying illustration is of a drill jig that solved a vexing problem.

The pieces shown at *A* were drop-forged number plates for typewriters, and were fastened to the frame of the machines by spreading the lugs with a punch after drill-



A FLEXIBLE DRILL JIG

ing, as shown at *B*, which necessitated an even thickness of wall so that they would turn evenly. The center distance *C* of the lugs varied enough so that with a fixed center distance of the drill bushings an even thickness of wall was not possible; therefore a leaf as shown was made which would spring enough at *D* to allow for the variation. The taper holes in the lower end of the bushings were made to fit the lugs as closely as possible.

Another feature of the jig is the block *E*, which acts as a knockoff for the pieces when the leaf of the jig is unlatched and thrown back in the loading position.

Manufacturing 12-In. Shrapnel--II*

By Robert Mawson

SYNOPSIS—The operations of turning the inside and the outside form of the shell, machining the back end, turning the outside copper-band channel, knurling the channel, forcing and machining the copper band to the correct contour are described in this article. The various stages are illustrated.

After the shell has been nosed and returned to the machine shop, the next operation is turning the inside form. The shell is held in the chuck, Fig. 4. The boring bar and tool are shown in Fig. 25. The bar is held in the tool carriage of the lathe in the usual manner. The desired contour on the shell is obtained by the guide pin *A*, Fig. 26, which is attached to the bracket tee *B* and follows the path between the two former cams *C*. The latter are fastened on the cam bed *D*, which is held on the brackets *E*, fastened on the side of the lathe bed. The bracket tee is attached rigidly to the tool carriage of the lathe.

The manner in which the attachment is used on the lathe may be observed by reference to Fig. 27. The gage for testing the machined inside contour is illustrated in Fig. 28. A diagrammatical view of the operation performed may be seen in Fig. 29. The open end of the shell is next faced, the correct length being obtained from the powder chamber with a gage and straight-edge, as in Fig. 30. The hole is then bored to 8.23 in. in diameter, the pin gage, Fig. 31, being employed to test the machined bore.

A thread is machined in the bored hole, to suit the partly machined adapter, the manufacture of which will be treated in another article. Fig. 32 shows the lathe set-up for boring and machining the thread, and in Fig. 33 are given in diagrammatical form the surfaces machined. It will be observed that the shell is held in the chuck as in Fig. 4. The adapter is screwed into the shell, using the clamp, Fig. 34, in the way illustrated in Fig. 35.

After the shell has been placed in the lathe as just described, the chuck, Fig. 36, is screwed into the end of the adapter and the lathe center set up in the countersunk hole of the chuck. The outside of the adapter and also part of the outside of the shell are then turned to the correct contour. For this operation the link, Fig. 37, is attached to the bracket tee with the stud *A*, Fig. 37, after the guide pin has been removed. The fulcrum pin *B* is placed in position, fitting into a machined hole in the cam bed. The arrangement of the attachment may be seen in Fig. 38.

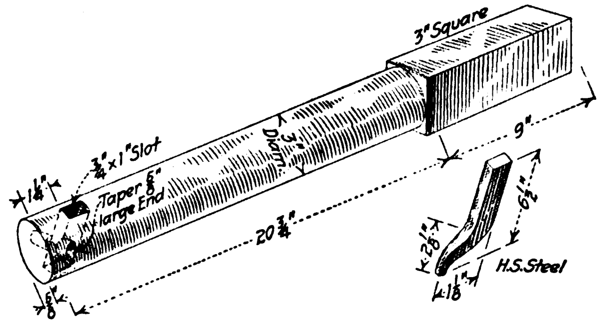


FIG. 25. BORING BAR—INSIDE OF SHELL

The turning tool is held in the carriage of the lathe. As the carriage is fed forward with the shell revolving, the link, fulcruming on the pin, draws the carriage and turning tool on an arc. Thus the desired contour of the part is obtained. The gage for measuring the length of the machined surface appears in Fig. 39. Fig. 40 shows the lathe set up for performing the machining operation, and in Fig. 41 is shown in diagrammatical form the work done.

The gage in Fig. 42 is for testing the machined contour while the shell is in the lathe with the chuck in position. Fig. 43 depicts the tool employed as the final profile test gage after the chuck has been removed.

In Fig. 44 is a special double-ended lathe designed for the work of machining the inside and outside profile surfaces on the shell. It will be observed that the operators work face to face, the tailstocks being placed in the center and the drives being at the outer ends of the lathe. This arrangement has proved advantageous, cutting down the floor space. As the machines are of the one-purpose type and the required length of lathe bed is thus known, the tools have been designed accordingly.

For the next operation the first suboperation is machining a surface

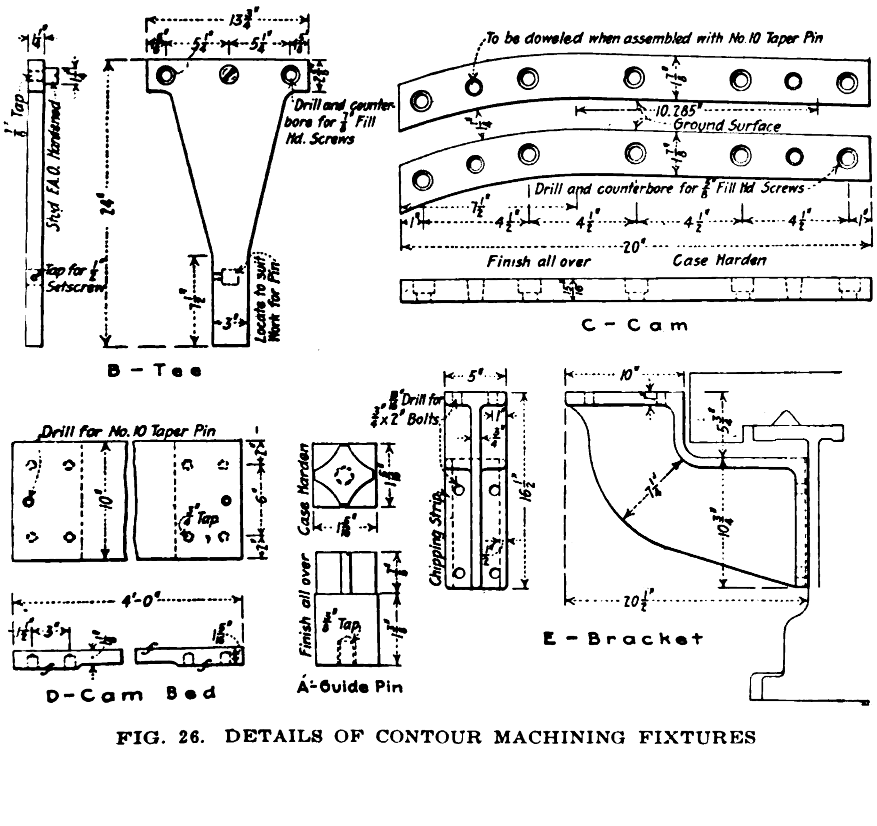

FIG. 26. DETAILS OF CONTOUR MACHINING FIXTURES

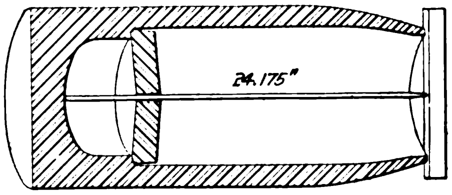

FIG. 30. GAGE AND METHOD OF USING IT TO TEST DEPTH OF BORE

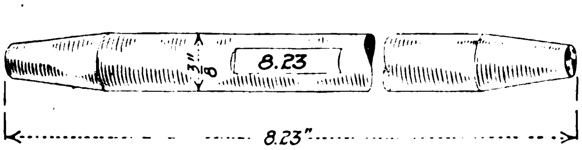

FIG. 31. GAGE FOR OPEN END OF SHELL

to suit the steadyrest, Fig. 8, and at right angles to the end already faced. The chuck, Fig. 45, is screwed into the open end of the shell after the adapter has been removed. A strap held on the faceplate of the lathe comes in contact with one of the lugs on the chuck, thus providing the driving medium. The chuck, Fig. 46, is placed on the base end, and the shell is adjusted with the four setscrews until it runs concentrically. A surface is then machined to suit the steadyrest. This operation is illustrated in Fig. 47. The chuck is then removed, and the base of the shell is faced to length, using the gage, Fig. 48, in the manner shown.

The gage, Fig. 69, is for testing the radius on the corner of the base and for turning the outer periphery. A notch is cut to suit the 0.9-in. section and to serve as a guide from which the channel will be machined.

The operation is shown in Fig. 50 and in diagrammatical form in Fig. 51. The outer periphery is also turned at the same setting to 11.94 in. for a width of about 1 in. The gage for the diameter is given in Fig. 52.

The chuck, Fig. 53, is slid on the turned portion at the base end and the lathe center set up. The steadyrest

is thrown back out of the way for the next suboperation—turning the remainder of the body. The gages for the turned diameters are seen in Figs. 52 and 54. The lathe set-up for performing the turning operation is shown in Fig. 55 and in diagrammatical form in Fig. 56.

In turning and knurling the channel the shell is held as described for the previous operation. It is, however, supported with the steadyrest, Fig. 8. The channel is machined with an undercut or bevel, on each side. For this purpose left- and right-hand side tools are set at the correct angle and held in the tool post of the lathe. The gage for testing the bottom diameter of the channel is shown in Fig. 57; the width and contour gage, in Fig. 58.

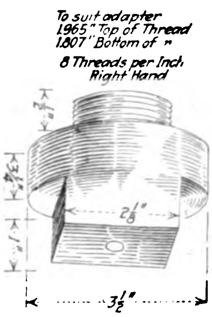

FIG. 36. CHUCK FOR ADAPTER END OF SHELL

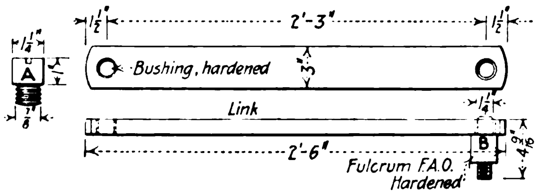

FIG. 37. DETAIL OF LINK

The next suboperation is knurling the channel. The tool, Fig. 59, for this operation is held in the tool carriage of the lathe and fed across the surface of the turned channel, with the shell revolving, until the desired depth of knurl is secured.

A view of the lathe set-up for performing the knurling operation is given in Fig. 60. The operation is shown in diagrammatical form in Fig. 61. The shell is then transferred to the forge shop, to have the copper band

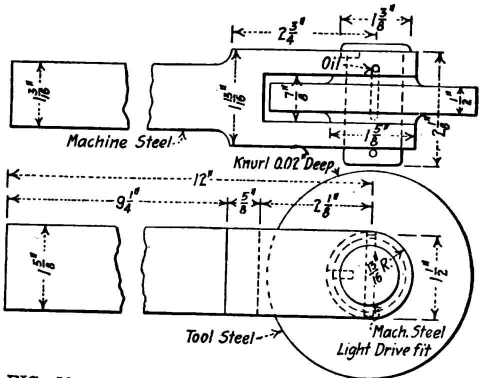

FIG. 59. THE KNURLING TOOL FOR CHANNEL

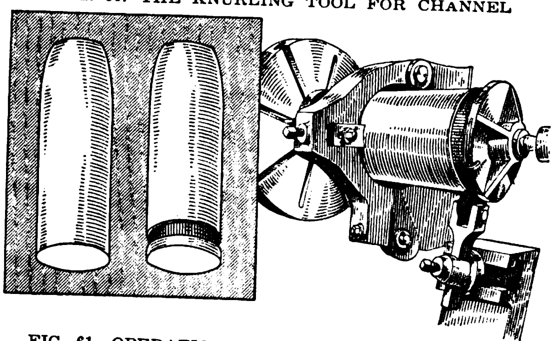

FIG. 61. OPERATION 13: TURNING AND KNURLING
Machines Used—New Haven, Boye & Emmes and special.
Special Fixtures—Two chucks and steadyrest.
Gages—Snap and form.
Lubricant—None.
Note—Between grindings of tool, 2 shells. Lathe operates at 20 r.p.m. with feed of $\frac{1}{16}$ in. per revolution.
References—Figs. 8, 56, 57, 58 and 59.

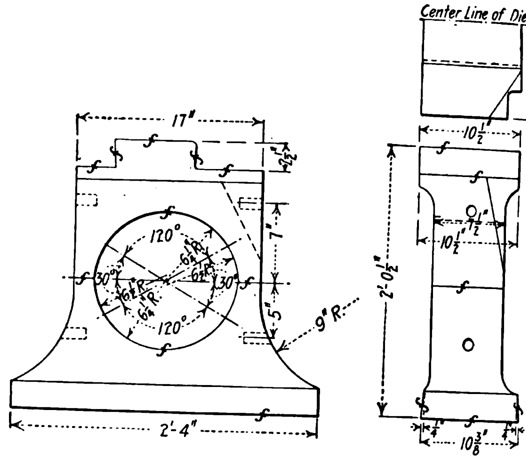

FIG. 63. DIES FOR COMPRESSING BAND

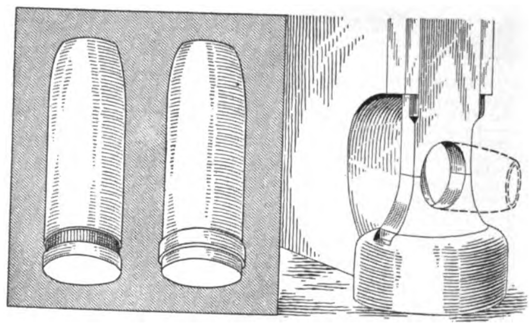

FIG. 65. OPERATION 14: COMPRESSING THE COPPER BAND
Machine Used—Niles-Bement-Pond steam hammer.
Special Fixtures—Dies fitted to steam hammer; special screw bar and clamp for turning shell between dies; trucks to convey between forge and machine shop.
Gages—None.
Production—Six per hour.
References—Figs. 61, 62 and 63.

The gang employed in compressing the band on the shell numbers three—one adjusting the crane that supports the shell, one operating the hammer and the other turning the shell around between the dies. For this purpose the rod that screws into the end of the adapter has a clamp fitted with handles, as shown. A leather cover is slipped over the shell, around which the crane sling is placed, so that the turned shell will not be damaged. A view of the steam hammer with a shell having the copper band compressed is presented in Fig. 64. A diagrammatical illustration of the operation appears in Fig. 65.

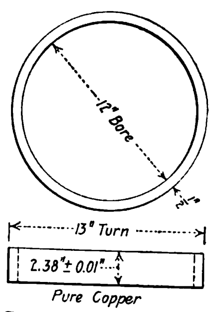

FIG. 62. DETAIL OF COPPER BAND

The shell is next returned to the machine shop for the operation of machining the copper band. The chuck, Fig. 53, is placed on the base end of the shell, and the threaded chuck, Fig. 66, is screwed into the threaded end

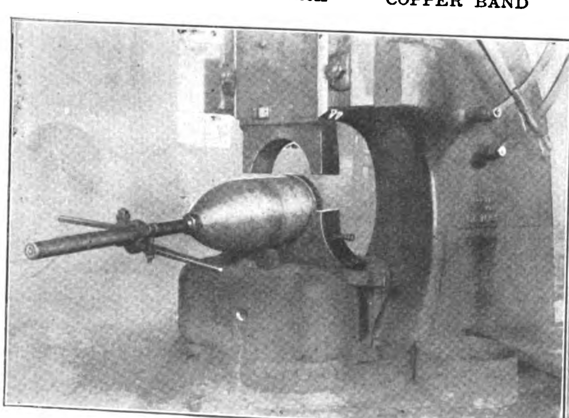

FIG. 64. COMPRESSING BAND ON SHELL

of the adapter. The dog, Fig. 67, is fastened on the threaded chuck. A plate held by a bolt on the faceplate of the lathe comes in contact with one of the arms on the dog and thus furnishes the driving medium. The form tool for machining the band is illustrated in Fig. 68.

The gage for testing the machined contour of the band is shown in Fig. 69, while the lathe set-up for machining the band is given in Fig. 70 and again in diagrammatical form, in Fig. 71. The shell is now ready for the final inspection before loading, weighing and shipping.

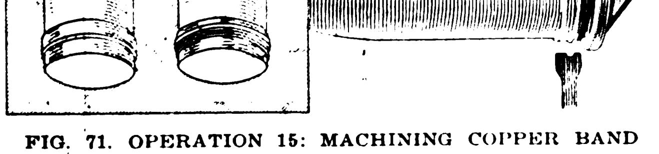

FIG. 71. OPERATION 15: MACHINING COPPER BAND
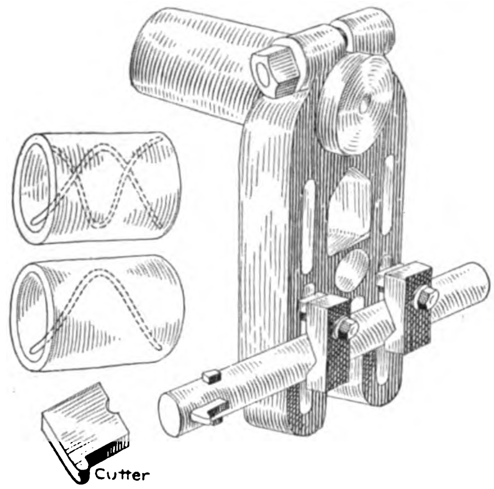
Machine Used—Boye & Emmes.
Special Fixtures—Threaded-plate chuck and form tool.
Gages—Form.
Production—One shell per hour.
Lubricant—None.
Note—Between grindings of tool, 2 shells. Lathe operates at 150 r.p.m., and feed is by hand.
References—Figs. 49, 52, 65, 66, 67 and 68.

Cutting Oil Grooves in the Miller

By C. E. Applegate

One of the propositions presented to all shops is to cut oil grooves in bushings. The work is frequently done in a lathe department, with a lathe fitted up with special leads. I find that the index head on a miller will serve as well, the spindle of the miller not being used for anything except feeds. A boring bar is clamped on the arm, as shown, and the tool is used in the same way as



CUTTING OIL GROOVES IN THE MILLER

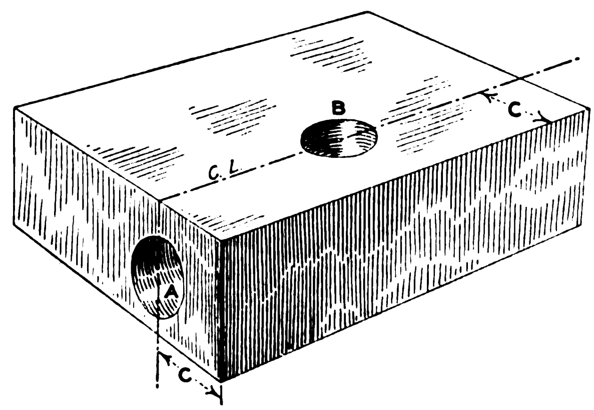
on a lathe. The only difference is that the table instead of the tool holder travels.

If a double oil groove is required, it will call for the second idler gear. For instance, 50 bushings are to be cut. Cut them with one idler gear, then rechuck in the universal chuck and turn the bushing halfway around, to recut and cross the first oil groove.

Drilling Central Crossholes in Round Bars

By W. D. Dawson

A tedious and common operation in the machine shop is the drilling of a hole accurately in a shaft or round pin at right angles to its axis. I need not explain any



THE JIG FOR DRILLING THE HOLES

of the many methods of laying out with V-blocks. The illustration herewith explains a tested method.

The holes *A* and *B* are accurately laid out and drilled on the same center line. *A* is drilled the size of the shaft or pin; *B* is drilled the size of the desired hole, after which the work is placed the required distance in *A*.

Good Toolroom Arrangement and Equipment

By F. C. Mason

Figs. 1 and 2 show two views of a toolroom that I installed for the Bissell Carpet Sweeper Co., Grand Rapids, Mich. In it are manufactured tools, dies, fixtures and special machinery, most of which is semiautomatic or full automatic. The accompanying pictures were taken on a dark day, and it will be noticed that the building it not of modern construction.

The points to be observed are the cleanliness and facilities for convenience, a few of which I think are novel. First, we had things arranged in such a manner that there was nothing on the floor; but everything is in its place and at least 12 in. above the floor, so that the floor can be kept clean. This floor is of hard maple and is scrubbed once a week. The machinery and benches are so placed as to get the best possible natural light.

Details that I desire to call attention to are found in Fig. 2. First, the benches are individual and extend outward from the window. They are made of a cast-iron top plate that weighs 450 lb. and are designed according to surface-plate construction. The top plate is 1 in. thick, ribbed to a depth of 3 in., and is supported on 2-in. iron-pipe legs that are tapped into corner bosses. The top and sides are planed and squared in a first-class manner, thus making the bench a squared surface plate for layouts. This feature can be readily appreciated by active mechanics. The vise is on the right-hand corner, and the workman can turn it in any manner.

To procure the best light, each bench has an adjustable lamp holder of the McCrosby type, which can be readily placed in any position desired. Each man also has a tool cabinet and a stock bench with three shelves, both of which can be plainly seen. These wall cabinets are made of maple, 20x24 in. by 10 in. deep, opened in the middle and locked with a regular chest lock when opened. They have two separate full-sized compartments—one about 3 in. deep and the other 5 in. deep. The shallow one is for the file rack; the back, or deep, one has a small drawer in the bottom and a shelf. These cabinets are furnished with the following tools: A full set of files and handles, two sets of drills—1 set 60 to No. 1; the other, No. 1 to $\frac{1}{2}$ in. by sixty-fourths—a full set of taps 4-36 to $\frac{5}{8}$ standard and two tap wrenches. These tools are charged to the employee and are replaced when necessary.

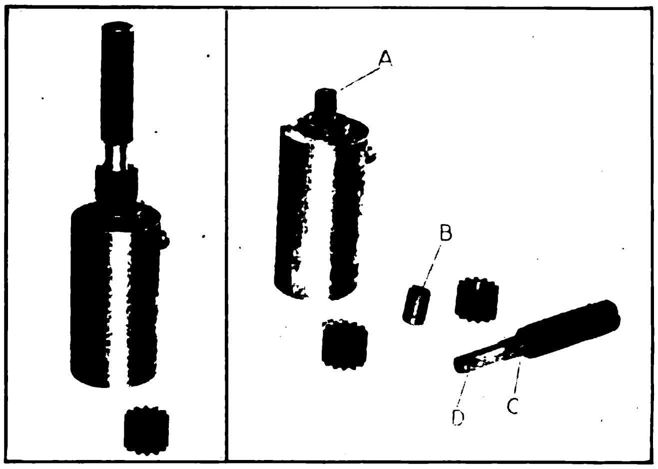
For the benefit of others I would say that the iron benches cost as follows:

Casting, 500 lb., at 3c.	$15.00
Planing	3.00
Pipe for legs, 11 ft., at 17c.	1.87
Four reducing couplings for feet	1.50
	$21.37

The total cost was somewhat more than that of a wooden bench; but when finished, it is always a real asset that can be moved to any place without tearing down, as in the case of a wooden bench.

Bushing a Small Pinion

A method of forcing bearing bushings into small steel pinions is shown in Fig. 1. These pinions are used in a speed-changing mechanism on Henderson motorcycles.



FIGS. 1 AND 2. FORCING A BUSHING INTO A PINION

At first, trouble was experienced in getting the bushings started straight, so this device was made.

As may be seen in Fig. 2, the pinion is placed over a centering sleeve *A*. A bushing *B* is then placed on the forcing pin at *C*. The pilot *D* fits down inside the sleeve *A*. As the pin and bushing are forced downward, the sleeve recedes, allowing the bushing to enter the hole of the pinion. As soon as the work is removed, the sleeve is again pushed upward by a spring underneath, assuming the position in which it is shown. By using this device the bushings are accurately guided the full length of the pinion bore and are not distorted or marred in any way.

Standard Product Inspection in a College Shop

By J. A. De Turk and G. H. Radebaugh*

SYNOPSIS—The methods and tools used in inspecting the parts of an 8-hp. marine-type gas engine in the shop of an engineering school. Material, both raw and semifinished, all component parts and the assembled units and machines are gone over in detail.

A vital requirement for the successful making of a machine is that the manufacturer deliver it into the hands of the user as nearly free from defects, according to his standard, as is possible. This involves close inspection of component parts, such inspections serving the double purpose of giving the buyer a good product and of eliminating unnecessary manufacturing expense by preventing the application of processes to parts whose eventual rejection is determined at a previous stage of construction. Defects may be discovered at any one of the three following stages of manufacture: (1) Design; (2) material; (3) workmanship. It is not within the scope of this paper to discuss the first two at any length, although it might be well to mention a few points that must be considered in inspection at these stages.

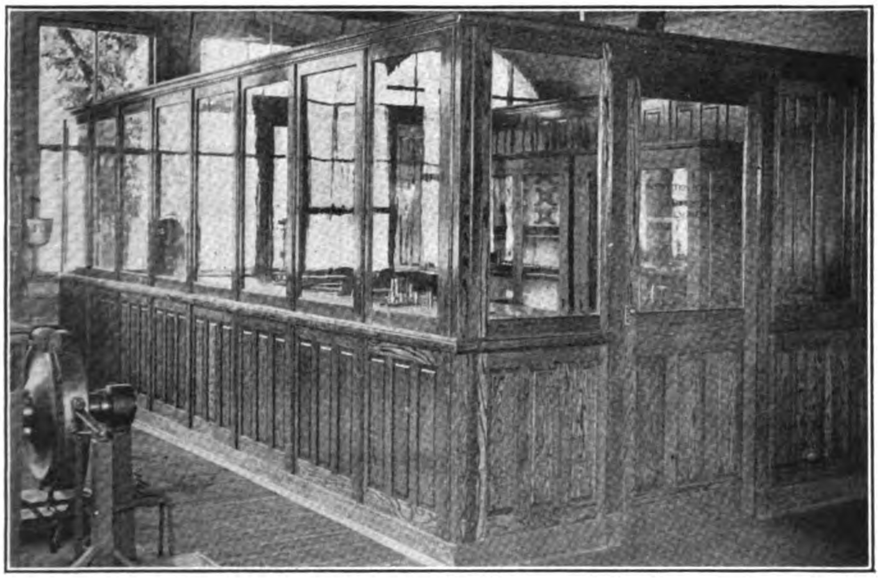

FIG. 1. VIEW OF INSPECTION DEPARTMENT THROUGH WHICH EACH PART MUST PASS

It is inclosed to prevent the workmen from disturbing the inspector or influencing his decisions

The questions arising under design will be somewhat as follows: Have the actual conditions been accurately noted when specifications were drawn up? Have the specifications been correctly interpreted? Have the calculations been checked as to correct assumptions and the factors of safety under which the machine is to give service chosen? Have calculations been checked as to correct formulas and with a view to detecting possible errors? Are the correct dimensions given on the drawing as required by specifications and calculations? Have the pattern, foundry, forge and machine departments been duly considered in the making of the drawing for economical manufacture? Are the drawings accurate, clear and conventional as to views, dimensions, notes, specification of materials and required number of parts?

If the parts are purchased, some consideration must be given to market conditions and to whether the parts may be bought from standard stock or whether they must be ordered as special.

The material to be inspected divides itself into two classes: First, that purchased in either raw or finished form; and, second, that on which the manufacturer does some work later. Before the order for purchased parts is placed, requisitions should be carefully checked. Upon the receipt of the parts, the shipment should again be checked for both quality and quantity. The quality must be determined by general appearance, physical and chemical tests, name and trade-mark, dimensions and weight. Damage in shipment, etc., should be carefully gone into.

Many of the material inspections may be more properly described under workmanship defects, because it is only raw, unalloyed elements of material that man accepts as nature provides. These defects may be classified according to the department in which they arise. Classification of departments depends of course entirely upon the nature of the final product. We may justly assume that the organization required for proper workmanship inspection is larger and more complex, although not more important, than any one of the other three mentioned. This is owing to the fact that there is a larger and more varied human element to consider, this element entering as parts are formed to proper shapes and sizes. The question as to the sources for procuring men sufficiently versed in the foundation of modern inspection to be capable of organizing and directing such a department in any of its modified forms becomes a pertinent one to the manufacturer.

There is no doubt in our minds that colleges and universities should keep abreast of the times and endeavor to give sufficient training along manufacturing lines to enable manufacturers to draw from the graduates men who have at least a fair conception of logical and scientific production. Dean W. F. M. Goss, of the College of Engineering at the University of Illinois, in his paper before the Boston convention of the Society for the Promotion of Engineering Education in 1912, emphasized the fact "that changing conditions in industry and engineering demand the consideration of educators." B. W. Benedict, director of the shop laboratories at the same

*Instructors in machine-shop practice, University of Illinois.

institution, further stated in his paper before the same society at its meeting in Ames, Iowa, in 1915, that "the old formulas which served so well in the pioneer day of industry no longer fit in the new order of things, and failure on the part of educators to grasp the significance of the upheaval going on in the industrial world would be disastrous to the shop and correlative subjects" and, furthermore, that "industry in the past was effective, but not efficient."

In compliance with these convictions a standard product of manufacture in the form of an 8-hp. two-cylinder four-cycle marine-type gas engine was adopted as a product of manufacture at "Illinois." All the parts of this engine, with the exception of the timer and a few auxiliary parts, originate and are developed in the proper correlative departments. The work of the shop is carried on in a rather intense manner, the object being not to attain quantity, but to illustrate the method of modern and scientific manufacture and to give actual practical problems for solution in each department.

Work Over Report

John Doe
Inspection Asst

FIG. 3. SPECIMEN INSPECTION CARD

It records the result of the inspection and indicates what corrections, if any, must be made in work that has failed to pass

One of these problems is inspection. Each of the four departments (pattern, foundry, forge and machine) maintains its own inspection department. The object of this instruction in inspection is fourfold—first, to illustrate methods of modern inspection; second, to insure the rejection of an imperfect part before a succeeding department has expended labor upon it; third, to prevent an imperfect part from finding its way into the finished product; and, fourth, to furnish data for calculating each student's efficiency and grading his individual work.

Pattern Shop and Foundry Inspection

In the pattern department each pattern is inspected for defects of dimensions according to drawing figures, defects in quality and color of painting according to color table specifying a particular metal, defects in glued joints and in shrinkage, draft and finish allowances. Core boxes and core prints are compared with the pattern, to insure proper matching. It must be noted whether dowel pins and rapping plates are sufficient and properly located, fillets sufficient in size and securely held and pattern number correct and securely attached.

In the foundry the raw materials are subject to such inspection as will guarantee the proper selection of molding and core sands, core binders, flasks, fuel and the raw metals. The molds are inspected before they are closed, to insure properly tamped sand, cleanliness of mold, proper setting of cores, venting and location of chaplets. Gages are used to test the accuracy of the cores, thus eliminating filing and fitting by the molder. The mixtures and the temperature of the pouring metal must pass inspection before the metal may be poured. Knock-out and a trimming inspection are made to avoid the cleaning of an imperfect casting. The first casting from the pattern is checked with the drawing, to determine if shrink and finish allowances are correct. The following questions are tabulated, and each casting is checked for each item before it is delivered to the machine or assembly department:

FIG. 4. A TYPICAL INSPECTION CARD

There are 167 of these cards standardized for inspecting the main parts of the engine

(1) Is the material the kind specified? (2) Are cores and core rods properly removed? (3) Are castings properly cleaned and chipped? (4) Are there any overlapping parting lines? (5) Do any cold shuts or shrink cracks exist? (6) Have any of the cores shifted? (7) Are there any sand or blow holes? (8) Does the casting have a solid and nonporous appearance? (9) Has there been any filing, painting or calking done to cover defects? After each casting has passed these requirements, it is further tested with templets and solid fixed gages for accuracy of important "close" and "finish" dimensions. The final inspection is entirely on the quantity delivered to the machine or assembly departments.

The inspection of purchased materials plays a large and important part in the forge department. All bars, tubing, sheet metals, etc., are examined for both quality and quantity. The various grades of steels are marked and tabulated according to composition. The finished

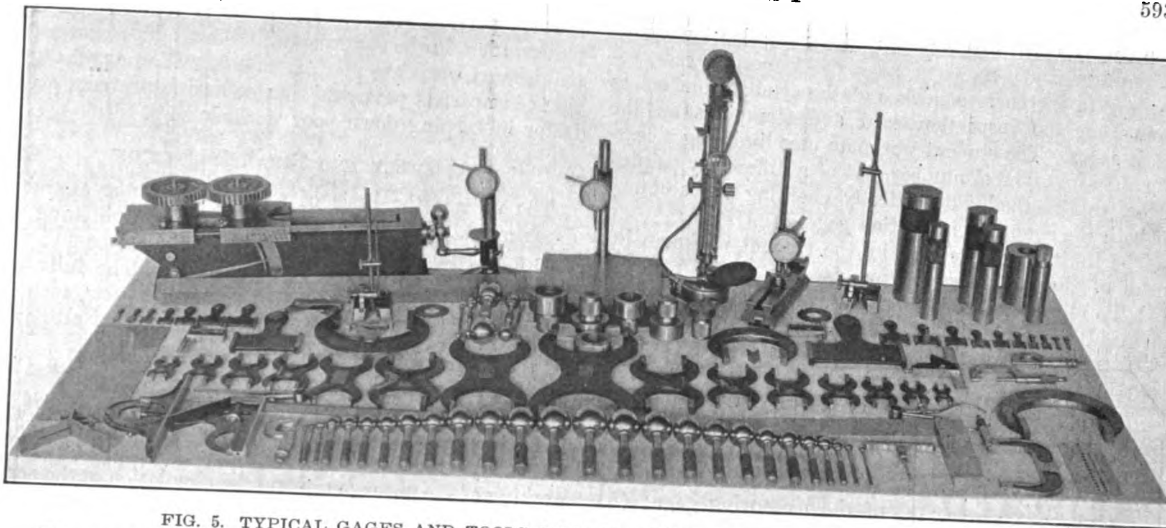

FIG. 5. TYPICAL GAGES AND TOOLS USED FOR INSPECTING THE STANDARD PARTS
The gear-testing machine, scleroscope, celluloid templets and dial gages are clearly shown. Each tool bears a symbol number, the corresponding number being specified on the shop instruction and inspection cards

forging is examined according to the following questions: (1) Is it made of specified material? (2) Are there any pipings or seams? (3) Are there any faulty welds? (4) Was the metal overheated to such a degree as to leave any burns? (5) How do the dimensions compare with those of the drawing? (6) Is there a sufficient allowance of metal where the forgings have to be finished? (7) Do the templets and gages fit properly? (8) Are there any cracks or is there any warping of annealed or hardened parts? Samples of annealed and hardened pieces must be taken from each heat and tested for hardness with the scleroscope, according to the adopted standards of the Society of Automobile Engineers, before these pieces are delivered to the machine or assembly departments.

The machine shop necessarily requires a larger inspection department than does any one of the other three mentioned, owing to the numerous operations and extremely accurate dimensions required on many parts. It is necessary to bring out, and often to use, one or more of the following styles of inspection: (a) First piece, (b) selective, (c) operation and (d) final; the nature of the part and operation determining which style or styles must be used. These may be applied on the floor, at the machine or in the inspection room, Fig. 1. The operation and inspection-room styles play an important part in the college shops.

Assuming that a student is assigned to grind a lot of five pistons, he is directed by his work-order card to the machine, where he finds his stock in the tote-box. On the outside of the box is a card holder bearing the letter of the section and the "move" card, Fig. 2, properly filled out. Since grinding is the fifth operation, we find the grinder number indicated in the corresponding fifth-route column.

On the completion of the five pistons the student secures another job. The routing assistant takes the pistons to the inspection department, where he reverses the "move" card, bringing the "inspection" side front, Fig. 3. This is an indication for the inspector to examine the pistons.

The inspector turns to this particular stock number in his inspection book and inspects the items *G* and *H* under the operation No. 5, as shown by the inspection instruc-

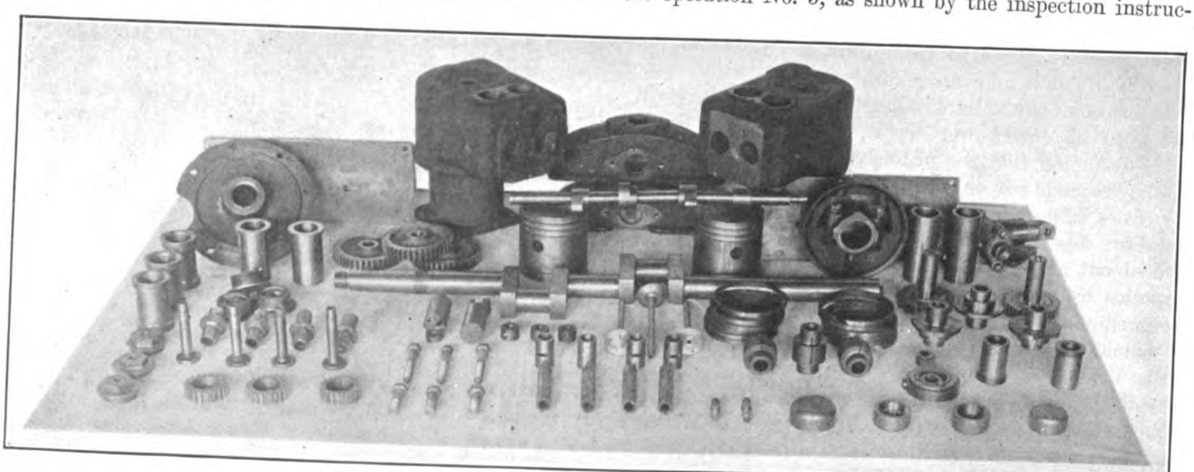

FIG. 6. TYPICAL SET OF PARTS FOR INSPECTION
Each embryo student inspector is required to inspect and report the errors in this set. The pieces are improperly finished gas-engine parts

tion card, Fig. 4. He looks for the inspection tools, Fig. 5, required and gets them from the inspection case, according to the correspondence of the symbol numbers as shown on the inspection card and stampings on the limit gages. The student workman uses limit gages bearing the same symbol number, but of a differently painted color, this method automatically checking the accuracy of both the shop and inspection gages.

The limit gages are used by the student workman instead of the customary micrometer for several reasons: (1) To eliminate the personal judgment of "feel"; (2) to avoid the accidental use of a strained or inaccurate micrometer; (3) to save the micrometer from rough usage, thereby avoiding frequent testing for inaccuracy; (4) to increase production by eliminating the adjusting of the measuring gage; (5) to obviate possible mistakes due to setting or reading a micrometer inaccurately.

DATE INSPECTION ASST.

FIG. 7. DEFECTIVE WORK TAG

Each part found defective, due either to material or workmanship, is tagged with one like this. Replacement orders are placed according to the tabulated information given by these tags.

The grade of finish required is designated by one of the finish symbols; for instance, *B2* calls for a "smooth machine-ground" finish. That the new inspector may acquire a degree of confidence, skill and judgment and at the same time become familiar with the instruction book, he is required to inspect a few sample parts.

A few of the engine parts, Fig. 6, have been purposely machined to prevent their coming to required dimensions. Some such imperfect pieces for inspection are too large, others too small; some have parts out of round or threads cut left hand instead of right hand. General appearances in finish and polish are usually correct, in order that the student may have some idea of the requirements. It may be noticed that there were originally six pistons in the lot, but that one piston failed to pass the inspector on operation No. 3. Had the failure to pass been due to an oversize dimension, the inspector would have indicated that fact on his "work-over report," Fig. 3. Assuming that the piston was beyond redemption on account of the groove s being turned too deep, the inspector tags it with a rejection card filled out as shown in Fig. 7. Parts spoiled by wrong workmanship are so tagged and placed in plain view of the shopmen. The psychological effect of the display is believed to decrease the spoilage. The tags are collected, and the information recorded on them is tabulated. Replacement orders are placed per information on thees cards. After inspecting the last operation of a part, the inspector directs correctly finished parts to the storeroom. The routing assistant places orders in the storeroom as the assembly department requires. Curves are plotted, Fig. 9, section against section of imperfect parts, this device having proved a great factor in keeping down poor workmanship.

Assembly and Final Inspection

The unit is the basis of assemblage in the assembly department. Each unit is inspected for tightening of nuts and bolts, form and location of oil grooves and for assurance that no part has been omitted. The fully assembled engine is inspected for the missing parts, such as oil cups, priming valves, etc., and to insure that all parts are securely and properly held.

The final assembled engine is next subject to a test or inspection under its own power in the testing department. Here, the heat of the bearings, the valve settings, etc., are accurately examined and adjusted if necessary. The working of the water pump and the circulation of the cooling water through the cylinders are carefully observed. After the bearings are sufficiently worn, the engine is coupled to the dynamometer, as shown in Fig. 8, a brake-horsepower test is made, and the curves are plotted under various conditions. Later, the engine is inspected for filling and painting and for shipping finish on polished surfaces. In shipping inspection it is necessary to see that polished parts are properly covered with nonrusting preparations, that the name plate is correctly stamped and securely attached, that the engine is suitably crated and that all the specified loose parts are securely packed. A few of the vital parts of the engine are periodically selected at random and taken to the physical-inspection department. Here they are placed in a 20,000-lb. testing machine and tested for tensile, compressive and bending strength.

The reader no doubt realizes that the inspection of the standard product is only a small part of the general inspection problems and that the necessity and methods of inspecting equipment, forms of belting, oils, machines, special tools, jigs and fixtures, safety devices, fire protection, sanitary conditions, transportation facilities, etc., present problems worthy of the closest consideration.

In conclusion, it may be well to state that the inspection department should be entirely separate from the production department. The chief inspector should have

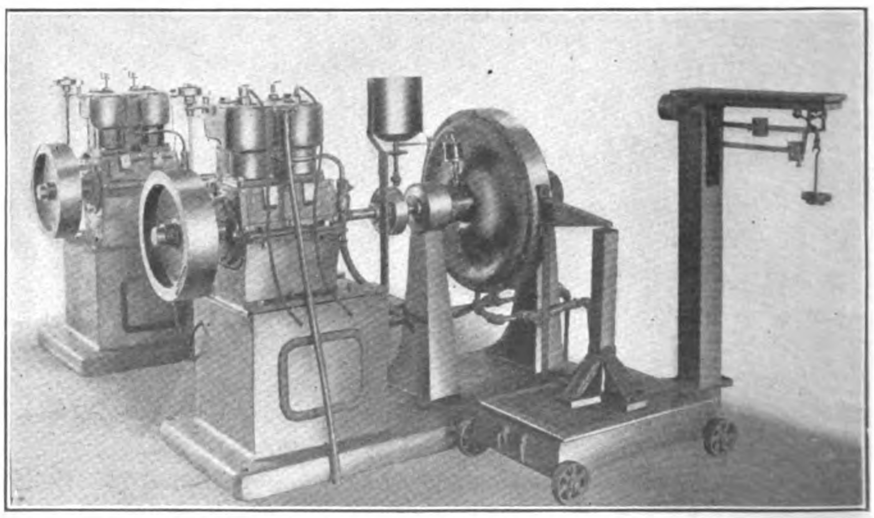

FIG. 8. VIEW OF THE TESTING BLOCK

Each engine is coupled to the Richards hydraulic dynamometer, which is bolted on one end of the test base

absolute and final say as to whether or not a part comes up to specifications, he alone being responsible for this matter to the general work manager. To be a good inspector, a man must work with the production department, not

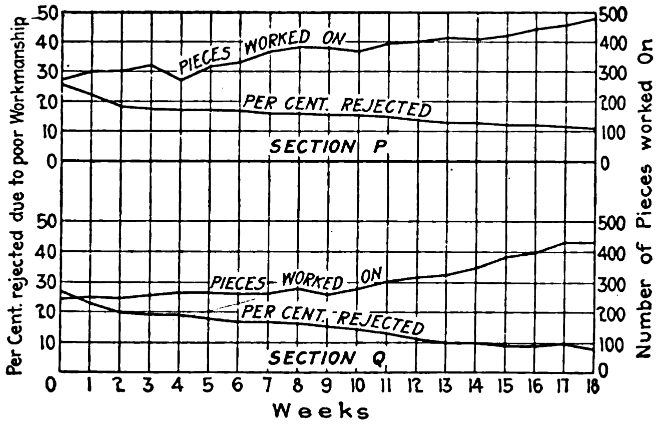

FIG. 9. SPOILED WORK REPORT

Curves similar to these are plotted weekly for each section or shift and posted in a conspicuous place. The rivalry created between sections to keep down the spoilage and increase the production more than warrants the expense for upkeep of the curves

against it; he must be a good mechanic and must be decisive in character; he must be even-tempered, firm, fair-minded and—a gentleman.

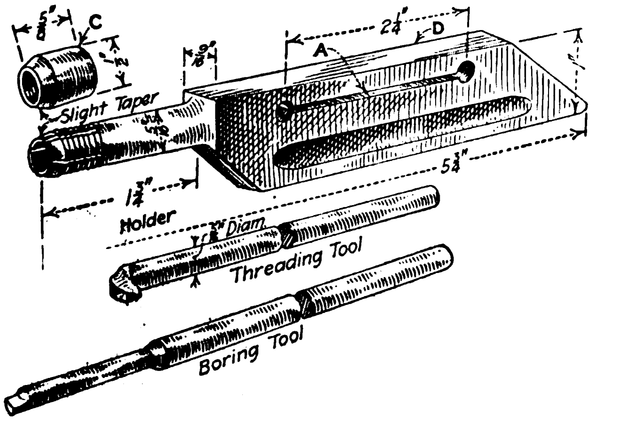
Boring-Tool Holder

By H. M. Darling

The tool holder in the accompanying illustration is intended for tool makers' use. It saves using clumsy, inefficient forged tools for light, accurate boring operations in the lathe.

The holder is made of tool steel, hardened and drawn to a spring temper. A $\frac{5}{16}$-in. hole passes clear through it lengthwise. At A is a $\frac{1}{8}$-in. slot, $2\frac{1}{4}$ in. long. The tapered nose B is split by four $\frac{1}{32}$-in. saw cuts.

The tools are made of $\frac{5}{16}$-in. drill rod. In use, one of these tools is inserted in the $\frac{5}{16}$-in. hole, with the cutting point projecting the proper distance. The knurled



TOOL HOLDER FOR LIGHT BORING OPERATIONS

nut C is screwed tightly on the tapered nose B, thus securely clamping the tool at that point. The holder is then placed in the tool post of the lathe. The tool-post screw clamps tightly at about the point D. The slot A permits considerable spring in the holder at this point, which causes the tool-post screw to secure the inserted tool very tightly. Thus, a boring tool is made as rigid as, and much more useful than, a forged tool.

Sammy's Shop—Time Keeping and Cost Keeping

By W. Osborne

Sammy did not really own the shop, but it was the place that he had possession of in his working hours to make a living in. It was a little shop, and Sammy was the foreman. A number—yes, a number of men and boys—worked there, and Sammy was the responsible working head of the working force. Mr. Brown, who owned the shop, expected Sammy to know enough to have things done right and material used right; and all matters of discipline were turned over to him.

If an employee came in late and Mr. Brown saw him, it was put up to Sammy; if a customer did not like the way his job was done or the size of his bill, it was put up to Sammy; and if a workman did not like the work he got or the amount of his pay, it was put up to Sammy; and if—but space is scarce, and some of you know the kinds of things that are put up to a fellow who is between the upper and the lower millstone, or the devil and the deep sea, or something like that, and they were all put up to Sammy.

You see, it was a little shop, and Sammy was the only one that there was to put these things up to, and so they came up from the bottom and down from the top. Really, though, Sammy was not much of a foreman; he had not served time enough to learn the business. To tell the plain truth about him, he had never served under instructions at it. It was a good thing for him that it was a small shop without much experience, either.

Mr. Brown wanted to make money from the shop. He took work from anyone that came along and made cornshellers or things like that, too. Each workman filled in a little slip of paper each day, to show what he had been doing. The time book was filled in from these slips, and the customer was charged from them. Sammy took these slips and looked them over enough to see that they stated facts. Then Mr. Brown did the rest of the office work with them.

Mr. Brown was a real captain of industry, for he spent all of his time with that shop. He could go out and hunt for work, and often hunt harder yet for the money that paid for it, attend to all of the office work and lend a hand in the shop when he was needed—and some fellows used to think that he lent a hand at times that made it embarrassing.

These things made him competent to ask a lot of questions about the work and the time it took to do it and all that sort of thing. Sammy soon found that he had to know how long it took to do each of the jobs that were done more than once, and of course that applied to all of the parts of the cornshellers. Sammy had a lot of things that he carried in his head and lots more that he put into private notebooks.

The shop grew—the corshellers were good ones—and Mr. Brown got so busy selling them and doing other things that he hired a bookkeeper. Then he began to ask the bookkeeper all sorts of questions about costs that the bookkeeper did not know anything about, but which it embarrassed him to have Mr. Brown ask for.

At first it seemed very easy to get the cost on a cornsheller. All one had to do was to charge up all of the material, labor and other things and add it up, and there

it was. Mr. Brown very readily called the bookkeeper's attention to it. In fact he called the attention of several bookkeepers to it. It seemed strange, but somehow bookkeepers did not get up much enthusiasm along that line; or if they did, it did not stay with them. Some of them got figures that were too good in results to be true, and some got figures that were too bad in results to be true, and some got only figures, without getting results.

Finally, one bookkeeper explained to Mr. Brown that cost getting required a cost keeper and not a bookkeeper. Mr. Brown was willing to agree, from his experience, with the last part of it. He got a cost keeper. Mr. Brown at once understood that a bookkeeper and a cost clerk were entirely different. The salary account showed it to him.

Sammy began to have troubles of a new kind. For a cost keeper to operate, he must have information. This information must come to him in a way that he determines. It *must* come to him. It *must* be in the form that he says. This is reasonable. As steam is to a steam engine, so is proper information to a cost keeper; and the supply should be regular and constant, just like the supply of steam to the engine. Sammy got his kind of information from the time slips. He thought that the cost keeper should be able to do the same. No, No! They were primitive, inadequate and some more things, but they were no good.

Sammy found that the shop now had two bosses. The one that must be pleased was the one that required the new records, and Sammy found that the records kept by himself—the boss who had to get out the work—showed not as well as they had been doing. He at once contended that the difference should be charged to cost keeping. He was shown how ignorant he was of such things; but not being able, or willing, to understand, there was nothing for the cost keeper to do but declare war against him. Then Sammy thought he had to fight back. Mr. Brown was drawn into the matter and was forced to give some attention. Fewer cornshellers were now being built by the same number of men working the same number of hours. Sammy said that it was caused by the records taking so much time and attention.

The cost keeper said that the shop had been running slipshod before, that the men did not like system and were trying to queer his work. Sammy asked Mr. Brown to fill out the records and time himself. The cost keeper explained to Mr. Brown that, if the shop was run as a shop should be run, fewer records would be needed. Sammy replied that he was not responsible for the way Mr. Brown got the orders. He would be very glad to have them come in bunches, but so far they never had.

Mr. Brown could not understand why cost keeping needed to interfere in any way with getting out the work. Sammy and his force were to get out the work. That was what they were there for. The cost keeper had been put on to give certain information that was needed by the sales department and was entirely separate and apart from the doing of the work. If the cost keeper needed more help, he should get it; and it should be subject to his orders and to his only.

To carry out such a plan, the cost keeper put on a clerk who went around once an hour and made records. It was very hard to get a man who could do this. A man who was clerk enough to do it would be without shop experience and mix things up. A man who had shop experience would not be clerk enough. Many ways were tried. Many men were tried. Many cost clerks were tried. Many systems were tried. The perfect cost keepers and the perfect systems were the ones that had not yet been tried. All of them had good points, and all of them had bad points.

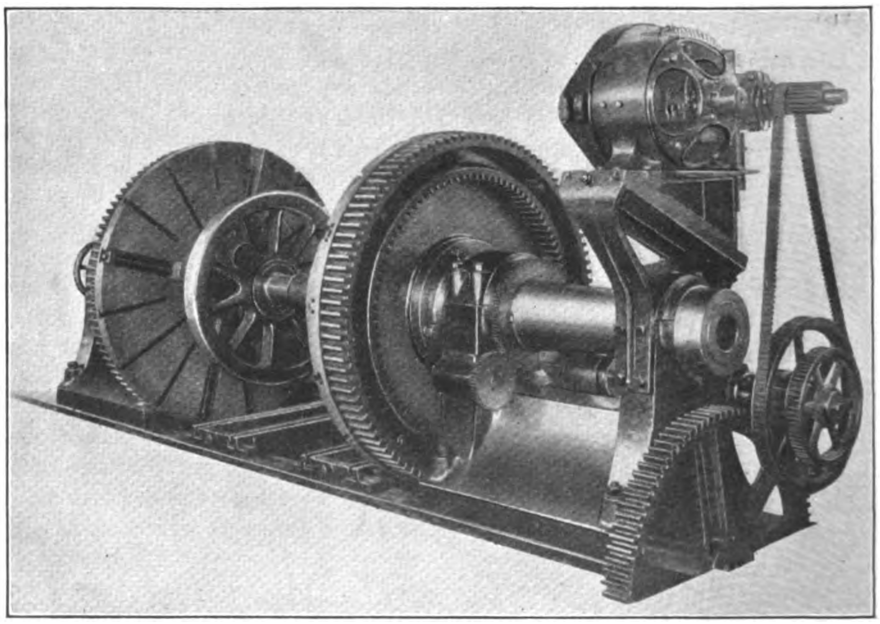
Mr. Brown has acquired a nice library that tells of many systems and is now using a sort of mongrel system that is full of faults and does not please anybody, but is the best compromise that he has been able to work to fit the shop conditions that he is able to supply. Perhaps if he had nerve enough and money enough, he could make some of these other systems work much to his profit. Sammy has not seen any system that is as good as his own for helping him get out the work.

First Wheel Lathe in Brazil

The illustration shows what is believed to be the first wheel-turning lathe that went to Brazil. It is of Niles-Bement-Pond make and was shipped in 1902 to the shops of the Mogyana Ry., at Campinas, in the State of Sao Paulo, Brazil.

The superintendent, Charles Stevenson, has introduced individual motor drive on nearly all his large machines, the method of applying it in this case being clearly shown at the right. The motor bracket is fastened to the outer bearing support and has an incline on which the motor base is supported. This arrangement makes it easy to adjust the different distances between belt centers so as to take up any slack, by simply moving the motor up or down the incline.

The motor is geared to the driving pinion shown, and two ranges of speed can be obtained.



THE FIRST WHEEL LATHE IN BRAZIL—INSTALLED IN 1902

Machine-Shop Small Tools*

By W. Rockwood Conover†

SYNOPSIS—An outline of the economic considerations underlying the design, making and stocking of small tools in the machine shop. Importance of insisting that wornout or broken tools be returned before new ones are issued is emphasized. The recutting of files is referred to as a questionable economy. It is pointed out that the standardization of tool heat-treatment is of vital importance to the manufacturer.

To discuss the subject of tools from the standpoint of the tool specialist would require a volume devoted exclusively to it. The subject offers opportunity, however, to suggest certain economies that may be effected through proper care and methods in the distribution and handling of tools, and to call attention to certain advantages, such as increased production and reduced labor costs, that may be gained through the installment of improved standard and special machine tools. To the manufacturer whose factory is not fully equipped with modern labor-saving tools or who has not already given the subject of equipment, care and use of tools exhaustive investigation and consideration, it is hoped some suggestion may prove of value and aid in saving no small percentage of waste and loss during the year.

In large manufacturing plants, and in those of lesser size as well, the central tool stockroom, under the supervision of a competent person, provides for the limitation of orders to a point within the demands of the several departments. It also permits the purchase of standard tools in such quantities as will secure the lowest market prices and prevents the accumulation of excessive stocks of duplicate tools in the various shops. In general, the keeping of tools in individual departmental stockrooms, except such standard tools as may be in frequent or constant use or such as are specially designed or purchased for specific purposes within the department, is uneconomical and tends to waste.

All orders from the department foremen for standard tools or special tools to be purchased from outside manufacturers and dealers should pass through the hands of the central toolroom keeper for his scrutiny and approval. A considerable percentage of these can be filled from stock on hand. It will also be found in frequent instances that orders placed by a foreman for tools for a new job can be filled with tools previously purchased for a partly, if not entirely, similar purpose, which are lying idle in some other department or shop and which may be adapted to the special work. The central toolroom keeper is in a position to know from his records whether or not such tools are on hand and to make investigation with the greatest facility and least delay.

All the tools of the individual shop department, except such as are in constant use, should be kept in the toolroom, arranged in systematic order so that they are easily accessible on requirement. It is bad practice to allow the workman to leave his tools lying about the benches or on the shop floor about his machine, awaiting another job requiring their use.

Special tools, such as special cutters, special hobs, etc., which have been ordered or made for occasional use in a given department, but which may be adapted to the work of another department, should be sent to the central toolroom on completion of operations, in order that they may be available for use wherever needed and save unnecessary duplication of orders either on the tool-making department or on the outside manufacturer. The same is true in reference to gages that are used only occasionally in a given department. Gages that are in constant use in any department may be kept to advantage in the toolroom of that department, but they should be sent to the central toolroom regularly at the end of each week for calibration or inspection. This practice will frequently avoid serious errors in dimension, which are otherwise likely to occur. Large special gages may also be retained to better advantage in the toolroom of the department where they are used, if not adapted to the work of any other department.

All standard-tool orders or applications presented to the tool stock-keeper by the workmen should be signed by the foreman and accompanied by the worn-out or broken tool that is to be replaced. This practice will prevent new tools being given out unnecessarily before the old have become sufficiently worn to require replacement. In the case of files there is always a tendency on the part of the workmen to obtain new ones before the old have become fully used or worn. If the worn file is taken to the foreman with the order to be approved, it gives the foreman opportunity for inspection and rejection of the order, if deemed necessary.

All new tools furnished individual employees should be given out on the check system and a record made of such delivery by the toolroom keeper. Each new employee engaged should be provided with a sufficient number of checks to obtain from the central toolroom a complete set of such tools as he requires for his work. On leaving the employ of the company his quit blank is checked with the record and bears the signature of the head tool-keeper, as evidence that the tools supplied him have been returned to the toolroom.

Designing and Making New Tools

In the making of new tools there is a large field, practically without limit, in which the designer or specialist may accomplish many important economies. The manufacturer who is confident that his tool account is already reduced to the lowest limit possible to attain and that his equipment is all that could be desired will find in frequent instances that tools of a different style, shape or dimension from those he has been purchasing, or from those previously made and in present use, are possible of design, which will not only do better work, but permit increased speed and consequent increased productive output. While these cases may not always be readily discovered by the average shop foreman, it is here that the man specially fitted and trained will, through long experience, effect many valuable substitutions.

*Prepared for the author's forthcoming book on "Industrial Economics." Copyright, 1916, Hill Publishing Co.

†Factory economist, General Electric Co.

The making of new tools should always be covered by a separate shop-order number or job number, against which all labor and material can be charged, in order that an accurate cost may be obtained. These data are valuable also in cases where it becomes necessary to make duplicate tools for the same purpose or similar tools for other purposes and are frequently the means of effecting a reduction in the amount of time required for the work.

It is often advisable to have one or more tool makers located in each department for doing work that can be more advantageously attended to close at hand, and also where frequent trying of samples or repeated fitting is required in the making of special fixtures or tools. This is equally true in the case of repairs, which, more often than otherwise, call for immediate attention. Although tool designing and tool making are in the largest degree specialties, there are many simple tools and appliances for facilitating his work that can be made by the average mechanic at a much lower cost than by the high-grade tool maker; and much valuable time may thereby be saved and long stoppages of machine tools be prevented.

Draftsmen as Tool Department Assistants

One or more draftsmen should always be located in the main, or larger, tool-making department as assistants to the tool foreman. The value of this suggestion is evident. Frequently, the shop foremen requesting tools to be made are able to furnish a rough sketch only, with oral explanations as to what style of tool is wanted or the work it is desired to do. These rough sketches should always be reduced to working drawings before they are turned over to the tool maker. It will quite often be found during the process of making these drawings that important changes can be substituted that will not only reduce the cost of producing the tool itself, but that will render it of better and more practical service to the department ordering it.

The employment of a draftsman is also necessary for doing a large amount of sketching or drawing in connection with various tools which the foreman of the tool department may design for new work or to increase production or for changes and improvements that may be discovered possible in tools already in use in the shops. A correct working drawing or sketch placed in the hands of the tool maker saves a large amount of time, which is usually wasted in studying rough pencil sketches, and enables him to proceed promptly and intelligently with his work.

It is well to divide the work of the tool department, assigning separate gangs of men to the various processes of machining—such as operations on lathes, shapers, surface grinders, boring mills and planers, millers and universal grinders—and other groups to the processes of finishing and assembling. By following this practice the machine tools are kept more nearly constantly busy and the work of the department is conducted more economically as a whole.

Regular weekly or monthly reports, showing the amount expended in the various departments, both for tools made and for those purchased or drawn from stock, should be furnished the central tool-keeper, the superintendent and the foremen of the shops. These statements should be prepared in comparative form, so that any increase in one period over another will be readily discovered. Data of this character in conjunction with reports on the direct labor output will be found valuable in revealing any excessive consumption of tools that the rate of production does not warrant. Consideration must be given to tools made to increase production or for closer precision or for special processes, which would tend to increase the consumption above the normal average.

A report of the labor and material charges on special shop orders for new and special tools, replacements, repairs, etc., which have been issued on the request of the foreman, should be sent to the superintendent weekly, as the charges appear on the payroll and in the accounting department. This system gives him an opportunity to follow up the cost of all such tools to see that they are built to the best advantage and that the expenditure does not exceed the original estimate which he has approved.

A most important feature in the economic control of tool stocks and tool consumption is that of keeping a card record in each department of all tools made or purchased for the department, except such tools as standard drills, taps, cutters, etc., which are kept in stock for frequent renewals on standard work. The reasons for this are evident. A proper record of each tool made or purchased enables the foreman to know, without loss of time or delay in searching, whether he has on hand the necessary tools to produce any specific piece of apparatus or to perform any individual set of operations. It will also prevent the making unnecessarily of duplicate tools, not only in his own department, but also in a contributing department, when such contributing department is called upon to furnish him with some part or all of a given line of work. The card record should show the drawing number, part number, name of part and number of shelf or bin in the toolroom where each tool is kept and such other classifications as may be necessary to designate it fully for accurate and rapid reference. Without such systematic keeping and recording of tools the manufacturer is subject to constant loss of time and delay.

Stocks of Duplicate Cutting Tools

A sufficiently large stock of duplicate cutting tools of all the various shapes should be carried in the central toolroom to supply all departments promptly on request and upon the return of the worn or broken tool.

Blueprints illustrating the different styles or shapes of cutting tools in use in the factory, each individual type having its own separate number, should be placed in the foreman's office of each machine department, where they will be accessible for ready reference. The workman can thus select the particular style of tool he requires and order or procure the same by messenger from the central toolroom by its identification number. This system is an excellent one. It avoids confusion of orders and precludes the necessity of the workman's leaving his machine and consuming valuable time in going, himself, to the toolroom to select the particular shape he desires.

There is always a tendency to accumulation of lathe and planer cutting tools about the workmen's machines and tool cabinets on the machine floor. Frequent investigations should be made and all tools not in use returned to the central tool stock department or to the forge shop or grinding room for repointing and sharpening. The desirability of following this practice in shops where high-

speed steel tools are in use is emphasized by the relatively greater cost of these steels.

The grinding of tools, particularly in large machine shops, is an important item of expense and deserves consideration. Whenever practicable, this work should be centralized as much as possible. Under this plan the number of grinding machines, and the number of grinders as well, may be limited more nearly to actual requirements; and the men will naturally become more rapid and proficient in their work.

Most skilled workmen prefer to do the final grinding on their finishing tools specially for the work they are doing, in order to obtain a special angle or one best suited to the particular cut they wish to take. The preliminary work on these tools, however, up to the point of the final operation, should always be done in the tool grinding room by the regular force of grinders assigned to the work.

There is also a large class of workmen capable of performing certain machine operations or of operating one or more machine tools, who are not practical or skilled tool grinders. Because of this fact they are often unable to take the full depth of cut possible without overheating the tool. Tools improperly ground not only give unsatisfactory results, but require more frequent grinding, which tends to increase the expense of the department. They are also a frequent cause of increased labor costs. The grinding of roughing-out tools, milling and profiling cutters, counterbores and similar jobs can be most economically done in the tool grinding room, and the leaving of machines for this purpose by the workmen should not be permitted except under some special and unusual condition or requirement. All cutting tools for each of the various classes of lathe, planer and boring-mill operations should be kept ground in the same shape, so far as the preliminary portion of the work is concerned. They should not be ground in irregular or special shapes to suit the peculiar judgment and ideas of the individual workman.

The central grinding room should be connected with the central tool stockroom and should be located within as convenient distance as possible of all the departments of the plant.

Importance of Proper Hardening and Standardization of Heat-Treatment

The operation of hardening tools should receive careful attention. Tools that have been too highly tempered are liable to breakage, and this should always be kept in mind when new tools are made or partly worn tools are reshaped or repointed. Different qualities of metals require varying degrees of hardness in the cutting tool, as in high-carbon tool steels as compared with the softer grades of steel. In like manner tools cutting yellow metals and tools operating on cast iron would, in general, require different heat-treatment.

The standardization of different heat-treatments for different types of tools is therefore of vital importance to the manufacturer. So far as present knowledge goes, it does not appear probable that a standard practice can be set up which could be advocated as capable of general or universal application, because of the variation in physical conditions.

The carbon properties of the steel of which the tool is made, the tensile strength and hardness of the metal to be cut, the conditions of operation must all enter into the character of the heat-treatment. Certain grades of high-speed steel can be preheated with good results at a temperature of 1,300 deg. C. (2,370 deg. F.) and drawn back after quenching at a temperature of 450 deg. C. (840 deg. F), while other steels would require treatment varying in degree, according to quality and conditions. Some of the ordinary grades of carbon tool steel commonly used for lathe centers, chisels, etc., may be preheated at 775 deg. C. (1,425 deg. F), and drawn back after quenching at 550 deg. F. These temperatures, however, cannot be set down as universal guides in practice.

The Influence of a Few Degrees Variation in Quenching and Annealing Temperatures

The exact point at which different heat-treatments can be carried out with the assurance of obtaining satisfactory results is difficult of determination and requires the most critical analysis and observation. A few degrees of variation in the quenching and annealing temperatures influence the results to a vast extent, as represented in the great physical differences that are observed.

Certain physical changes develop in the material itself at various stages of the process, which render it vitally important that these points of change be recognized and recorded. If we conduct the treatment to a point either above or below the critical point, modifications in tensile strength and hardness are certain to be produced. Experience demonstrates that the size of the material must also exert an influence on the results obtained.

It appears evident therefore that, in general, it is necessary for the individual manufacturer to establish such standards as will most satisfactorily and scientifically meet the conditions and requirements of his own shop. Also, in purchasing high-speed steels for making tools it is obviously essential that effort be made to obtain steel of uniform quality, as far as possible.

Recutting Files a Questionable Economy—Improper Tool Setting a Cause of Breakage

Recutting of files, which is a more or less common practice, is open to question as a matter of economy. The cost of freightage (usually large where the manufacturer is located at a distance from the file makers), added to the price of recutting, precludes any very considerable saving over the purchase price of new files. Files that have been discarded by the workman as unfit for further use can be cleaned by dipping in acid or by sand blasting, and this practice is followed by some manufacturers. It must be borne in mind, however, that the best quality of the file has been utilized during the first stage of its service, and it is therefore of relatively less value for efficient duty.

The improper setting of tools is often a frequent cause of breakage, and the operator, in addition to seeing that his tool is properly set, should make sure that the tool holder is in good condition, in order to avoid breakage from this source. The incompetent or careless workman is a constant cause of unnecessary expenditure; and the foreman, when selecting his machine hands, should give special attention to the matter of proper care and setting of tools and should make these two of the chief requisites for entering service in his department.

Tact in the Machine Shop

By Robert J. Spence

Very little tact is used in the shop. As a rule, we are a blunt, outspoken lot among ourselves. Very many unpleasantnesses, ill feelings and budding enmities might as easily be avoided in the shop as elsewhere by the display of tact. But some way or other, in our factory life we use a different set of rules in this respect than we do in our outside social life. Many a good man has been lost to a shop through lack of discernment on the part of the foreman, when a little skill in the choice of words would have conveyed the proper reprimand without arousing the workman's ire.

If a man has spoiled his first piece of work in six months, his future interest in the company is not improved by the foreman's raucous voice yelling at him from the center of the room: "You, Bill, can't you read a scale? If you can't do any better than this," (holding up the piece for all to see) "go get a job tarring roofs." Instead, a simple statement from the foreman, letting Bill know that he had found a spoiled piece, would have been sufficient.

One time a few cents were taken from my pay envelope for two small spoiled bushings. If I live to be one hundred years of age, I believe the untactful deduction will still rankle. If the job I was on had not been a stepping stone in my plans for the future, I should have left on the spot. As it was, my interest in the company thereafter was purely a selfish one.

Idiosyncrasies of Workmen

Nearly every workman has his idiosyncrasies, and the foreman who has the rare commonsense to overlook them, to an extent, without compromising himself or the company, will have a roomful of men coöperating with him. I remember one young toolmaker who pasted a few camping pictures on the inside of the cover of his tool chest. Whenever the chest was open, the pictures could be seen; but the young fellow never lost time looking at them. One day the foreman tore the pictures off. After a few heated words, in which they both lost their tempers, the young man packed up his tools and quit. A few years later this same young man was given a position in a neighboring city, where he needed a few good tool makers immediately. Naturally, he sought men whom he knew, with the result that he acquired the services, under contract, of the majority of his old shopmates; and the poorer tool makers, who remained with his old firm, had to be paid higher wages to be retained.

Tact is the peculiar skill of appreciating and accomplishing whatever is required by circumstance, in the shop or out of it.

Every man looks forward to a raise in pay. If he does not, he is not the man you want. This common trait in human nature offers a big target for the exercise of tact. A tactful voluntary raise of even ten cents a day, at intervals, is a judicious thing and goes very far toward promoting the best of good feelings.

Tact will get more out of men than driving or threatening in machine-shop work, or in fact in any work requiring the same high degree of intelligence. The day of the driver has gone. The value of tact has become so well recognized that employers give it an equal consideration with talent in choosing their shop foremen. Tact does not require profound wisdom or great talent. Neither is it a studied attainment. It is simply the exercise of horse sense to fit the occasion.

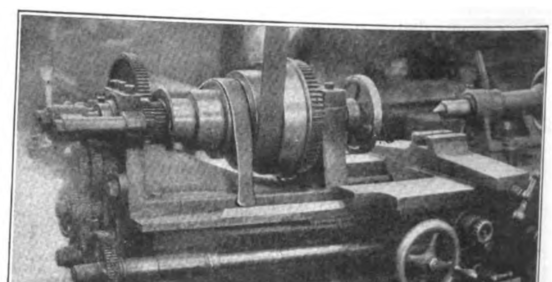
The brightest incident of original tact that I ever witnessed occurred in a small model-room adjoining a toolroom in a fair-sized factory. This model-room was the acme of cleanliness. The four men took pride in the appearance of the bench, the machines and the floor. The floor was always well scrubbed by the men themselves; but every time the owner of the factory came into the room he spat on the floor, not only once, but often. Being an eccentric man with sudden flashes of temper, the workmen hesitated about roiling him with regard to his disgusting practice. Possibly it meant the loss of a job; maybe it did not. At any rate, the gamble was a little too uncertain. They were afraid to ask him to refrain from spitting on the floor.

One day he entered the room and, according to schedule, expectorated as usual. The toolroom errand boy happened to be near. Then occurred the bit of tact to which I refer. Quickly taking a piece of chalk from his pocket, the errand boy stooped and with a deft motion drew a significant circle on the floor around the offending spit. The owner of the factory looked at the boy, looked at the circle, looked back at the boy, but said nothing. He never spat on the floor again.

A Time-Saving Simple Brake for the Lathe

By H. D. Holcomb

In studying and analyzing the individual operations performed in one of the largest industrial plants in this country it developed that over 10 per cent. of the lathe operator's time was lost, or wasted, on account of the length of time he waited for his lathe to stop after shutting off the power. This lost time was not so noticeable in the lathes that were driven by individual motors, but the majority of machines were driven from the main shaft by belt and the ordinary tight and loose pulley and belt shifter. At first it was thought necessary to equip each machine with a power brake, but one of the workmen solved the problem in the inexpensive manner shown in the illustration, which has been found a time-saver under practical conditions.



SIMPLE BRAKE FOR LATHE

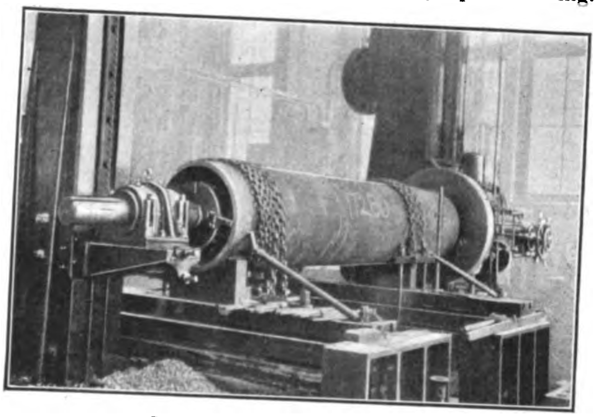
An old piece of leather belt is fastened to the back gear shaft; when it is desired to stop the machine, the piece that hangs over the front part of the lathe is given a slight pull.

Letters from Practical Men

Boring a Steel Casting

One of the awkward jobs that come to a machine shop doing general work is machining the inside surface of a cylindrical casting.

The accompanying illustration shows the machining of the inner surface of a cast-steel dredge-spud covering.



BORING A STEEL CASTING

This casting was machined 30 in. in inside diameter and 14 ft. in length over all. It was fastened to the blocking of the mill by means of chains, in the manner clearly indicated in the picture.

The long boring bar and the tool head were part of the standard shop equipment, and no special apparatus of any sort was employed. J. WALTER SWAREN.

Hayward, Calif.

Two Thread-Cutting Wrinkles

Here are a couple of thread-cutting stunts that I have tried out with success as well as with a great saving of time—no cut-and-try method, no calipers required. In cutting a thread, instead of setting thread calipers to the bottom of the thread of the size plug and calipering for each succeeding cut, then trying on the nut a few times, all that needs to be done is this: Grind a thread tool to gage, swing the compound around to 30 deg. for V or U.S.S. threads, set the tool up to the work, and set the dial at zero. Now multiply the depth of thread to be cut by the secant of 30 deg., or 1.155, which will give the required distance to feed in with the compound.

Example—Cut 5 threads per inch. Depth = 0.130 U.S.S.; 0.130 × 1.155 = 0.150, the amount to feed the compound.

For Acme Standard or 29-deg. threads swing the compound 14½ deg. The depth of thread times the secant of 29 deg., or 1.033 equals the distance to feed in the compound.

Example—Cut 5 Acme Standard threads. Depth = 0.110; 0.110 × 1.033 = 0.114, the amount to feed in the compound.

In threading nuts the same rule will apply, except that the tool is to be fed out.

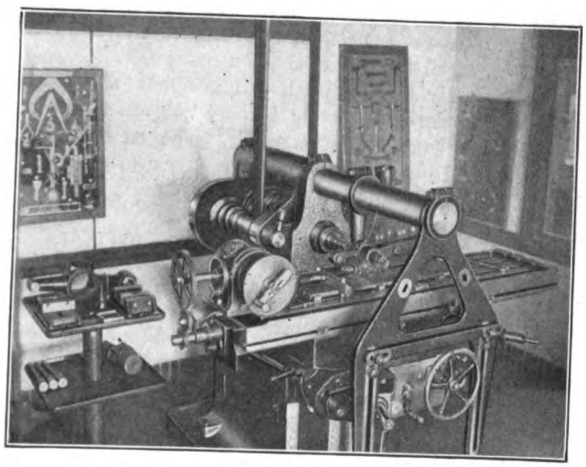
Another stunt I have tried: I saw a man cutting a triple thread and counting the teeth in the change gears to make the divisions. As he was feeding the tool in with the crossfeed screw, I suggested that he swing his compound around to 90 deg., set the dial at zero, cut his first thread, then advance the tool, using the compound one-third of the lead, which would be one-third of 0.333, or 0.111. Next, cut the second thread, then advance the tool, again using the compound one-third of 0.333, or 0.111, and cut the last thread. There is no fussing with gears, etc. O. F. PHILLER.

Beloit, Wis.

[With both of these methods dependence is placed on the accuracy of the compound-rest screws. These are seldom accurate.—Editor.]

Accurate Spacing of Rack Teeth

Anyone who has cut racks on a miller, using the graduated dials to get the tooth spacing (circular pitch), will agree at once that to get 0.3927-in. pitch on a long rack



ACCURATE SPACING OF RACK TEETH

or to get 0.2618 in. each time for 115 times is a difficult thing to do.

If, then, it is a hard job for a careful machinist, and you have to change men on the job every few hours, it is a safe bet that you would not get much perfect work.

Recently at Wentworth Institute we had about three dozen 12-pitch racks to cut 30½ in. long. After several different methods had been tried with very poor results, the following scheme was suggested by M. W. Hartmann:

A dividing head was placed on one end of the miller table, as shown, and geared up to the lead screw of the miller. In our case we used a ratio of 3 turns of the screw to 1 of the spindle in the head (84 teeth on the spindle and 28 teeth on the gear), but the computation

is much simplified by using a 4 to 1 ratio, as is shown later.

Given a dividing-head ratio 40 to 1 and a lead screw with ¼-in. lead, then

$$\frac{1}{40} \times \frac{3}{1} \times \frac{1}{4} = \frac{3}{160}\, in.$$

advance of table to one turn of the crank.

$$\frac{0.2618}{\frac{3}{160}} = \frac{0.2618 \times 160}{3} = \frac{41.888}{3} = 13.96266$$

turns of the crank for each spacing. To find the proper fraction equivalent to the decimal 0.96266, the easiest method is to look up a table of decimal equivalents of gear ratios. In such a table I found $0.9623 = \frac{51}{53}$. Now $13\frac{51}{53}$ turns of the cranks times $\frac{3}{160}$ equals 0.26179 in.

However, the lead screw itself averages 0.0005 in. long for each 6 in. of length, as found on final inspection at the factory. This would give an error of 0.0025 in. too long in 30 in. length of rack. By choosing a decimal slightly smaller than 0.9626—say, 0.9615—the pitch would be 0.261778 in., or 0.000022 in. short for each tooth. In cutting 115 teeth the total error would be

$$115 \times 0.000022 = 0.00253 \text{ in.}$$

short, which would compensate for the 0.0025-in. error of the machine screw. Since there is no 26 circle, we can use the 51 circle, as follows: 12-pitch; 13.9608, or $13\frac{49}{51}$, turns; error, 0.004 in. short in 115 teeth; net error, 0.0015 in.

This point of correcting for the error of the machine itself is put in, not because it is necessary to take such precautions in any ordinary work, but because it is just as easy to choose a decimal a few thousandths of a crank turn small in each case when one knows his lead screw is slightly long in pitch. It is almost always as easy and far more interesting to do a job exactly right than to slight even the little points. The racks we cut by the method outlined herewith were so nearly perfect that, after straightening, two could be meshed together, the teeth fitting in the entire length.

Using a 4 to 1 gearing ratio, we have $\frac{1}{40} \times \frac{4}{1} \times \frac{1}{4}$, or 0.025 in. to one turn of the crank.

For a 10-pitch rack, circular pitch 0.31416,

$$\frac{0.31416}{0.025} = 12.5664 = 12\frac{30}{53}\ turns;$$

error, 0.001 in. short in 96 teeth.

For an 8-pitch rack,

$$\frac{0.3927}{0.025} = 15.708 = 15\frac{41}{58}\ turns;$$

error, 0.0022 in. short in 76 teeth; net error, 0.0003 in.

For a 14-pitch rack, 8.9756 turns ($8\frac{40}{41}$); error, 0.001 in. short in 134 teeth.

For a 12-pitch 10.472 ($10\frac{16}{34}$) turns of the crank; 0.0041 in. short in 115 teeth; net error, 0.0015 in.

Having obtained the turns of the crank for accurately spacing 8-, 10-, 12- and 14-pitch, we can get the proper turns for 4-, 6-, 16-, 20- or 24-pitch, without even the slight trouble of the foregoing calculations, as follows:

For 6-pitch, $20\frac{32}{34}$ turns of the crank; error, 0.004 in. short in 58 teeth; net error, 0.0015 in.

For 24-pitch $5\frac{8}{34}$ turns of the crank; error 0.003 in. short in 230 teeth; net error, 0.0005 in.

For 16-pitch, 7.8511 turns; $7\frac{40}{47}$ error; 0.003 in. short in 152 teeth; net error, 0.001 in.

At first thought this method of spacing may seem complicated. Actually, it was practical and also easily carried out.

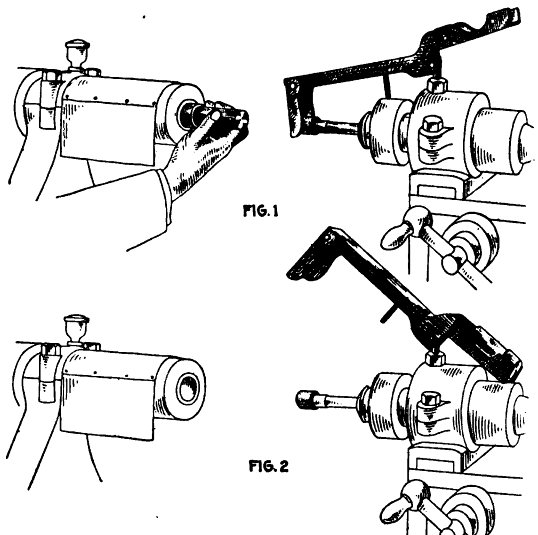
Boston, Mass.

Guarding Users of Internal Grinding Wheels

The two illustrations show different positions of a type of guard we have recently put in use to cover the spindles of our internal grinding machines. Fig. 1 shows the guard down over the wheel as the operator places the test plug in the bushing. This is where we have been continually having trouble with our workmen grinding their fingers. The view illustrates clearly how this may be prevented.

On the extreme right-hand end of the sheet-metal guard there is a small pocket, or receptacle, in which the operator places the plug gage as soon as it is removed from the bushing. The weight of this plug raises the



GUARDING INTERNAL WHEEL GROOVES

guard above the wheel as shown in Fig. 2, giving free access for the grinding operation. When the gage is removed the guard drops over the wheel.

Since this guard has been put in use grinding accidents on these machines have been entirely eliminated. This suggestion may be of benefit to others who may have had similar trouble.

CHARLES E. CARSON.

Allegan, Mich.

Drawing a Motorcycle Handle-Bar Sleeve

In the illustration, Fig. 1, are shown the successive drawing operations required for making a handle-bar sleeve, as manufactured and used by a motorcycle concern.

A combination blanking and drawing tool is used for the first operation, to be put in a blank-holder press. The

blank holder punches the blank and holds it while the drawing punch is coming down to accomplish the drawing part. The drawing punch, in Fig. 2, is shown in a position where it just begins to work. The second and third operations are performed with ordinary single-acting reducing dies and tools, shown in Figs. 3 and 4. Tools

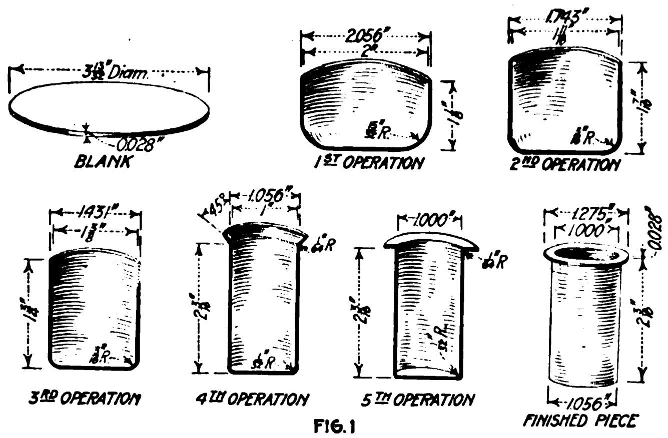


FIG. 1

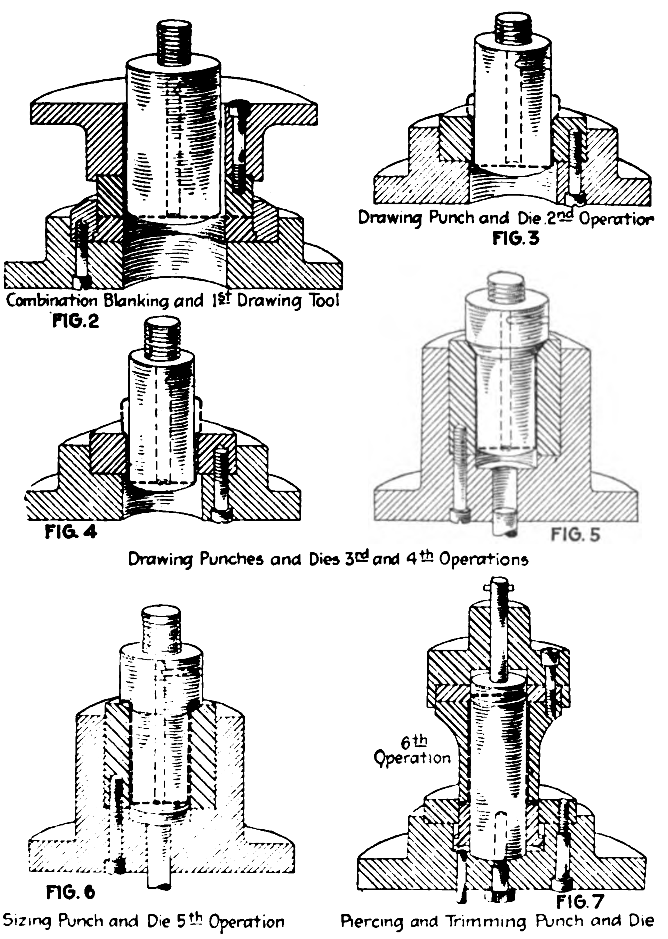


DRAWING A MOTORCYCLE HANDLE

for the fourth operation are shown in Fig. 5. The manner of working is made clear in the illustrations.

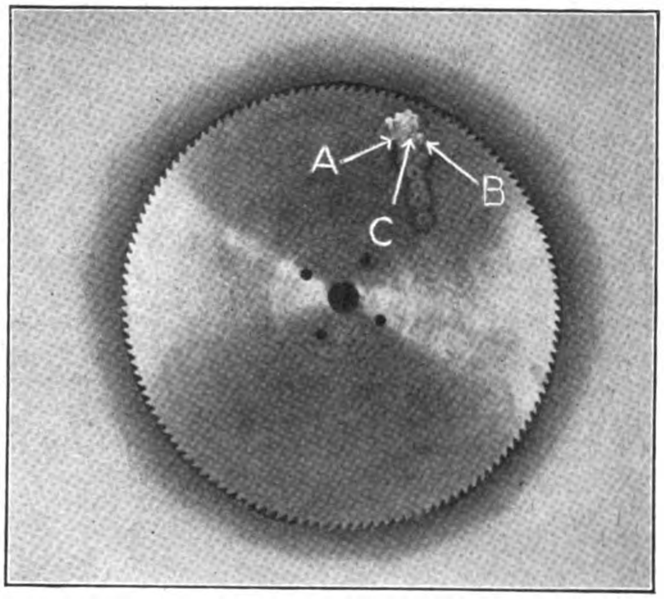
Tools for the fifth operation, which consists chiefly of sizing up and flanging after the fourth operation, are shown in Fig. 6. After the fifth operation the drawn cup is annealed in a furnace. Then the flange has to be trimmed and the bottom of the cup punched out. Both operations are done with a combination trimming and piercing punch and die, shown in Fig. 7. The job is thus completed and ready for the stockroom.

Milwaukee, Wis. P. Baldus.

Spot-Welding a Coldsaw

The illustration shows a saw blade 19 in. in diameter, made of "Semhi" steel and used for coldsawing. It was broken as shown and mended by electric welding in both sides a piece of soft steel 5/8x1/8 in., as at *A, B, C*.

It was spotted at *A* and *B* first and allowed to cool, which closed the crack; then it was spotted at *C* and at



SPOT-WELDING A CRACKED COLDSAW

several places along the line of fracture. The excess of metal was removed. The saw has been in constant service for some time. S. A. Eaton.

Worcester, Mass.

Savings That Mean Profits

It has been said that saving in small things has been the making of some of our most successful men, and the neglect of the little things in some of our manufacturing plants is the cause of small profits, if not actual loss.

In the pattern shop one of the little things that run into dollars faster than the average foreman or owner of plant realizes is the making of round core prints for locating the core in the mold.

It is customary in many shops for the patternmaker, when he has a hole to core out in a pattern, to make a pair of core prints for the job. This means the sawing of a piece of wood large enough to turn the required diameter and lengths, the centering of both ends of the block, hunting up and sharpening turning tools, setting up the lathe for the work and then making.

The two prints, the size of the dowel for locating the print on the pattern and the taper of the top, or core, print are made big or little, according to the individual's idea.

Several years ago I decided to emulate more modern methods of making core prints and standardize the sizes to cover the length, the taper of core prints, the size and length of the dowel and to make them in quantities, so as to have them on hand when needed.

I found that the advantages of having a standard size were many: There was a great saving by making the core prints in quantities, and having standard sizes

always on hand enabled me to get a hurry-up pattern into the foundry for the day's cast; if a core print was lost in the pattern storage or foundry, it could be quickly replaced from stock or by taking a print of the same diameter from another pattern already in the foundry, thereby saving sending the pattern and core box to the pattern shop to have another print made, with the consequent delay and cost.

As a further saving for this work I had a set of taper reamers made to fit the taper of the core print for making the taper hole in special boxes. The stock was first planed in thickness to the length of the prints and then planed parallel in width. Two pieces were clamped in the wood jig, shown, with the taper wedge driving it firmly in place. The small diameter of the hole was bored exactly on the joint between the two pieces. After boring, the taper reamer was put in the boring machine and the holes reamed to fit the prints. By this method I got a standard taper end for the core box and greatly reduced costs. JOHN J. EYRE.

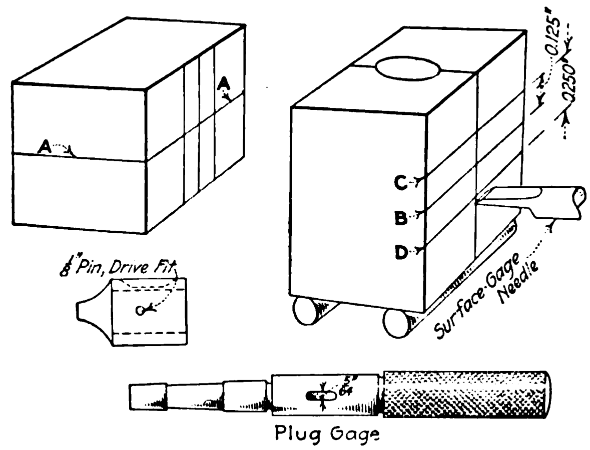
TABLE AND DETAILS OF CORE PRINTS

Laying Out a Jig for a Gage

In the construction of the taper plug gage shown it was necessary to have a jig for drilling the $\frac{1}{8}$-in. hole in the sleeve and also three $\frac{1}{8}$-in. holes in the gage itself. It was essential that the holes be drilled as nearly as possible through the center of both the sleeve and the gage body. While there is $\frac{1}{64}$ in. allowed for error in the location of the hole in the sleeve and the slot in the body, lack of truth of the body after hardening may cause the slot to become more or less out of center in the gage body. Therefore, it was important to drill the holes as nearly through the center as possible.

There were 26 of these gages to be built, so the simple jig shown was made for the job. The first interesting feature in the making of the jig was the squaring of the block, which was done in a small engine lathe, as no other machine was available at the moment. By swinging the piece in the lathe, strapped to an angle plate, which in turn was strapped to the faceplate, the six sides were faced off, flat and square, in a reasonably short time. The points for boring were laid out accurately with a surface gage, as follows: Line A was laid off at one setting, and line B was next marked off. Then two short pieces of 0.125-in. drill rod were placed under the surface gage, and the line C was marked off. The drill rod was removed from under the surface gage, the pieces were placed under the jig block and the line D marked off. The various points were prick-punched and bored in the ordinary fashion. It was necessary to have the hole on the line B a trifle smaller than $\frac{1}{8}$ in. in order



LAYING OUT A JIG FOR A SPECIAL GAGE

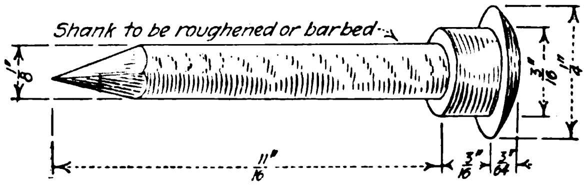
that there might be a wall between the holes. The large hole was bored to fit the sleeve, and a bushing was made to fit over the gage body and also fit the jig.

I have greatly improved my surface-gage needle, as shown. With such a point a tool maker may feel surfaces and mark lines in the same manner as when using a height gage, and by using parallel pieces, as described, a fair degree of accuracy may be obtained.

Newark, N. J. GUSTAVE A. REMACLE.

Who Can Make This Nail?

The illustration shows a special nail that has been submitted by us to about 75 manufacturers in the United States, all of whom have stated that they cannot supply it made to the measurements given.



THE NAIL TO BE MADE

We at first thought that it could be made by an upset die operation, but are beginning to believe that it cannot be turned out in this way. We should like to know who can manufacture this article in ton lots and how it can be made commercially. F. P. RONNAN.

Halifax, N. S.

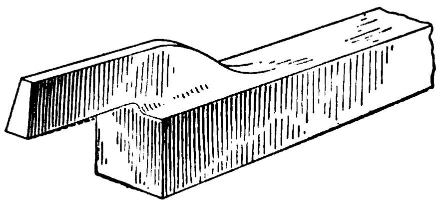
Oxyacetylene Cutting Played an Important Part in the dismantling and removal of fourteen large boilers at the plant of the Union Electric Light and Power Co., St. Louis, Mo. Each boiler was 11 ft. in diameter by 21 ft. long. The oxyacetylene blowpipe permitted the cutting up of the boilers into small sections, such as could be easily removed without the necessity of tearing down a part of the building.

Discussion of Previous Question

Cutting Downward in the Lathe

On page 432 there are a sketch and a description of a parting tool to be used on a lathe running backward. I notice that the cutting edge of the tool has not the proper shape. The correct shape is as in the accompanying illustration.

I have secured exceptionally good results from such a tool when properly made; but considerable care should be exercised in using it, since the chuck is apt to become loose when the material is not supported by a dead-center, as the pull is in the opposite direction to a right-hand thread on the spindle. J. H. MADGETT.



GOOSENECK LATHE TOOL

New York City.

Best Way To Do Certain Things

John E. Sweet struck the "keynote" when he sent in his little article on page 936, Vol. 43, telling how to secure a machine part on the end of a shaft. His method of describing the thing he had in mind impresses me more forcibly than the thing itself. He gives a vivid word picture enabling one to see clearly and to understand without a sketch just what he himself sees.

It is just as important a matter to tell correctly how to do a thing as it is to do the thing in the right way. If all information that goes to the workman could be made as clearly understandable as Mr. Sweet's article, it is probably safe to say that about 90 per cent. of the blunders made would be eliminated. Most of the disagreement and misunderstanding between office and shop, engineering departments and factory, bosses and men would disappear if as much attention were given to the "telling" as to doing things.

It is a well-known fact that what is good practice under some circumstances is very poor under others. Where a taper hole is secured on a taper spindle nose, with a threaded end on which a washer and nut or a threaded collar is screwed, as in the Brown & Sharpe cutter grinder, a good method was adopted and one which in that case gives splendid results.

Under entirely different usage and conditions a similar spindle nose on another make of machine is not good design, because the length of the taper in proportion to the diameter is not enough to insure a chuck or faceplate always running true after being used a few times. Then, too, in the case of the Brown & Sharpe grinder the taper hole in the grinding-wheel hub can be cleaned and placed true on the spindle, while the other lathe chuck will retain chips that persist in getting in the taper hole and causing trouble every time the chuck is screwed on the spindle.

I am speaking from my own experience and mention these two cases more to emphasize the fact that care and judgment should be used by those who adopt the good points of one machine to use on another.

I am of the opinion that much can be done to simplify technical information, so that a clear understanding can more easily be gained by those without the advantage of good schooling or manual training.

A great deal of shop information and many calculations can be "brought to their lowest terms"—made easily understandable. When this is done and a move made to standardize the right way of manufacturing machine parts, the workman's burden will be lessened and the bosses will do less worrying GEORGE G. LITTLE.

Rochester, Minn.

Manufacturing Rifle Cartridges

Mr. Dinger's criticism, on page 475, of my article on the manufacture of rifle cartridges has come to my notice. In reply I should like to quote from the original manuscript as it was sent to the *American Machinist*.

"The indenting operation forms or indents a small depression in the center of the head for a seat for the primer, and pierces a small hole through the head for the percussion to travel to the explosive with which the cartridge is loaded. This indented impression is of a great variety of sizes, depth and shape dependent upon the size and style of primer used.

"For different charges different primers are used; that is, percussion material used in the primer differs with the different powders used, such as black powder, semi-smokeless, etc. The many brands of powders on the market differ so in their characteristics, such as amount used, density, rapidity of combustion, chamber pressure, etc., and all this tends to vary the size and shape of the indented impression," etc.

If Mr. Dinger will notice the primer cap of a cartridge loaded with the common black powder, he will see at once that it is different from one of the same caliber that is loaded with dense smokeless powder. If he opens that primer, he will find that a different material is used and the primer constructed differently with the different powder used. The piercings are all a very simple operation, either alone or in conjunction with other operations.

If Mr. Dinger will send a letter to me addressed in care of the *American Machinist*, I will tell him where he can see in operation any or all of these machines that I have described in my articles.

J. S. Glew's suggestion on the same page is a very timely one, and I should say a valuable one. I have been in the habit of annealing old dies and reboring them for the next larger size of redrawing tools, thus saving a good deal, but I think this idea is possibly better.

Pittsfield, Mass. G. R. SMITH.

Side Shield for Emery Wheels

I notice another article, on page 344, about and against the use of the side of a common tool-grinding emery wheel. I have been working in, or in charge of, machine shops for the past 20 years and have seen a good many articles against the use of the side of a wheel, but I have never been able to figure out why. I have never once seen any reason, good or bad, given for not using the side, simply the arbitrary statement that it is dead wrong. Will someone tell me why?

Personally, I use the side of the wheel fully as much as the face, simply because it gives better results or is handier for a great deal of grinding. In grinding a V-point tool it is always easier to grind one side on the face and the other on the side. A small blanking die or punch that is not very dull can be ground on the side of a wheel just as well as, and faster than, on a surface grinder.

In my own shop I had no surface grinder for a number of years, and got along very nicely, grinding all my dies on the side of a wheel. I was never in a shop where all the men did not use the side of a wheel constantly—why not?

Of course, the side may be all grooved up, but so may the face. That is the normal condition in some shops. One can be kept in good condition just as easily as the other. The grinding-stand makers seem to expect the side to be used, for most of them furnish an L-support to be used either for the face or the side.

There is certainly nothing in the composition of the wheel to prevent side grinding.

Plymouth, Mich. W. B. GREENLEAF.

Machinist Instruction in the Public Schools System

The discussion concerning prevocational and trade schools is of great interest to the man who is unable to visit these schools. The interchange of views by instructors also affords a comparison of methods as well as gives an opportunity to the shopman to express his ideas in regard to their utility.

Several letters indicate that some foremen are prejudiced against the school graduate. My contact with the students has been pleasant. Those working with me display a thoroughness, an intelligent interest and a desire to make good that are greatly to their credit. After they lost the desire to explain how work would be done in the school and became accustomed to the swing of machine-shop methods with the somewhat ancient tools in use, they went along O.K.

One correspondent states that each boy is supplied with certain tools, among them a monkey wrench. This implement is quite essential in the kit of the repairman or farmer, but in a trade school it is quite out of place. In these days of good machine wrenches at such reasonable cost every machine should be furnished with a complete set within easy reach. This equipment will be educational as well as economical.

Two young men whose foundation for the trade was laid in one of the large corporation trade schools told me that the only wrench they had for the Almond chuck of the sensitive drill was a blunt chisel and hammer. Such conditions are directly the fault of the instructors.

One difficulty is in securing for the students commercial work that can be disposed of upon favorable terms. I would suggest circularizing manufacturers to provide steel screws, bolster plates for holding dies and other articles used in manufacturing establishments.

South Acton, Mass. I. K. MACKENZIE.

A Flat-Sided Brass Lap

I am afraid that the brass lap described by Mr. McIntyre on page 414 is likely to be misleading to the majority. It seems like a very easy way to make a lap. Probably grinding the sides on a rough wheel instead of milling would be quicker. I do not doubt that the lap would do as good a job if it were ground, but I do doubt its turning out accurate work either way. No doubt, Mr. McIntyre knows that a lap made of that shape would not make a round hole, but would all the readers looking for information in your paper know this fact?

It is generally recognized among those who have done much lapping that, to get a round hole, the lap must be as round and straight as possible. It does not seem to me as if the tool referred to could be straight after peening, and it is not round to begin with. Therefore, I

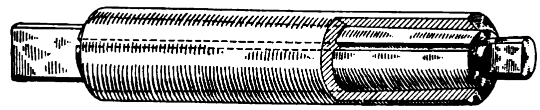


Fig.1

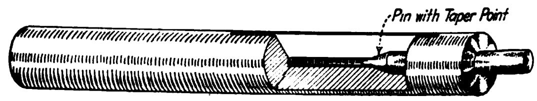

Fig.2

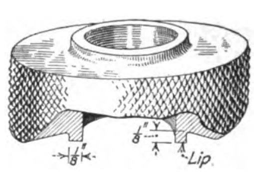

Fig.3

LAPS FOR ROUND HOLES

do not see how even a satisfactory job could be done in a ring gage. I have found that for lapping holes requiring as much accuracy as possible, from ¼-in. diameter up, a lead lap on a taper arbor, as in Fig. 1, is the most accurate, as it can be rapped on the arbor and expanded to hold the size. For holes smaller than ¼ in. I use a diamond lap.

I have made satisfactory small laps as in Fig. 2. If laps are slit from the end, they will always bell-mouth, as the spreading all comes on the end. I have always made ring gages with a lip, Fig. 3, which is ground off after lapping to the correct dimensions. They then close in slightly, according to size, and are lapped again to the proper measurements. This method leaves very little bell mouth, apparently none. The lap should be at least 2½ times as long as the work. In cylindrical work this ratio should be reversed; that is, the work should be 2½ times the lap. J. C. STUART.

Hartford, Conn.

Armored Motor Truck

The International Motor Co., New York City, in co-operation with the Carnegie Steel Co., has developed the armored car shown in the illustrations. The design is the result of considerable experiment, and full detailed drawings have been prepared of the various elements.

In Fig. 1 are shown the internal construction of the frame and also the streamline body. A view of the truck with the plates raised to show the accessibility to the power plant and accessories is given in Fig. 2. A short description of the unit parts and their approximate weights should be interesting.

The truck is of standard Mack 2-ton worm-drive pattern, with the steering and controls arranged to allow the driver to sit very low, thus permitting the guns to be fired over his head. The weight of the chassis is 5,000 lb. The electric equipment comprises a Bosch electric starting and lighting system with inclosed drive for generator and to flywheel. The ignition system is a Bosch magneto with dry batteries and a vibrator coil fitted for starting.

A 10-in. Gray & Davis searchlight is supplied and so arranged that it can be shut into the driver's cab, away from damage. The lamp is operated by a separate switch for signaling purposes. Two small headlights are fitted in the front of the car. They are arranged so as to concentrate the light low, eliminating any reflection on the sides of the car.

Two rear side and tail lights are placed on the extreme lower corners, and there is a dash light to enable the driver to read the gages. The engine is fitted with a special Newcomb carburetor.

Description of the Armor Plate

The armor plate is of special steel, heat-treated, and is proof against regulation army-rifle fire at 50 yd. It was manufactured by the Carnegie Steel Co. and cannot be machined or drilled without annealing. The armor plate weighs 2,400 lb. and is supported by a light iron framework built up in four units—one covering the motor, another forming the driver's cab and two rear units for the guns, ammunition and men. The parts are first riveted together, then the four units are joined by bolts into one complete structure.

The two rear units can easily be dismounted without disturbing the floor. This provision is convenient, as it furnishes a plain platform body for transportation purposes. The platform consists of metal cross-members with a wooden floor and steel wheel boxes and weighs 200 lb. The weight of the framework is 600 lb.

The towing arrangement is attached to the main chassis, which takes the strain directly through a spring to the main chassis frame. An eye suitable for chain or rope extends beyond the armor.

Position of Portholes and Motor Protection

The portholes are suitably placed for the operation of the car and for taking outside observation without harmful exposure. They are arranged as follows: One on each side of the driver's cab, two on each side of the body and one in the door at the rear, making a total of seven. The porthole doors, of armored steel, are made to slide and have anti-rattling latches. The truck is entered through the rear door.

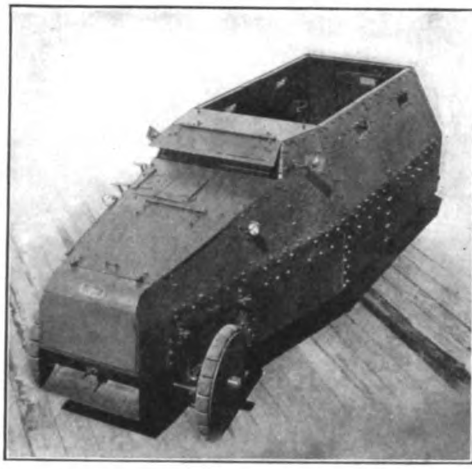

FIG. 1. PLAN VIEW OF TRUCK

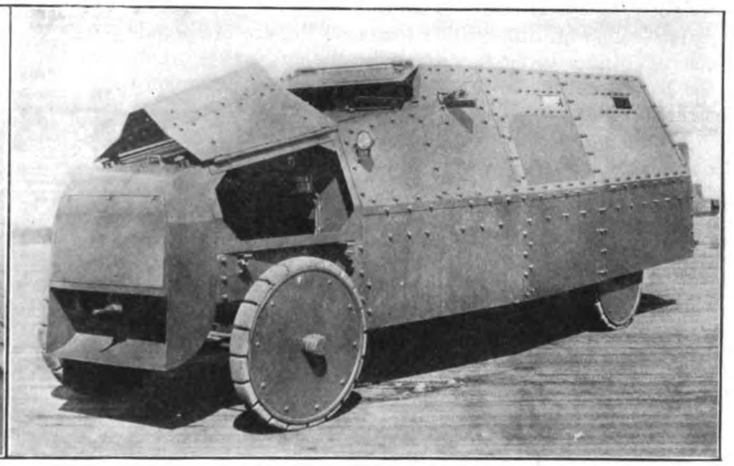

FIG. 2. VIEW OF TRUCK, SHOWING ENGINE

The driver is protected by a complete armored cab. The front door opens with adjustable racks, so that a larger or smaller vision can be obtained. Over the head of the driver and extending the full width of the cab is an adjustable trapdoor. It can be opened or closed at will, in order to cool the car when it is not under fire. Each of the four wheels is protected with armored plate attached to the felloe.

The motor is shielded by an armored hood that can be divided into a top, sides and protection behind the wheels for stopping bullets intended for the crank case. The top of the hood consists of hinged armor plate, which can be raised so as to reach the radiator. An anti-rattling device is fitted to hold the plate down.

The hood has sloping sides in two pieces, hinged on the top edge. They can be raised to allow ready access to either side of the motor. The doors can be folded back on top of the hood; and when they are closed the top can be lifted without disturbing the sides. The lower protection behind the wheels is of such shape as to give wheel clearance in turning.

An unusually large radiator is provided to cool the engine. There is a special device, weighing 120 lb., for radiator protection, so that air can be introduced without permitting bullets to be deflected into the radiator itself.

The gasoline supply consists of a special tank fitted behind armor plating and mounted below the floor. The gasoline is supplied to the carburetor by a Stewart vacuum system. The weight of the tank, piping and fittings is 50 lb.

The storage battery is mounted behind armor plating and becomes part of the electric starting and lighting system, but not part of the ignition system. Therefore, if the battery should be depleted, ignition would not be interfered with. The weight of the battery and mounting is 67 lb..

As the armor is all on a slope, to turn bullets, it is very difficult to make a perfect butt joint with the armor plate. To overcome any defects in this direction, butt straps are put on all exposed plates, thus preventing a bullet from breaking off the edges of a plate. The weight of the butt straps is 250 lb.

The bolts and nuts, which weigh 60 lb., are of special steel, the nuts being heat-treated and hardened so that the bolts will not be shot away, thus injuring the construction.

In order to provide for special rifles or rapid-fire guns, detachable barbettes are supplied. They are supported on bronze brackets, which in turn rest on adjustable tripods on the floor. There are two of these rapid-fire gun mounts. The total weight of the armored car is 9,052 lb.

This description covers the first of the units of the armored train that has been given to the New York State National Guard for the protection of New York.

The makers of the car, owing to their experience in designing and supplying a large number of motor vehicles to the Allies, were picked to manufacture this truck.

Assembly Record Form Used in Manufacturing Lathes

By H. B. McCray

The problem of parts inspection is generally worked out to a fairly satisfactory degree in most small and medium-sized shops, but the manufacture of machine tools adds a further complication—inspection during assembly. The successive operations are interdependent to such an extent that poor workmanship or misalignment in any one seriously impairs the accuracy of the completed machine. If no readily accessible record is kept of these operations, it is next to impossible to locate the careless or ignorant workmen, especially where two crews are at work on the same lot of machines.

Such a condition is always a source of a great deal of trouble; in our case, with a considerable number of inexperienced men, it assumed grave proportions. Various schemes were tried and finally resulted in the adoption of the form shown herewith. It is printed on a medium-weight card and is held by spring clips in a light-weight sheet-iron back or container, similar to those used in cash-register accounting systems. This form is attached to the machine when the legs, pan and bed are set up and stays with it until the machine passes final inspection and goes into the car.

When a workman has completed an operation, he calls an inspector, who must pass on it and sign up for it before the next operation is begun. The workman then signs his name and number and is given a credit slip by the timekeeper, if the work is on a piecework basis. If an operation is unfinished when the crews are changed, the inspector decides that part is completed and notes this on his card, but does not O.K. it until the work is done.

Per.................Inspector.

If the work is "day rate," there is usually no discussion; if "piece rate," the number of unfinished operations is surprisingly small.

The adoption of this plan not only ended our troubles in final inspection, but effected a marked improvement in the quality of work.

Tool Builders' Conference

In view of the exceptional activity in the machine-tool building industry the Executive Committee of the National Machine Tool Builders' Association has decided to forego the regular spring convention.

In its place an informal conference of members will be held at the Hotel Astor, Apr. 29. This date has been selected as the most convenient, as it immediately follows the convention of the National Metal Trades Association, for which many members will no doubt be in New York.

Editorials

Metric System in Export Trade

An editorial in these columns in last week's issue pointed out what appears to be a carefully prepared attempt to commit the United States to the metric system for export trade. Manufacturing and commercial interests became aroused, and several cablegrams of protest were sent to Secretary of the Treasury McAdoo. The one from the National Association of Manufacturers, signed by George Pope, president, reads as follows:

Hon. William G. McAdoo, care of the American Embassy, Buenos Aires, Argentina: Many manufacturers, including some using metric system in their export trade, protest against any change of present status of United States laws as between systems now in use here.

These actions indicate the attitude of responsible manufacturing and commercial interests of the country toward any attempt to change the present status of our weights and measures.

Take Double Warning!

Too late for insertion in our last week's issue, we learned of the introduction in Congress of a bill for the compulsory use of the metric system. *Read Section 4. The Congressional Record* has the following:

"Mr. Dillon introduced in the House of Representatives on December 6, 1915, the following bill, which was referred to the Committee on Coinage, Weights and Measures and ordered to be printed:

"A BILL

"to establish the metric system as the standard for weights and measures for other purposes.

"Be it enacted by the Senate and House of Representatives of the United States of America in Congress assembled, That the weights and measures of the metric system shall be the sole standard of weight and measures in the United States on and after July first, nineteen hundred and twenty: Provided, That in the meantime such metric system shall be permissive.

"Sec. 2. That all equivalents between the units of the metric system and the system now in common use throughout the United States shall be calculated from the fundamental relation, one meter being equivalent to 39.37 inches and one kilogram being equivalent to 2.204622 avoirdupois pounds.

"Sec. 3. That the Director of the Bureau of Standards, with the approval of the Secretary of Commerce, shall prescribe rules and regulations for carrying out the provisions of this Act, and shall prepare and promulgate tables based upon the fundamental relation established in section two showing the equivalents of the weights and measures of the metric system to those of the system in customary use in the United States.

"Sec. 4. That any person, corporation, company, society, or association who shall use, or offer and attempt to use, in any industrial or commercial transaction in the sale or purchase of any commodity any other weights and measures than those of the metric system on and after July first, nineteen hundred and twenty-four, shall be guilty of a misdemeanor, and upon conviction thereof in any court of competent jurisdiction shall be punished by a fine of not more than $500 or by imprisonment for not more than three months, or by both such fine and imprisonment."

One does not need the gift of second sight to recognize the connection between this bill and the plan for committing the Government to the adoption of the system through the action of the Joint High Commission on Uniform Law now in session at Buenos Aires. Full particulars of this scheme were given in our editorial of last week.

The following is our interpretation of this connection, which we submit to the judgment of our readers:

1. The pro-metric party had this bill introduced early in order to give time to work on the Committee on Coinage, Weights and Measures through hearings or, more probably, by lobbying with individual members.

2. It expects to secure action at Buenos Aires committing this Government to the adoption of the metric system.

3. It expects to have the committee convinced of its wisdom and to have the bill reported to the House of Representatives at the opportune moment.

4. This opportune moment will arrive when Secretary McAdoo returns from the meeting of the Joint High Commission with resolutions committing the participating governments to the metric system.

5. It then expects to rush the bill through Congress with a hurrah and as an act of good faith with the South American republics.

According to an article in *Munsey's Magazine* for April, Doctor Stratton has already secured the favorable impression of the committee.

Read Section 4!

Conduct of Salesmen in South America

No discussion of the possibilities and methods of South American business would be complete without comment upon the proper conduct for salesmen who visit the countries of that great continent and perhaps even a few words of friendly advice to them. As regards personal habits: Live clean, be abstemious; get on the water wagon and stay there. More northern salesmen have failed in South America because of dissipation than from any other one reason.

The necessity of knowing the languages used in business intercourse has already been emphasized. No salesman should expect to make a circuit of South America unless he can speak both Portuguese and Spanish.

The old saying, "When in Rome do as the Romans do," applies with peculiar force to the attitude and methods employed in reaching South American customers. The men whom the northern salesman will call upon are well

read, educated, cultivated, and gracious in manner. They very properly expect to be treated as they treat others. Thus the northerner, when he approaches them, must be equally polite, courteous and affable. At the same time he must ring true; he must be genuine. If he has this attitude and feeling toward his customers and is possessed of all the necessary technical qualifications, selling goods in South America should be easy. It is perhaps not going beyond the bounds of truth to say that the South American business man dislikes to say "No." He would rather buy of you than not, if you approach him in a proper manner; and even when he does refuse your offer, he will in most courteous fashion ask your forgiveness for not being able to give you an order.

The general attitude of the South American business man toward his North American visitor is one of appreciation and admiration for North American energy and practicability. This prepossession at once paves the way for cordial relations, if the approach and business interview are properly handled on the part of the caller. There are some things that must be absolutely avoided. A patronizing attitude is at once resented. The rough and ready methods of the north must be completely dropped. When an office is entered, the caller must remove his hat at once. When he greets his customer, it must be in a formal way. Never slap a South American business man on the back; do not lean back in your chair in his office; do not call him by his first name; do not aim your cigar at the ceiling—or better still, do not have a cigar in evidence when you enter. All these things, which are a part of the North American game of bluff, are exceedingly distasteful. So much are they despised and so greatly is familiarity resented that the American word "bluff" has been adopted bodily into South American Spanish as describing these disagreeable traits of conduct.

Hospitality, as invitations to dinner or the theater, must be sparingly and judiciously offered. If they are refused, the invitation should never be pressed. This comment applies to the native South American and not to the executives of foreign birth, as men from the United States, England and Germany. The latter expect to be entertained in about the same way as in this country.

The personal appearance of the salesman counts more in South America than it does here. At all times he must be neatly and tastefully dressed. A walking stick is a common detail of his business equipment; and if his personal wishes are not offended, a flower in the buttonhole may perhaps have its effect. Not only do these small things aid when the salesman has reached his prospect, but they are of direct service in passing those minor barriers with which every business man is surrounded.

It is always necessary to ask for an appointment in business dealings in South America, and these engagements are usually fixed for the hours of 7 a.m., 11 a.m., 2 p.m. and 5 p.m. There is no uniformity either as regards industries or localities. The personal wishes of each man who is to be approached must be consulted and his convenience met. This is one of the reasons why business goes as slowly as it does in those countries. The hustle of the north must be completely laid aside, and the salesman must adapt himself to the traveling, living and business conditions that he finds. He cannot change them, and his own attitude must be one of patient tolerance with the delays that are inevitable.

As regards his technical equipment, it must be of the best. The northern salesman who purposes to make a South American trip must have a thorough knowledge of his line down to the most minute details. Many unfortunate occurrences in the past have been due to salesmen's mistakes in making quotations, figuring exchanges, transposing dollars to South American currency and changing English units of weight and measure to the metric equivalents. Much of this work has to be done on the spot and, of course, with celerity and certainty.

A journey to South America down the west coast and up the east, or in a reverse direction, should take about nine months from New York to New York. It is better, as a rule, for the salesman to confine himself to the coast towns, for the customers whom he will meet there consider the interior as their legitimate market. They are apt to be unfriendly and hostile, if they know that a salesman purposes to travel to inland cities. The expenses of such a trip will run about $100 per week, which will include a reasonable amount of entertainment for foreign employees of the South American houses. The climate is, of course, trying, and care must be taken to guard against its effect. Gastric troubles are common, and it is wise for the northern salesmen to eat freely of fresh vegetables and of the native fruits, after judicious trial has proved that they agree with him personally, and to drink nothing but bottled water.

Finally, in all dealings with South American business men never under any circumstances knock a competitor or his product.

Attempt To Kill Time Study

Another attempt is being made in Congress to prohibit time study, motion study, the setting of tasks and the paying of bonus to any employee in the Government service. This is a continuation of the attack made last year, which resulted in adding riders to the army and navy appropriation bills prohibiting the use of any of the money there appropriated for these purposes. Bill H. R. 8665, introduced by Mr. Tavenner, reads as follows:

That it shall be unlawful for any officer, manager, superintendent, foreman or other person having charge of the work of any employee of the United States Government to make or cause to be made with a stop watch or other time-measuring device a time study of any job of any such employee between the starting and completion thereof or of the movements of any such employee while engaged upon such work. No premiums or bonus or cash reward shall be paid to any employee in addition to his regular wages, except for suggestions resulting in improvement or economy in the operation of any Government plant.

That any violations of the provisions of this act shall be deemed a misdemeanor and shall be punished by a fine of not more than $500 or by imprisonment of not more than six months, at the discretion of the court.

The other bill, presented by Mr. Van Dyke, applies to employees in the postal service and is similar in wording to the first.

It is needless to enumerate the pernicious effects that would follow the passage of these bills. Readers of the *American Machinist* appreciate these results without any detailed explanation. Once such bills become law for Government plants, kindred efforts will be made to enforce similar prohibitions in the shops of private manufacturers who are working on Government contracts. This is the danger behind the present attack.

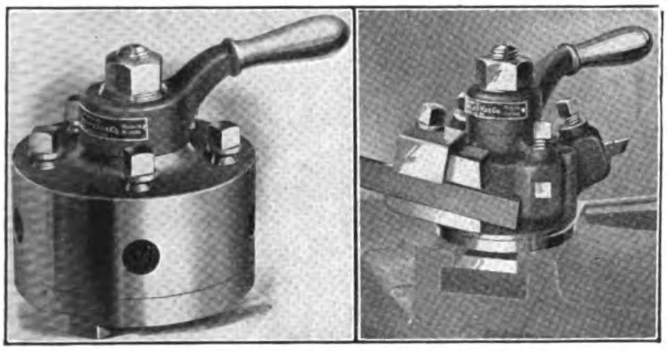
Communicate at once with your Congressional representatives, stating your opposition to these bills.

Shop Equipment News

Turret Tool Holders

The type of tool holders illustrated were designed to provide the advantages of several ordinary tool holders and a turret.

The form shown to the left is especially designed for inside work, such as drilling, boring, reaming, etc. It is readily attached directly to the compound rest similarly to a regular tool post. An indexing plunger is actuated automatically with the loosening and tightening of the clamping handle. This form is provided with five holes, unless otherwise specified.



TURRET TOOL HOLDERS

The one shown to the right is three cornered, having two square bits and a cutoff tool. The cutoff tool may be removed, if desired, and another square bit inserted.

These turret tool holders accommodate ordinary toolholder bits and represent a recent line developed by the McCrosky Reamer Co., Meadville, Penn.

Lubricant-Circulating Pumps

The illustrations represent a line of geared circulating pumps recently developed by C. F. Roper & Co., Milford, Mass., for pumping oil, lubricants or water to the cutting tools on machines, for cooling engines and for other similar purposes.

The type shown in Fig. 1 is designed to be used on machines where the cutting tools operate in one direction only. It is simple, consisting of two accurately cut steel gears running in an accurately machined casing. A relief valve forms an integral part of the mechanism, by which it is possible to shut off the delivery of oil without stopping the pump. This relief valve is instantly adjustable by means of a knurled thumb-screw on the outside of the pump. While the construction is such that the oil is held in the pump when it is not in operation, thus making priming unnecessary, the manner of attaching the suction and delivery pipes to the top and bottom of the pump avoids a complicated piping system.

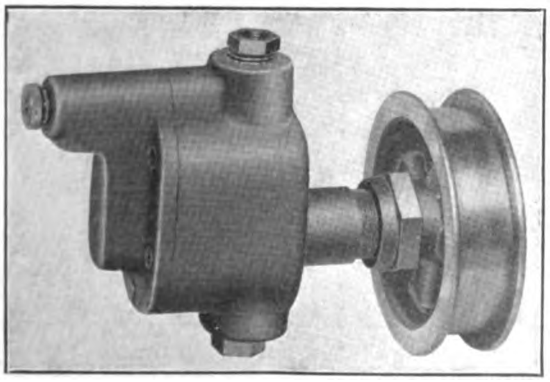


FIG. 1. GEARED LUBRICANT-CIRCULATING PUMP

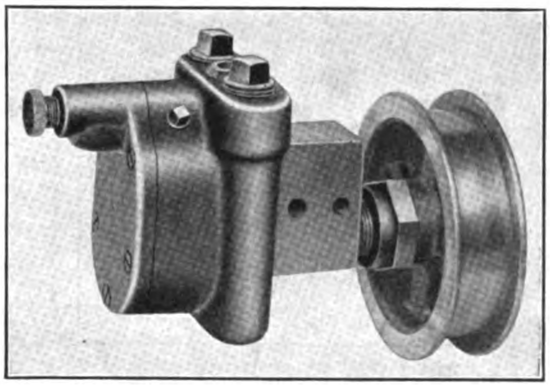

FIG. 2. REVERSING LUBRICANT PUMP

The pump shown in Fig. 2 is of an automatically reversing type especially adapted for use on machines in which the cutting tools operate in both directions. In general, the design and construction are similar to those of Fig. 1.

Both styles are made in five sizes, with capacity for delivering from $2\frac{1}{2}$ to 46 qt. per min.

Compact Electric Hoist

The latest form of electric hoist made by the Franklin Moore Co., Winsted, Conn., is shown in the illustration. In the design, steel has been substituted for cast iron on all parts subjected to tensile stresses, and all superfluous metal has been eliminated in order to construct a light-weight compact hoist.

In the new line of hoists represented by the illustration each size is built up and planned for an individual size of motor. All-steel cut gears are used, and the shafts are babbitt bushed. The gears operate in a bath of oil, and the drum is supported by roller bearings. Owing to its mechanical features this hoist, when equipped for direct current, is said to offer a smooth speed control especially adapted for foundry practice in the handling of molds.

The hoist is equipped with two brakes—a solenoid brake and a mechanical brake of the multiple-disk friction type. It also has an upper automatic stop that cuts off the power instantly when the lower hook reaches its upper limit of travel.

To provide accessibility in case of repairs, the construction has been made such as to permit the removal of either the motor end or the mechanical end without disturbing the other parts or taking the hoist down.

COMPACT ELECTRIC HOIST
Capacity, 500 lb.; lifting speed, 45 ft. per min.

The hoist is built either in the hook type or in combination with plain, geared or motor-driven trolleys, floor or cab control. This type of hoist is made in a variety of sizes ranging in capacity from 500 to 10,000 lb.

Special-Purpose Lathes for Machining Projectiles

Three special-purpose lathes for machining shrapnel and high-explosive shells are being manufactured by H. C. Dodge, 176 Old Colony Ave., Boston, Mass. The largest of these is a turret lathe for performing turning, boring and waving operations on 3 to 6-in. diameter shells of both shrapnel and high-explosive types. A smaller turret lathe is made for the principal operations on 3-in. and smaller shells, while the third machine is a special speed lathe for filing and polishing 3-in. shrapnel.

The 6-in. machine, known as the "Dodge Special," is shown in Fig. 1, which illustrates the turret set-up for the boring operations. The spindle is of unusual size, as will be noticed from the specifications under Fig. 1; and an even better idea of its proportions may be had from Fig. 2, which shows the spindle suspended above the main bearing housing.

This machine is of the constant-speed drive type, two speeds being obtained by gears mounted upon a Johnson friction clutch within the headstock, operated by the lever seen near the top of the headstock. An additional pulley on the countershaft provides for two more speeds, but they are not ordinarily required in the machining operations on the 6-in. shell. The headstock bearings are of compressed babbitt. The feed box is of the tumbler-gear type and contains three feed changes. The feed shaft is driven from a pulley on the rear end of the spindle, and a weighted idler pulley is furnished to give proper belt tension and to act as a preventive of gear breakage in cases of overloading. One of the interesting features of this lathe is the carriage-stop mechanism, at *A* in Fig. 1. The adjustable stops are so arranged as to disengage the feed clutch at a predetermined distance from the fixed stop, so that, after the power feed is off, the tool that is cutting may be advanced by hand to secure a smooth finish.

The apron gearing may be seen in Fig. 3. The worm gear is of bronze, running in oil.

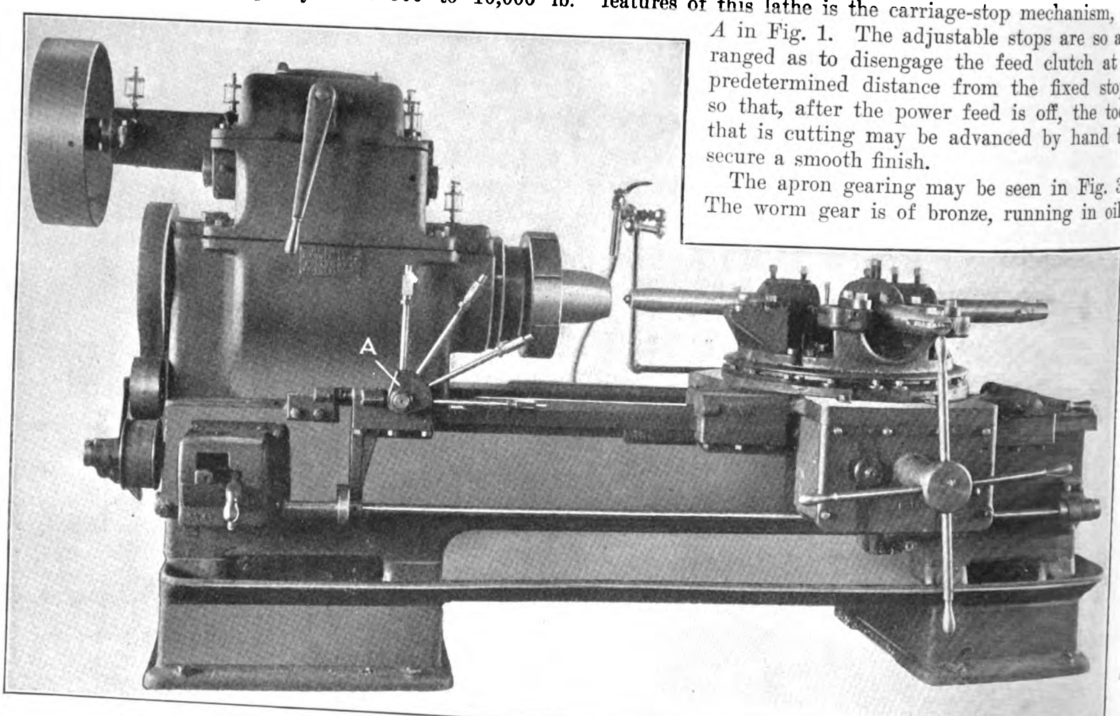

FIG. 1. DODGE SPECIAL-PURPOSE LATHE FOR MACHINING OPERATIONS ON 6-IN. SHELLS
Length of bed, 8 ft. 6 in.; width of bed, 27 in.; length of carriage on V, 40 in.; extreme travel of carriage, 30 in.; front bearing, 9½ in. diameter by 8 in. long; rear bearing, 7½ in. diameter by 7 in. long; swing over ways, 24 in.; swing over turret, 6 in.; diameter of turret, 24 in.; floor space, 10 ft. by 4 in.; drive pulley, 20x5½ in.; weight, 8,000 lb.

and the spur train is of steel. A fiber friction disk locks the feed. The turret locking pin, which of the wedge type, is released by the hand lever at A.

The carriage has a V-guide in front and a flat guide at the rear, as shown in the end elevation, Fig. 4. The tooling on this machine has been worked out so as to balance cuts by opposing front and back tools, as far as is possible. Consequently, neglecting the cam action that arises from eccentric shell forgings, there is slight tendency for the cuts to lift the carriage. Notwithstanding this fact, however, heavy flat gibs have been provided at front and back.

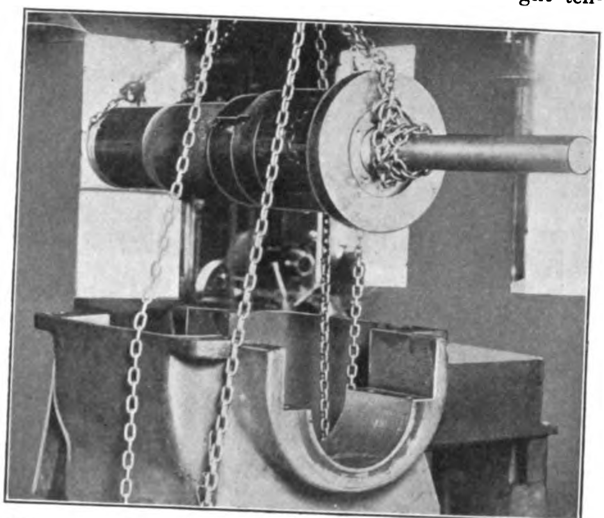

FIG. 2. MAIN SPINDLE OF "DODGE" SPECIAL-PURPOSE SHELL LATHE

The turret tooling varies for the type and size of shell being finished. In the case of the 6-in. high-explosive four different set-ups take care of the entire machining, except the nose threading and the band turning. Three of these toolings are illustrated in Fig. 5, the fourth, not shown, finishing the contour of the bessemer steel fuse plug after it is inserted in the shell.

For the first operation the shell is chucked by the nose end. The sequence of suboperations may be seen by in-

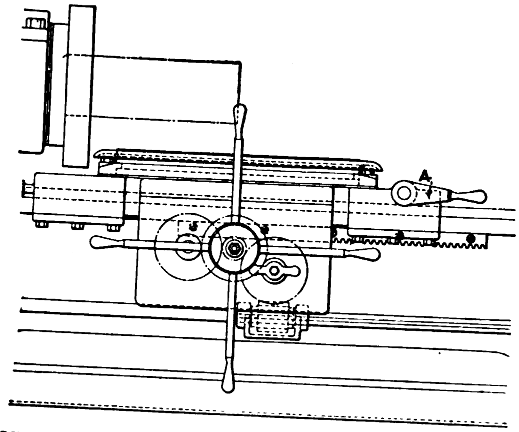

FIG. 3. APRON GEARS AND TURRET RELEASE OF DODGE LATHE

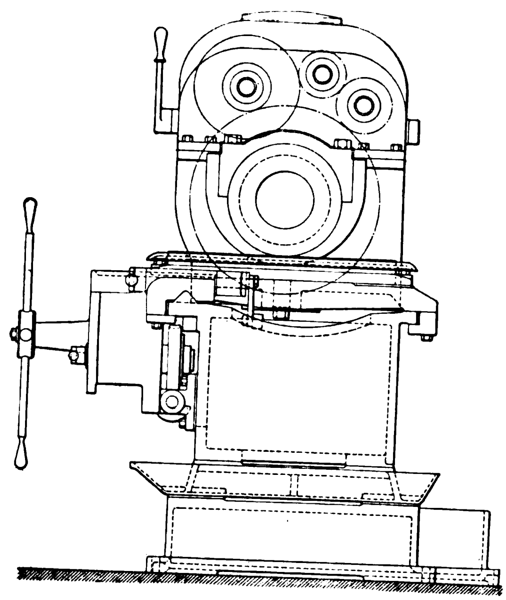

FIG. 4. END ELEVATION OF 6-IN. SHELL LATHE

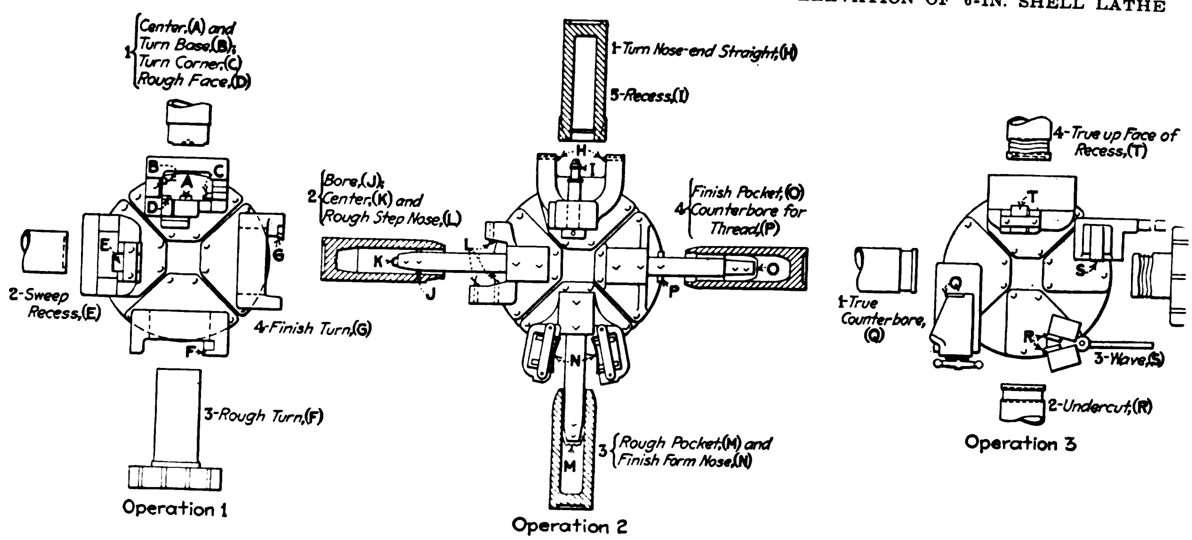

FIG. 5. TOOLING OF DODGE LATHE FOR MACHINING 6-IN. HIGH-EXPLOSIVE SHELLS

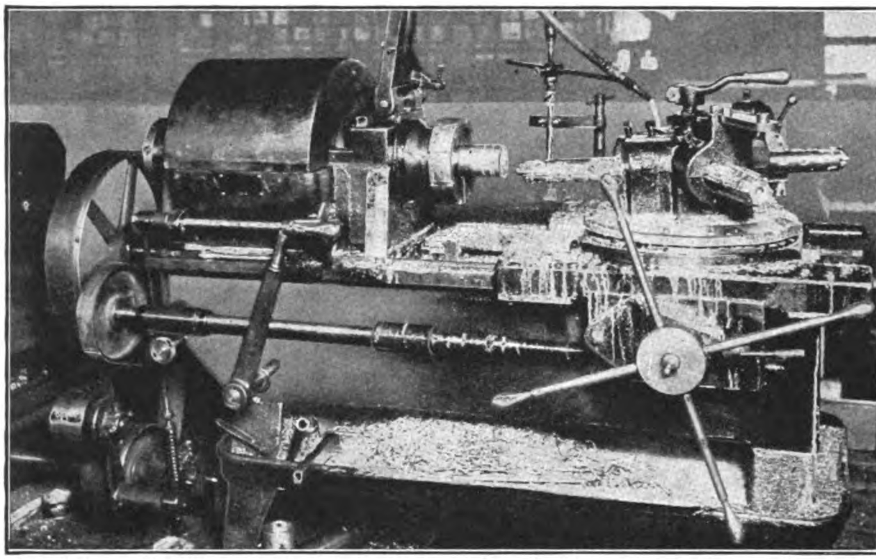

FIG. 6. SPECIAL-PURPOSE "BLOOD" LATHE FOR 3-IN. AND SMALLER SHELLS

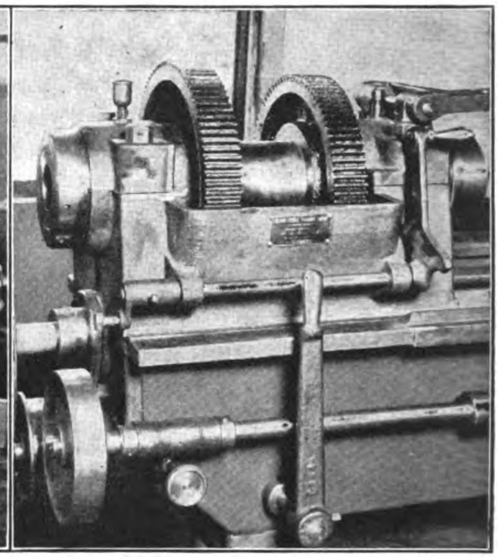

FIG. 7. HEADSTOCK OF "BLOOD" LATHE WITH COVER REMOVED

Swing over turret face, 4 in.; swing over shears, 20 in.; size of front spindle bearing, 5½ in. diameter by 6 in. long; size of rear spindle bearing, 5½ in. diameter by 5 in. long; maximum hole through spindle, 3¼ in.; maximum carriage travel, 12 in.; weight, 2,800 lb.; driving pulley, 20x4½ in.

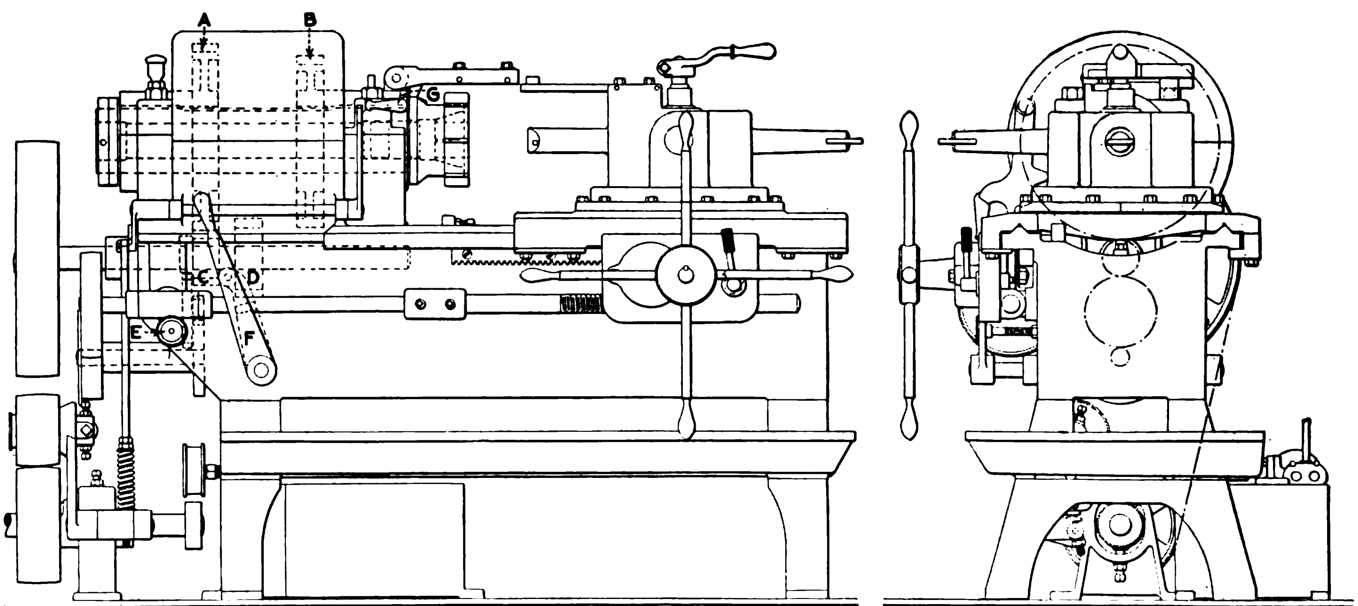

FIG. 3. OUTLINE DRAWING SHOWING ASSEMBLED ELEVATION AND END VIEW OF SPECIAL-PURPOSE "BLOOD" TURRET LATHE FOR 3-IN. AND SMALLER SHRAPNEL AND HIGH-EXPLOSIVE SHELLS

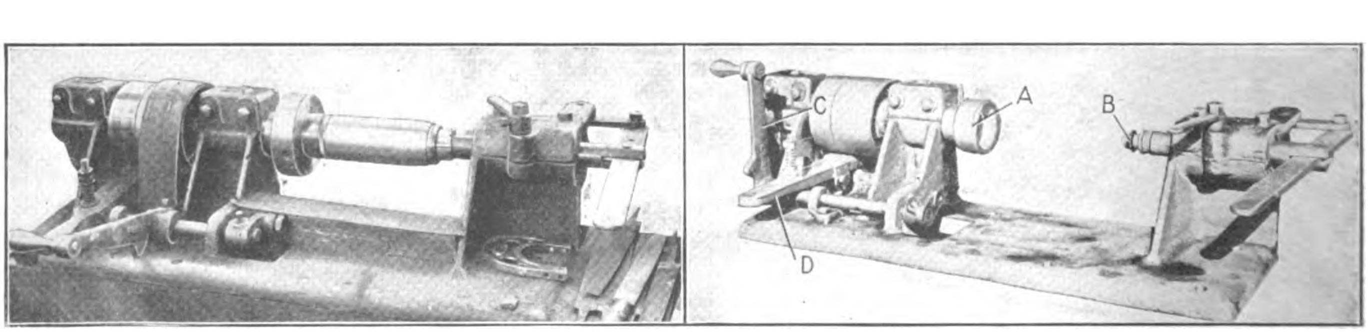

FIGS. 9 AND 10. SPECIAL SPEED LATHE FOR FILING AND POLISHING 3-IN. SHELLS

Swing, 10 in.; length between centers, 10 in.; weight, 250 lb.; driving pulley, 6x3½ in. Base plate may be extended so that the length between centers will accommodate 14 in. when required

spection of Fig. 5, the tools for each one being indicated by reference letters. The second chucking is on the base end, this operation finishing the shell bore and profiling the nose. An ingenious set-up permits a four-station turret to serve five stations, the first and fifth suboperations taking place on the same turret face. On the first position, second operation, the tools *H* rough-turn the nose end, as shown by the full lines on the shell, simply taking a parallel cut over the stock that was left for chucking from the first operation. After the fourth sub-operation the shell nose has the shape shown by the dotted lines and hence is not touched by the tools *H* on the fifth suboperation. At *I* is a recessing tool, mounted on an eccentric spindle. This enters the shell the proper distance to cut the recess back of the thread seat, thus completing the cycle on the same turret face on which it was begun.

The third chucking holds the shell for undercutting, wave cutting and base finishing. The waving tool *S* is oscillated by a roller on a faceplate cam on the spindle. The facing tool *T* merely takes a slight scraping cut in the recess. This machine is driven either by overhead or floor countershafts. The cutting coolant is distributed by an independently driven geared pump, the reservoir being in the base of the headstock, which is fitted with a chip strainer.

Special Purpose Turret and Polishing and Filing Lathes

The 3-in. special-purpose turret lathe, which is shown in action in Fig. 6, was designed by Charles W. H. Blood, of the S. A. Woods Machine Co., and is known as the "Blood" lathe. The machine here illustrated is tooled up for boring 3-in. Russian shrapnel shells, but the same lathe with different tooling is used for body turning, base finishing, band-groove machining, nose finishing, tapping, etc. Several hundred of these lathes have been in use for the past year in plants turning out Russian shells, and production records obtained on them were published in the series of articles beginning on page 89.

These machines are preferably driven by floor countershafts, through belts having spring-actuated idler pulleys, which are used for starting and stopping, by tightening or loosening the driving belt. There are two speeds, obtained through sliding gears in the headstock. The spindle gears may be observed in Fig. 7, which is a view of the headstock with the gear cover removed.

In Fig. 8 are side and end elevations of the Blood lathe, showing these same gears at *A* and *B*, the sliding pinions at *C* and *D*, the belt-tension adjustment at *E*, the gear-shift lever at *F* and the starting and stopping lever at *G*. In both of these turret lathes the turret face is set extremely low, bringing the tool centers close to the ways, thus insuring rigidity.

The special polishing and filing lathe may be seen in Figs. 9 and 10. The shell is held and driven through friction by the cup chuck *A*, which centers its base end, the shell being pressed into this chuck by the ball-bearing spring-actuated tailstock *B*. The drive on this machine is also preferable from a floor countershaft, the lever *C* starting and stopping the machine by varying the belt tension. Owing to the high speed at which a machine of this kind is operated, a hand brake *D* is provided for the purpose of quickly bring the spindle to a stop with considerable saving in time.

Cleveland Twist Drill Co.'s Plant Uninjured

In our department devoted to "New and Enlarged Shops," on page 76 of the American issue of Mar. 2, we incorrectly stated that the Cleveland Twist Drill Co., Cleveland, Ohio, was about to rebuild its plant, which had been destroyed by fire. This erroneous information was sent us by our Cleveland representative. As a matter of fact, the fire was confined to an unused shed, and the damage was trifling.

In our issue of Mar. 9 (American edition), on page 439, in the column devoted to "Business Items" we published a correction. Unfortunately, our original notice has been widely copied and quoted, and in a further effort to correct our mistake these paragraphs have been written.

The injury to the plant of the Cleveland Twist Drill Co. was slight, and regular production has not been interfered with in any way.

PERSONALS

William Arend has become general superintendent of the Cisco Machine Tool Co., Cincinnati, Ohio, succeeding George Spinner.

F. L. Cone, for more than 20 years associated with the Windsor Machine Co., Windsor, Vt., for the past 11 years as general superintendent, has resigned.

C. Earle Hoover has been elected president of the Hoover, Owens, Rentschler Co., Hamilton, Ohio, filling the vacancy caused by the death of his father, J. C. Hoover.

A. B. Hutchison, formerly machine and tool foreman of the Buckeye Traction Ditcher Co., Finley, Ohio, is now superintendent of the Dayton Pipe Coupling Co., Dayton, Ohio.

James McIlvrid, for many years manager of the Cockburn Co. and its successor, the Standard Gas Power Corporation, has resigned, in order to establish the Mutual Iron Works, Jersey City, N. J.

C. J. Hopkins, until recently a member of the engineering department of the Deere & Co., Moline, Ill., has been appointed production superintendent of the Curtis & Co. Manufacturing Co., St. Louis, Mo.

J. R. Stine has been appointed chief of the routing and controlling department of the Bullard Machine Tool Co. Mr. Stine was for several years head of the production department of the Locomobile Co.

Ross Anderson has resigned as factory superintendent of the Flannery Bolt Co., Bridgeville, Penn., to accept the position of factory manager with the Poole Engineering and Machine Co., Baltimore, Md.

Boyd Nixon, who for many years was connected with Harron, Rickard & McCone, San Francisco, Calif., has joined the selling organization of the Niles Tool Works Co., with headquarters in Cleveland, Ohio.

J. D. Cudney, who for some time past has been sales manager of the Alberger Gas Engine Co., Buffalo, N. Y., and its subsidiary companies, Alberger Heater Co. and the Howard Iron Works, has recently resigned to become sales manager of the Rathbun-Jones Engineering Co., Toledo, Ohio.

Arthur Falkenau, vice-president of the Hooper-Falkenau Engineering Co., New York City, has become acting consulting engineer of the Canadian Car and Foundry Agency which is carrying on the production of Russian munitions in more than eighty plants in the United States and Canada.

BUSINESS ITEMS

Modern Tool Co., Erie, Penn., has appointed the Walter H. Foster Co., 50 Church St., New York, agents for the Eastern territory for its grinding machines.

Rickert-Shafer Co., manufacturer of tapping machines and self-opening dies, moved on Apr. 1 into its new and larger shop at West 12th and Cherry St., Erie, Penn.

Prices--Materials and Supplies

IRON AND STEEL

Pig Iron—Quotations were current as follows at the points indicated:

	Mar. 31, 1916	One Month Ago	One Year Ago
No. 2 Southern Foundry, Birmingham	$15.00	$15.00	$9.00

MIDDLE WEST

Preliminary plans are being prepared for the construction of an addition to the plant of the Enterprise Manufacturing Co., manufacturer of fishing tackle and metal specialties, at Akron, Ohio. Estimated cost, $25,000. E. A. Pfluger is Pres.

Plans are being prepared for the construction of an addition to the plant of the Twentieth Century Heating and Ventilating Co. at Akron, Ohio. Noted Feb. 24.

The Canton Sheet and Mill Co. plans to build a 3-story, 50x55-ft. and 97x172-ft. addition to its plant at Canton, Ohio.

Bids are being received for the construction of a 2-story, 35x80-ft. factory at Cincinnati, Ohio, for the Cincinnati Lathe and Tool Co. Estimated cost, $20,000. Noted Mar. 16.

The Elmwood Castings Co. plans to construct a 114x200-ft. addition to its plant at Murray Rd. and Cleveland, Cincinnati, Chicago & St. Louis Ry., Cincinnati, Ohio.

The Gruen Watch Manufacturing Co. has been granted a permit for the construction of a 2-story, 60x160-ft. factory on McMillan St., Cincinnati, Ohio. Estimated cost, $30,000. Noted Jan. 20.

The contract has been awarded for the construction of a 1-story, 130x140-ft. addition to the plant of the Ajax Manufacturing Co., manufacturer of nut and bolt machinery, at Cleveland, Ohio. Noted Mar. 23.

Plans are being prepared by George S. Rider & Co., Arch., 512 Century Bldg., Cleveland, Ohio, for the construction of a factory on Harvard Ave., Cleveland, for the Cleveland Wire Spring Co., Hamilton Ave. Estimated cost, $100,000. Noted Mar. 23.

Bids have been received for the construction of a 2-story, 150x160-ft. addition to the factory of G. F. Mitchell & Son, manufacturer of sheet metal work and die stamping, at Cleveland, Ohio. Estimated cost, $20,000.

The Newburgh & South Shore Ry. plans to construct a machine shop at 4190 East 71st St., Cleveland, Ohio. H. L. Scheular, Western Reserve Bldg., Cleveland, is Ch. Engr.

The Overland Cleveland Co., 6604 Euclid Ave., Cleveland, Ohio, has awarded the contract for the construction of a 4-story garage, service and sales building on Euclid Ave., Cleveland. Estimated cost, $200,000. Noted Nov. 18 and Feb. 17.

The Packard-Cleveland Motor Co., 5206 Prospect Ave., Cleveland, Ohio, plans to construct an addition to its plant at Cleveland. Estimated cost, $100,000.

The Republic Structural Iron Works Co., 1270 East 53rd St., Cleveland, Ohio, plans to enlarge its plant on Lakeside Ave., Cleveland. Estimated cost, $250,000.

The Pittsburg Sheet and Tin Plate Co. has purchased the old steel mill at East Norwood, Ohio, Cincinnati post office, and will remodel it into a tin plate mill.

The American Shipbuilding Co. plans to construct a foundry addition to its plant at Lorain, Ohio.

Plans are being prepared for the construction of a factory at Loudonville, Ohio, for the Flexible Side Car Co.

The American Sheet and Tinplate Co., Wheeling, W. Va., plans to improve its plant at Martins Ferry, Ohio. Estimated cost, $100,000.

Plans have been prepared for the construction of a factory at 1787 East 40th St., New Haven, Ohio, for the American Stove Co. Estimated cost, $50,000.

The American Steel and Wire Co. will rebuild its plant at Salem, Ohio, recently destroyed by fire with a loss of $10,000. R. W. Ney is Gen. Mgr.

Carl F. Baker, 63 East 74th St., New York, N. Y., has purchased the plant of the Cyclops Steel Works at Titusville, Ohio, and plans to build additions.

The National Malleable Casting Co., 2126 Front St., Toledo, Ohio, will construct a garage at Toledo.

Bids will soon be received for the construction of a 1-story, 80x250-ft. factory at Brazil, Ind., for the Wood Turrett Machine Co. David Wood is Mgr. Noted Nov. 11.

Plans are being prepared for the construction of three 2- and 3-story, 65x150-ft. factory buildings for the General Electric Co. at Ft. Wayne, Ind. Estimated cost, $200,000. F. S. Hunting is Gen. Mgr.

The contract has been awarded for the construction of a 1-story, 50x120-ft. garage on North Mitchell St., Cadillac, Mich., for George F. and Clarence F. Williams.

The contract has been awarded for the construction of a factory at 2nd and Amsterdam Ave., Detroit, Mich., for the Chicago Pneumatic Tool Co.

The Stewart-Warner Speedometer Corporation, 1828 Diversey Parkway, Chicago, Ill., plans to construct a factory on Woodward Ave., Detroit, Mich.

The Brownwall Engineering and Pulley Co. has awarded the contract for the construction of a 2-story, 50x100-ft. factory at Holland, Mich. Estimated cost, $22,480. F. A. Wall is Mgr. Noted Mar. 9.

The Chicago Link Belt Co., 329 West 39th St., Chicago, Ill., will construct a 2-story addition to its plant at Chicago. Estimated cost, $35,000.

A. Finkel & Sons, 1322 Cortland St., Chicago, Ill., will build a 1-story, 25x110-ft. machine shop at Chicago. Estimated cost, $4,000.

F. W. Gehrer, Lincoln and North Ave. Chicago, Ill., plans to build a 2-story factory at Chicago for the manufacture of metal specialties. Estimated cost, $7,000.

The Illinois Steel Co. has awarded the contract for the construction of a 1-story garage at 1653 McHenry St., Chicago, Ill. Estimated cost, $15,000. Noted Mar. 16.

Plans are being prepared by Albert P. Dippold, Arch., 1330 East 47th St., Chicago, Ill., for the construction of a 2-story, 100x200-ft. garage at Chicago, for the William Rudd & Co.

F. V. Wolcott, 1958 Montrose Ave., Chicago, Ill., plans to construct a 1-story machine shop at 4437 North Lincoln Ave., Chicago. Estimated cost, $8,000.

Wright & Street, 233 West 63rd St., Chicago, Ill., manufacturer of jewelry, plans to construct an addition to its plant at Chicago. Estimated cost, $10,000.

The contract has been awarded for the construction of a 2-story garage at Jerseyville, Ill., for William Simmons. Estimated cost, $19,000.

The contract has been awarded for the construction of a 2-story, 50x139-ft. garage for William Brandt at Winnetka, Ill. Estimated cost, $15,000. Noted Oct. 14.

H. F. Wetter, 22 North Park Ave., Fond du Lac, Wis., has awarded the contract for the construction of a reinforced-concrete garage and machine shop at Fond du Lac. Estimated cost, $12,000.

Bids are being received for the construction of a garage and machine shop for J. C. Harlow at Janesville, Wis. Noted Feb. 10.

Bids will soon be received for the construction of a 2-story, 48x60-ft. reinforced-concrete garage and repair shop at Poynette, Wis., for Jamieson Bros.

Plans are being prepared for the construction of a tin shop at Sheboygan, Wis., for the Prange Geussenhainer Co., 802 North 8th St., Sheboygan, manufacturer of hardware and plumbing.

The Pioneer Manufacturing Co. plans to construct a machine shop and factory at 6703 Greenfield Ave., West Allis, Wis.

WEST OF THE MISSISSIPPI

The Tri City Railway Co. of Iowa, Davenport, Iowa, plans to construct a machine and repair shop at Rock Island, Ill. J. G. Huntoon, Vice-Pres. and Gen. Mgr.

Plans are being prepared for a 2-story garage for the Gohring Auto Co., Iowa Falls, Iowa. Estimated cost, $12,000.

Bids are being received by the King Ventilator Co., Owatonna, Minn., for the construction of a 2-story factory. Estimated cost, $4,000.

C. E. Rossman and associates, Thief River Falls, Minn., plan to construct a garage on North Main St. Estimated cost, $10,000.

Plans are being prepared for a garage for Bloom Bros., Osage City, Kan. Estimated cost, $10,000.

C. F. Sands, Kirksville, Mo., will construct a 2-story garage. Estimated cost, $15,000. W. H. Johns, 4029 Tracey St., Kansas City, Arch.

According to press reports the Wyeth Hardware and Manufacturing Co., St. Joseph, Mo., plans to construct a 6-story saddlery plant at 2nd and Faaron St. Estimated cost, $150,000.

The Missouri, Kansas & Texas Ry. plans to construct car shops at Muskogee, Okla. Estimated cost, $166,000. L. F. Lonnbladh, Dallas, Tex., Ch. Engr.

The Chevrolet Motor Car Co., Flint, Mich., plans to construct an assembling plant at Ft. Worth, Tex.

The Colorado Motor Car Co., Pueblo, Colo., plans to construct a garage at 9th and Main St. Estimated cost, $20,000.

WESTERN STATES

The contract has been awarded for the construction of a 50x100-ft. garage and machine shop on Woodlin Ave., Chelan, Wash., for Hendricks & Braden.

Yakima County plans to construct a garage at North Yakima, Wash.

Harris Bros., Ritzville, Wash., plans to construct a garage and machine shop at Ritzville.

The Gerlinger Motor Co., Portland, Ore., will construct a factory at Tacoma, Wash.

The North Bank Railroad Co., Vancouver, Wash., plans to build a plant for reclaiming scrap iron, enlarge its roundhouse and purchase new machinery. Estimated cost, $20,000.

The J. A. McEachern Co. plans to construct a shipbuilding plant at Astoria, Ore. W. W. Clark is Mgr.

The J. C. Braly Auto Co. plans to construct a machine shop at 19th and Washington St., Portland, Ore.

Plans being prepared by Arthur G. Lindley, 310 Hollingsworth Bldg., Los Angeles, Calif., for garage and machine shop on West Broadway, Glendale, Calif., for L. E. Brockman, 1102 West Broadway, Glendale.

Plans are being prepared for the construction of a factory on Boyle Ave., Laguna Beach, Calif., for the Cochise Machine Co., 405 Aliso St., Los Angeles.

The contract has been awarded for the construction of a 1-story factory at Folsom and Ritch St., San Francisco, Calif., for the Johnson Gear Co.

CANADA

Plans are being prepared by L. H. Taylor, 13 St. George St., Brantford, Ont., for the construction of a garage at Brantford, for C. J. Mitchell, 53 Darling St. Estimated cost, $20,000.

The Stanley Steel Co., recently incorporated, will build a plant at Hamilton, Ont. E. A. Moore, New Britain, Conn., is Pres.

The E. T. Wright Co., manufacturer of tinware, plans to construct an addition to its plant on Cathcart St., Hamilton, Ont.

Plans are being prepared for the construction of a plant at Harrow, Ont., for the W. Clark Canning Co., Montreal, Que. Estimated cost, $25,000.

The Brown Copper and Brass Rolling Mills, Ltd., is constructing a brass rod and shape mill at New Toronto, Ont. Estimated cost, $125,000.

The Galbraith Co., Ltd., plans to install new machinery in its plant at Owen Sound, Ont., for the manufacture of toys. E. Galbraith is Pur. Agt.

The Renfrew Machinery Co. will rebuild its plant at Renfrew, Ont., recently destroyed by fire with a loss of $100,000. Noted Mar. 30.

GENERAL MANUFACTURING

NEW ENGLAND STATES

Plans are being prepared for the construction of additions to the woolen mills at Franklin, N. H., of the M. T. Stevens Co.

The contract has been awarded for the construction of a 2-story, 32x150-ft. factory at Gardner, Mass., for Nichols & Stone Co., manufacturer of chairs.

The contract has been awarded for the construction of an addition to the plant of the Nonotuck Paper Co. on Mosher St., Holyoke, Mass.

The Wattaquottoc Worsted Co. plans to construct a 1-story, 75x180-ft. addition to its plant at Hudson, Mass.

The Boston Duck Co., Bondsville, Mass., plans to construct a 5-story, 130x400-ft. mill at Palmer, Mass.

The contract has been awarded for the construction of a 4-story factory at Bridgeport, Conn., for the Holmes & Edwards Silver Co., 874 Crescent St., Bridgeport. Estimated cost, $50,000.

The Vincent-Doyle Hat Co. contemplates rebuilding its factory at Danbury, Conn., recently destroyed by fire with a loss of $30,000.

MIDDLE ATLANTIC STATES

The contract has been awarded for the construction of a 3-story factory at 3rd and Walnut St., Niagara Falls, N. Y., for the Defiance Paper Co. Estimated cost, $175,000. Noted Jan. 13.

The Niagara Electrochemical Co., Niagara Falls, N. Y., will reconstruct the 4 buildings of its plant at Buffalo Ave. and 24th St., recently destroyed by fire. H. R. Carveth is Gen. Mgr.

R. Neumann & Co., Hoboken, N. J., manufacturer of leather goods, has acquired a site on Ferry St. on which it plans to build a plant. Robert T. Heitemeyer is Pres.

The Union Terminal Cold Storage Co., 13th and Provost St., Jersey City, N. J., has awarded the contract for a 7-story addition to its plant.

Plans are being prepared by Lee & Hewitt, Arch., 1123 Broadway, New York, N. Y., for 3-story factory on Union Ave., Paterson, N. J., for Harris Bros. Silk Co., 25 Manchester Ave., Paterson. Estimated cost, $20,000.

The plant of the William F. Taubel Hosiery Co., Trenton, N. J., recently destroyed by fire, will be rebuilt. Contract has been awarded. Estimated cost, $80,000. Noted Feb. 24.

The Susquehanna Cut Glass Co., Altoona, Penn., will construct an addition to its plant.

The contract has been awarded for the construction of a 2-story factory for the Swiss Cleaners and Dyers and the International Bag Co., Bethlehem, Penn. Estimated cost, $10,000.

The Mt. Holly Paper Co., Mt. Holly Springs, Penn., contemplates an expenditure of $100,000 for improving its plant.

Plans are being prepared for a loom factory at North Wales, Penn., for L. H. Gilmer Co., 52 North 7th St., Philadelphia, Penn. Estimated cost, $10,000.

D. G. Berry, Olyphant, Penn., manufacturer of silks, will build an addition to his plant on Lincoln Ave. and Main St.

The contract has been awarded for the construction of a 3-story factory at Emerald St. and Allegheny Ave., Philadelphia, Penn., for the Cleveland Worsted Mills, 5932 Broadway. George Hodgson is Gen. Mgr. Noted Mar. 23.

The Pennsylvania Shipbuilding Co., 407 East Tulpehacker St., Philadelphia, Penn., plans to construct a plant on the Delaware River. George S. Hoell is Secy. and Treas.

The contract has been awarded for the construction of a plant at Allegheny and Front St., Philadelphia, Penn., for the Philadelphia Tapestry Mills. Estimated cost, $15,000.

The Atlantic Refinery Co., Pittsburgh, Penn., has awarded the contract for the construction of a 12-story building on Duquesne Way.

SOUTHERN STATES

The Kessler Manufacturing Co., Salisbury, N. C., manufacturer of sheeting, plans to construct an addition to its plant.

The P. H. Hanes Knitting Co., Winston-Salem, N. C., has awarded the contract for the construction of an addition to its plant. Estimated cost, $90,000. Noted Oct. 14.

The Huntley Furniture Co., Winston Salem, N. C., plans to construct a 4-story addition to its plant.

John D. Wylie, Lancaster, S. C., plans to construct a knitting mill at Lancaster. Estimated cost, $25,000.

The Star Hosiery Mills, Spartanburg, S. C., recently incorporated, has awarded the contract for the construction of a 2-story mill. Estimated cost, $50,000. Noted Mar. 23.

The Yargan Rosin and Turpentine Co., Brunswick, Ga., plans to rebuild its plants recently destroyed by fire. Estimated cost between $400,000 and $500,000.

The Mertas Mills, manufacturer of cotton cloth, Columbus, Ga., will soon award the contract for an addition to its plant. Estimated cost, $275,000.

The Grantville Cotton Mills, Grantville, Ga., contemplates an expenditure of $35,000 for improving and enlarging its plant.

The Chattanooga Aseptic Cotton Co., Chattanooga, Tenn., will rebuild its plant recently destroyed by fire with a loss of $75,000.

MIDDLE WEST

The Glidden Varnish Co. has awarded the contract for the construction of a 4-story, 50x108-ft. factory at Cleveland, Ohio. Estimated cost, $80,000. Noted Feb. 24.

H. E. Hyman has purchased a site on East 79th St., Cleveland, Ohio, and plans to build a 150x160-ft. rubber factory.

The Incandescent Lamp Works will construct an addition to its plant on Collamer Ave., Cleveland, Ohio.

The contract has been awarded for the construction of a 2-story, 45x55-ft. addition to the plant at Greenville, Ohio, of C. R. Patterson, manufacturer of carriages.

The Champion Coated Paper Co. plans to build an addition to its plant at Hamilton, Ohio. Estimated cost, $10,000.

The Marion Tire and Rubber Co. plans to build a plant at Marion, Ohio. Estimated cost, $20,000. J. Wilbur Jacoby is Secy.

The Evansville Veneer Co. plans to reconstruct its plant at Evansville, Ind., which was recently destroyed by fire. Estimated cost, $10,000.

The Olds Soap and Chemical Co., 534 West McCarty St., Indianapolis, Ind., will rebuild its plant recently destroyed by fire with a loss of $15,000. Charles E. Sheets is Pres.

The contract has been awarded for the construction of a 4-story, 80x120-ft. packing and cold-storage plant at New Richmond, Wis., for the Inter-County Co-operative Packing Co. Estimated cost, $100,000. Noted Mar. 9.

The E. I. Du Pont de Nemours Powder Co. contemplates an expenditure of $225,000 for improving its Barksdale plant at Washburn, Wis. F. T. Beers, Gen. Supt.

WEST OF THE MISSISSIPPI

Plans are being prepared for a factory for the Nelson Dry Cleaning Co., Ft. Dodge, Iowa. E. O. Damon, Jr., Mason Bldg., Arch.

The contract has been awarded for the construction of a 4-story factory on 9th St., St. Paul, Minn., for Maendler Bros., 42 East 3rd St., manufacturer of brushes. Estimated cost, $50,000. Noted Feb. 10 and Mar. 9.

The Carey Salt Co., Hutchinson, Kan., plans to construct a 1-story, 160x200-ft. packing plant. Estimated cost, $30,000.

Plans are being prepared by C. W. Terry, Arch., Wichita, Kan., for a 2-story addition to the factory of the Daniel Shoe Co., 415 South St., Wichita. Estimated cost, $15,000.

Plans are being prepared by Klipstein & Rathmann, Arch., Chemical Bldg., St. Louis, Mo., for a 2-story factory for the American Manufacturing Co., 220 North 4th St., St. Louis, manufacturer of cordage and bagging. Estimated cost, $25,000.

The Newark Canning Co., Newark, Ark., plans to construct a canning plant.

We have been advised that the Western Gin Co. will rebuild its plant at Seymour, Tex., which was recently destroyed by fire with a loss of $20,000. Noted Mar. 23.

The American Beet Sugar Co., Denver, Colo., plans to improve its plant at Rocky Ford, Colo. Estimated cost, $75,000.

WESTERN STATES

The Du Pont Powder Co., Stanfield, Ore., contemplates the construction of a plant at Meacham, Ore.

Press reports state that the Knight Packing Co., 474 East Alder St., Portland, Ore., contemplates constructing a canning plant at Medford, Ore. C. L. Knight is Pres.

The Long Fruit Products Co. has leased a 2-story factory at Portland, Ore., and will improve and install new machinery. Estimated cost, $20,000. Frank A. Long is interested.

Plans are being prepared for the construction of a 7-story packing plant at Portland, Ore., for the Union Meat Co. Estimated cost, $150,000. C. C. Colt is Mgr. of the company's interests at Portland.

Eugene Bosse, Salem, Ore., contemplates constructing a plant at Roseburg, Ore., for retting and scutting flax.

The Sonoma Valley Canning Co. plans to construct a cannery at Sonoma, Calif. Estimated cost, $20,000. T. A. Van Guredy is Supt.

The Western Meat Co., San Francisco, Calif., has awarded the contract for the construction of a 5-story, 75x95-ft. cold-storage plant at South San Francisco.

The Foothill Orange Grove Co. plans to construct a packing plant at Strathmore, Calif. Estimated cost, $100,000. W. L. Crowe is Mgr.

CANADA

The Ontario Yarn Co., Markham, Ont., will construct a factory at Hamilton, Ont., and will be in the market for machinery estimated to cost, $20,000. J. A. Kammerer, Toronto, is Pres.

The York Knitting Mills Co., 993 Queen St. W., Toronto, Ont., plans to construct a factory at Toronto. Estimated cost, $40,000.

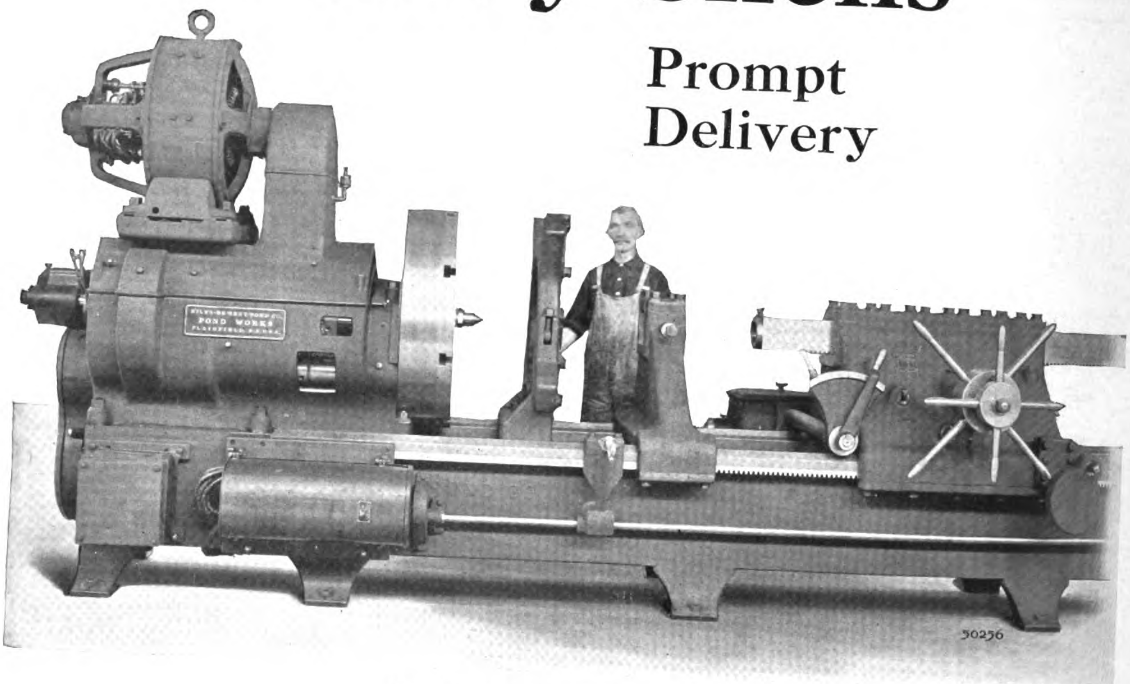
Lathes for Boring Heavy Shells

Prompt Delivery



36-In. Heavy Lathe with boring tailstock.

All Steel Gears

Lathes are equipped throughout with steel gears and are driven by 20-hp. motors. Rear end of spindle is provided with a special thrust bearing of heavy construction to take the end thrust due to boring large holes.

Boring Tailstock

The boring ram is forged steel 6-in. square, and has a very long bearing in the tailstock. The ram feed is driven from the feed shaft, at the rear of the bed, through worm and worm wheel giving a smooth motion for boring. By means of two levers, four feeds can be obtained without changing any gears. These levers are attached to the tailstock and hence are always in a convenient position.

Supports for Work and Boring Ram

A steady rest is provided to support the shell or other work. There is also furnished a special rest to support the end of the boring ram. This rest moves along the bed with the ram as it feeds.

Specifications, Delivery, Prices, etc., Promptly Furnished on Request.

Golden Rule is the Law of Success*

By Elbert H. Gary
Chairman of the Board, United States Steel Corporation
**Extracted from a recent address*

"But after all differences are adjusted, the nations now or to be engaged in this colossal conflict, though terribly crippled, will take a new start and in many respects a new course, and will begin immediately to build on a better and firmer and more permanent basis for success and high achievement in everything that adds to national wealth, power, energy and enterprise.

"These nations will not remain inactive or despondent or indifferent.

"We shall see the most active and persistent efforts to rebuild and extend and to succeed in the international race for supremacy that the world has ever witnessed.

"From adversity will come greater prosperity than ever before. From necessity will spring thought and study and effort that will enable the survivors to reach greater heights of success than has been supposed to be within the reach of humankind.

"Now, what should the United States prepare for? If we conduct our affairs properly, if we make the most of our opportunities, if we cooperate with one another, if the government and governmental agencies and the business people are allies one with the other, we shall become stronger and richer and more potential in our influence, and we shall be able to take a place in the van of nations, progressing toward results more satisfactory than ever before.

"Assuredly we may build our hopes and expectations on the opportunities which this country offers.

"It seems to me at this moment the outlook for improvement in our lines of activity are better than they have been for more than a year. This is undoubtedly in part the result of increased exportations at fair prices, due to the European wars, but in my opinion also because of a change in sentiment toward business, which now seems apparent.

"Now the time is come when the business man, even if he represents large interests, may speak frankly and freely about any of the important questions which affect him or those whom he represents.

"When and while our attitude and conduct are above reproach, others will be willing to heed what we may say concerning any question in which they or we may be interested.

"The captain of industry is again to be popular in the United States and this has been brought about by the effort of business men to satisfy the public in regard to their reasonable demands.

"The individual, or aggregation of individuals, or the nation, whose standard of conduct conforms to the golden rule will on the average secure the largest pecuniary success.

"The clouds of distress, suspicion and hostility are breaking. In the rift we may see the sunlight of better things and better conditions."

Automatic Double-Spindle Surface Grinder

SYNOPSIS—This machine is not merely a double-end grinder, but it is fitted with two separate spindles and other mechanism that make it in reality two distinct machines on a single base. This construction gives a minimum of floor space covered and at the same time allows two operators to work independently of each other.

To be successful, a machine must be designed with the thought of the work it has to do, the way a workman will use it and the ease with which the various parts can be manufactured. Of course, there are other things to keep in mind; but the three mentioned are extremely important, and one or the other is frequently overlooked by designers without practical or shop experience. The grinder described in this article is the product of a shop engineering staff accustomed to making precision gages, dies, jigs and fixtures of all kinds where accuracy is essential. At the outset it was realized that, owing to the numerous adjustments, a universal type of machine was not desirable for very accurate work. For this reason something along the lines of the plain surface grinder was decided upon. The average toolroom is unusually crowded for space, so for both toolroom and manufacturing purposes the grinder is of the duplex type, carrying two distinct machines on a single base. Made in this way, it embodies the advantages of two separate machines.

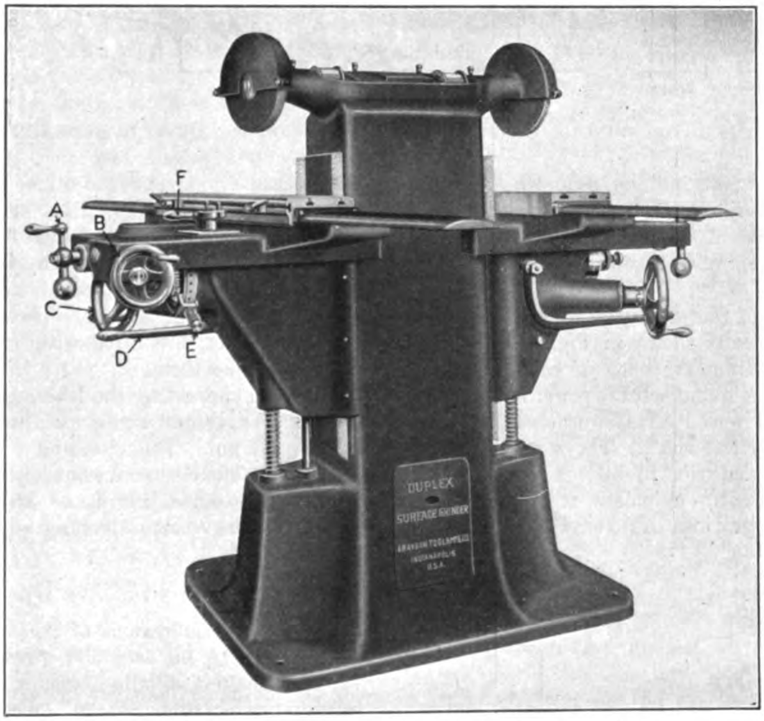

FIG. 1. AUTOMATIC DUPLEX SURFACE GRINDER

This grinder, which is shown in Fig. 1, is the design of the Grayson Tool and Manufacturing Co., Indianapolis, Ind. Briefly stated, the main features are ample weight and proportions to give the required rigidity, long knee bearing on the column, automatic and hand feeds, protected bearings throughout, ample table stroke, separate grinding spindles, cushioned table stops to avoid communicating jar to the opposite side, convenient grouping of handles and levers, special wheel-changing sleeves, wipers on all slides and an effective oiling system. The various controlling levers are as follows: *A* is for hand crossfeed; *B*, fine hand crossfeed; *C*, handwheel for elevating screw; *D*, neutral lever; *E*, feed-change lever; *F*, feed-clutch lever.

A single spindle for a double grinder of the type shown is not desirable, for the reason that one operator frequently has to stop his wheel while the other operator is working. This item alone is considerable; but add to this the fact that a bump or a jar on one end of the spindle is almost certain to affect the grinding on the other, and the idea of a single spindle at once becomes untenable where accurate work is required.

By referring to Fig. 2, where the spindle construction is shown in detail, the way the idea has been carried out is evident at once. The two spindles are duplicates. On one end they carry the grinding wheel and on the other a grooved pulley, from which the feeding mechanism is driven by means of a round belt working on the inside of the column. The spindle itself is of tool steel, hardened and ground, and runs in phosphor-bronze bearings. Oil reservoirs are provided underneath the bearings, from which oil is fed by wipers in direct contact with the spindle. The spindle itself is so made that it may be ground all over, as there is not a thread on the outside of it. The only threads are internal ones in the spindle ends. The adjusting collars are carried on a threaded sleeve that is shrunk on the spindle after it is ground. Both spindles have taper bearings at each end, these tapers being of uniform angle.

The thrust collars are hardened and ground steel, and the bearing dust caps are provided with felt washers. The bearings are long enough, and the adjusting collars are suitably placed, so that play may be taken up and still have a cool-running spindle. A feature is that all grinding wheels are carried on $1\frac{1}{4}$-in. sleeves, shouldered and threaded for a locknut. These sleeves accurately fit the tapered end of the spindle, so that special or formed wheels may be used at any time without the necessity of re-dressing each time. A number of extra sleeves are furnished with each machine.

A special spindle attachment is also provided for carrying a smaller wheel than the usual run. This attachment fits the end of the spindle and will hold wheels ⅛ in. or less in thickness and 3 in. in diameter. With a wheel of the size mentioned, slots $\frac{3}{32}$ in. may be ground out. From these small wheels others up to ¾x8 in. may be used. The countershaft has three speeds, so that a 3-in. wheel may be run at 4,300 r.p.m., a 5½-in. wheel at 3,200 r.p.m. and an 8-in. wheel at 2,150 r.p.m. This gives very closely the right number of feet per minute of peripheral speed. The countershaft may be stopped for each spindle without interfering with the other in any way.

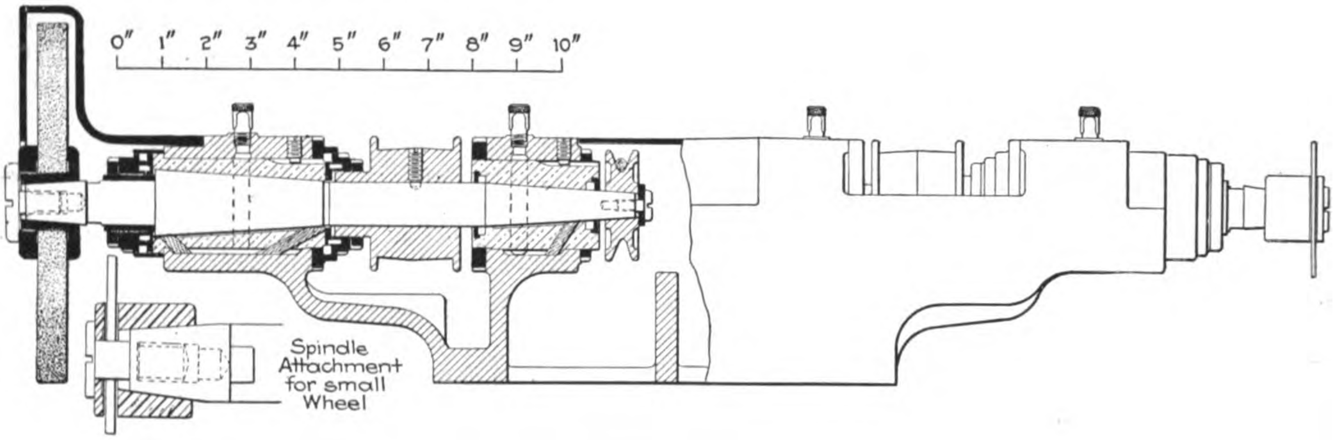

FIG. 2. DETAIL OF SPINDLE CONSTRUCTION OF AUTOMATIC DUPLEX SURFACE GRINDER

The arrangement of the principal parts of the feeding mechanism is graphically shown in Fig. 3. The round belts leading down from the ends of each spindle are easily seen. From the round belt the power is transmitted to a cross-shaft and worm. This worm meshes with a worm gear on a vertical shaft. The worm and worm gear are hardened and run in oil. A neutral clutch lever throws out the entire automatic feed when desired. Other clutches are provided for throwing either table traverse or crossfeed in or out. The table automatic traverse is regulated by adjustable stops, which are cushioned to prevent the jar of the reverse from being communicated to the other parts of the machine.

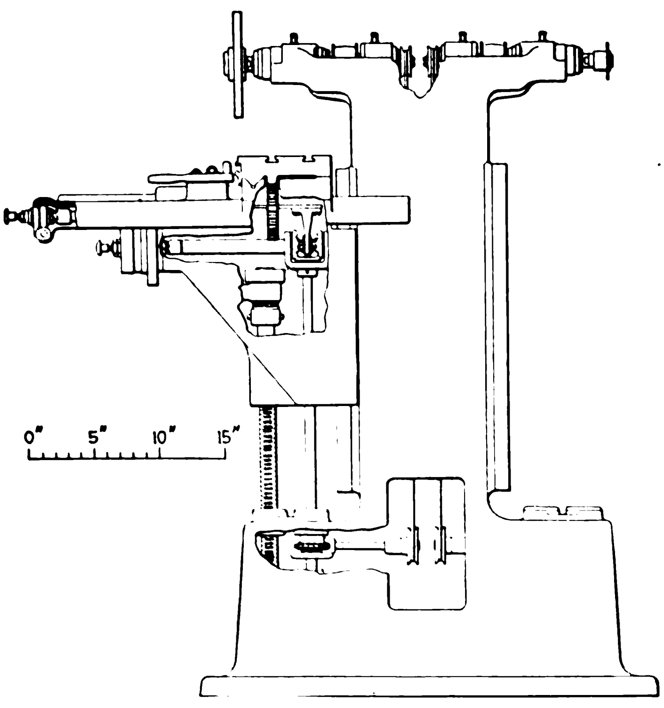

FIG. 3. DETA... AND DRIVE MECHANISM

There are ten changes of crossfeed available, regulated by a stationary and a movable dog on a perforated disk in front of the knee. For hand crossfeeding, two means are provided: One is by direct crossfeed screw turning, with a ball crank, and the other—for fine work—is by a geared handwheel that gives an extremely fine feed. The crossfeed and elevating screws are provided with dials graduated to read in thousandths, for convenient setting. The table has long way guards bolted to each end to protect the bearing surfaces. These, as well as all other sliding surfaces, are fitted with wipers to prevent grit from damaging them.

The knee supporting the table and mechanism is made especially heavy and rigid, with unusually long bearings on the column. The elevating screw has ball-bearing thrust and felt wipers. A convenient handwheel, angling out from the knee, affords an easy means of elevation without unnecessary stooping on the part of the operator.

Machine Specifications

The main specifications of the machine follow: Spindles, each 14½ in. over all; greatest spindle diameter. 1¼ in.; smallest spindle diameter, $\frac{9}{16}$ in., at inner end: front taper bearing, 3¾ in. long; rear taper bearing. 2¼ in. long; regular wheel sleeves, 1¼ in. in diameter where wheel goes on; spindle pulleys, 1-in. bore, 2½ in. in diameter and $1\frac{1}{16}$ in. between flanges; maximum distance from top of table to center of spindle, 14½ in.; width of table, 7 in.; table traverse, 18 in. with hand or automatic feed; crossfeed, 6½ in.; table T-slots, ½ in. wide; ten crossfeeds ranging from 0.025 to 0.250 in.; three spindle speeds, 2,150, 3,200 and 4,300 r.p.m., intended for 8-, 5½- and 3-in. wheels respectively; elevating screw, 1¼ in. diameter; column ways, 24½ in. long; knee bearing on column, 13¼ in.; base of machine, 24x35 in.; outspread of levers, handles and all, 6x5½ ft.: height over all, 50 in.; weight, about 1,200 lb.

⌘

The Sensitiveness of the Human Eye and its ability to distinguish color were made the subject of an interesting experiment by Professor Nichols, of Cornell University. Ninety-two different shades of blue were placed before 54 observers, and the general average for placing these shades in proper relation was over 95 per cent.

Limiting Improvements in the Small Shop

By John H. Van Deventer

SYNOPSIS—Dave Hope tells of the small-shop experiences of two of his acquaintances. One of them was a "stick-in-the-mud" who became a Captain of Industry; the other, a brilliant but erratic individual, finished up as he began—in a nut factory. This article explains why some of us are not millionaires.

"No, sir! It's a very promising machine, but I don't want to make it."

Dave Hope was delivering this ultimatum to a young mechanic and inventor who had worked out an ingenious device and wanted Dave to manufacture it. The lad had brought for inspection a working model that was beautifully finished and that went through its motions in such an unusual yet precise way that no real mechanic could have examined it without being interested. In fact, the interest that Dave had displayed and the way that he had fingered the model had raised the inventor's hopes to a high point, and his keen disappointment at the final decision was evident.

"I'm too much of a mechanic to manufacture a machine of that kind, or in fact to manufacture anything at all," said Dave, taking note of the young man's feelings. "That is why I stick to contract work and to making experimental machines to order. No machine that I could manufacture would ever suit me, and I should be adding and improving all the time, which would be fatal to the finances."

"If a good mechanic won't manufacture a good machine, who is a fellow to go to?" asked the inventor despondently, reaching for his model.

"Wait a bit—don't go yet," said Dave. "I want to tell you about Jones and Jenks; perhaps it may help to answer your question.

Albert Jones, the Natural Improver

"Albert Jones was one of the smartest mechanics that ever lived. It came natural to him to improve things, and when he was in a shop he was always suggesting better ways of doing things. At night he'd spend his spare time thinking up new machines and making sketches of them, just for fun, throwing them away after they were all completed.

"Al got a job as 'improver' in a big shop. He was right at home at this work and made himself valuable. One day, perhaps, he'd be figuring a new way to chuck pistons and the next be sketching up an attachment to convert a drilling machine into a die sinker. Variety was his spice of life, and he never had to do the same thing twice.

"A man who lived as quietly and got as good pay as Al did couldn't help but save money, and after a few years he had a lump salted away so big that it bothered him to decide what he ought to do with it. Finally, he concluded to open a shop of his own and start manufacturing.

"The day after he had arrived at this decision he was called into the blacksmith department to scheme some way of keeping nuts from bouncing off the helve-hammer bolts and to prevent the bolts themselves from breaking. He sat up until 3 a.m. the next morning, scheming and sketching and scratching his head, and finally invented a shock-absorbing locknut. The following day he quit his job and filed a patent application.

"That locknut was the best thing of its kind that ever was. It would hang on like a suffragette, and its shock-absorbing qualities were without equal. A mighty good thing to start a manufacturing business on, was that nut, because it could be made in three operations by the crudest kind of help and sold for a price that was an inducement, even if it hadn't had such good qualities besides.

Al Gets Busy with Patent Lock Nuts

"Al had his plant going two months before the patent was issued and was forced to add a couple of men every week to keep up with the demand of a public that was hungry for shock-absorbing locknuts. In six months he had designed and built special machines that would turn the nuts out almost as fast as a boy could carry them away. Things looked very rosy indeed for Al—to an outsider.

"There was one big defect in it from his point of view—the thing couldn't be improved upon. It was so simple and perfect that nothing in that line could be any better. An ordinary man would have been very well pleased at such a state of things, but not Al. All of the inventiveness and ingenuity in his system was corked up, so to speak, and was building up a pressure that was bound in time to blow the cork out—that cork being the shock-absorbing locknut! He began to detest the sight of one. 'Why should a man with brains tie himself up for life to a dinky one-piece contraption like that?' he would ask himself. Then he would lay off for the rest of the day, go back to his room, put his stocking-clad feet on the radiator and dream of complicated mechanical stunts that would make an ordinary man dizzy to think about.

William Jenks Parts with Ten Thousand Plunks

"Al was a man who had to act quickly when an idea struck him, so he sold out his shock-absorbing nut business to a boob by the name of William Jenks, who had as much inventive ingenuity as an Eskimo's totem pole, but who seemed perfectly satisfied to give $10,000 for a business worth five times as much. Then our inventive friend turned himself loose again like a colt in a pasture and began to put lines on paper and take a fresh interest in life.

"The result of his mental cyclone was a patented adjustable universal reamer that had a range of something like an inch in diameter for one tool as against the ordinary range of adjustment which begins with a decimal point followed by a naught. Where the locknut had been but a one-piece article, this tool had 37 parts, not

counting the screws, and therefore looked 37 times as good to Al, who saw plenty of opportunity for improvements and evenings filled with enjoyable mechanical meditation.

"It took considerably longer to put the reamer on a paying basis than it had to make a go of the locknut. In fact, it cost Al so much money to start things and improve them a bit that he was forced to take in a partner—a mean man of money without high mechanical ideals, whose motto was, 'Let well enough alone!' Of course, Al couldn't work in harmony with a dub of this kind, so in a year he sold his interest to the dub for $5,000 and breathed freely once more.

A Vertical Lathe for Shaft Turning

"The next venture of friend Al was a duplex lathe that would turn two shafts at once and which, to save room, stood in a vertical position instead of horizontal. Al said that, while there were a number of vertical machines for chuck work, the vertical center-work field needed considerable improving. He produced a design that had several original features, one of them being the feed screw that was exactly in the center of the tool carriage, this latter sliding within the body of the lathe, a pair of headstocks and tailstocks being arranged on each side. He had quite a bit of fun improving this machine, especially in getting oil to stay in the vertical headstock bearings. By the time the sheriff came to the rescue and the last balance sheet was struck, Al came away with $2,500 and a sense of relief at the prospect of tackling something new.

"One of his friends told him that if he wanted a chance to let loose the full power of his wonderful improving ability he should get into the automatic game, where there was a chance to pull off something big. This sounded pretty good to Al; but $2,500 wasn't enough to break into the automatic game with, so he decided not to manufacture the machine, but to design one and get somebody else to build it.

"He had considerable trouble with his landlady, who insisted on getting into his room once a week to pick the papers off the floor, she being afraid to let them accumulate for a longer time than that because of the fire-insurance policy. This upset the inventing process badly, Al needing one or two days after each weekly clean-up to get the papers back on the floor again in their proper order. In spite of this, after a year of scheming and scratching he had an automatic machine that had more improved features than anything made before. It wasn't hard to get a patent on such an original batch of improvements, and a few months later, armed with official documents from Washington, Al started out to find a builder.

Finding a Builder for the Superautomatic

"He called on a man in the automatic business and explained in detail how superior the Jones superautomatic was to the machine produced by the company. He not only told it, but proved it, convincing the engineers and experts who were called in to examine the plans. Evidently, the Jones superautomatic would be a clean sweep! Al was told to leave his plans and to call again in a week.

"He was received very cordially by the president. 'My dear Mr. Jones,' said this gentleman, 'we will offer you an exceptional contract for your invention. We wish the exclusive right to this and all improvements that you may make and in return will pay you a royalty of $500 per machine. At this extraordinary figure we will expect you to act as consulting engineer and give a portion of your time to improving this device. Sign here on the bottom line!'

"I hardly need to say that Al signed. The president's words about 'improving' were even a stronger inducement than the $500 per.

"For several weeks the inventor of the Jones superautomatic lived in the clouds. He worked out all sorts of further improvements and turned them over to the company, which seemed to be rather slow in getting started on the first machine.

"After six months passed in the same way, our friend began to be worried, especially as he was no longer admitted to the plant. He lay in wait for the president one day and accused him of not living up to his contract. 'My man,' said this individual, 'go back and read your contract. We agreed to give you a royalty of $500 for each machine built and so far have lived up to your agreement absolutely.'

"What the president of the company had really done was to get Al out of the automatic field, where he would have been a dangerous man. His endless improvements would have kept things in an everlasting state of change, just as the man who finds out how to turn lead into gold will make a lot of trouble for everybody, including himself.

Al Jones Gets a Government Position

"The last I heard of Al Jones was that he had a Government position with board and lodging, but no pay. He was engaged in making chalk marks on the floor of the harmless ward; and when a visitor to the asylum asked him what he was drawing, he'd say it was an improved automatic automatic-machine-making machine!

"As time went on, the asylum got to be overcrowded and a new building badly needed. Nothing could be done by the state, however, owing to the high cost of legislators, and it remained for a public-spirited Captain of Industry to donate two or three millions for the purpose. Rather a coincidence it was that this money to build a home for harmless nuts should have come from manufacturing shock-absorbing locknuts! But then William Jenks, who gave it, although a boob, was a good-hearted sort of chap."

Dave paused a moment and then continued with specific advice to the young inventor. "Now, if you want to make a success of your machine, find some man with money, but without ideas, to get back of it and push it."

Factory Wastes and Remedies

By F. E. Merriam

In most factories there are many wastes and losses that are usually preventable by the exercise of care and vigilance. A number of the most common are here given, together with simple remedies that have been found effective.

Sweepings, waste paper, soiled wiping waste, etc., are generally considered a nuisance and source of expense, though many factories are finding them a source of profit. Sweepings from machine shops contain babbitt,

brass, copper and other valuable metals in addition to soiled wiping waste and materials that can be segregated and sold. The metals can be separated from the other materials and one another by machinery and hand picking; the waste paper can be picked out and baled and the soiled wiping waste cleaned for further use.

To handle the soiled wiping waste at a profit requires organization and systematic methods. The most effective manner is to have the used waste placed in suitable receptacles and regularly gathered, washed and redistributed. The sweepers should place in the receptacles all waste found on the floor. During the reclaiming process some oil will be saved, which is good enough for rough purposes, although it contains different kinds of oil besides a considerable amount of grit. Wiping towels instead of waste are often productive of saving, since all the towels can be easily recovered, while it is difficult to reclaim over 50 per cent. of the waste. Wiping towels cannot replace waste universally; but wherever suitable, they are economical.

Wooden Barrels Waste Oil

The ordinary methods of handling oil are inefficient and productive of considerable losses, even in small factories. The trouble originates with the wooden barrels in which oil is shipped and stored, since they frequently leak, even when new. This leakage increases and continues as long as any oil remains in the barrel. Every time oil is drawn, some escapes, owing to dripping and often to overflowing. Some waste there will be even with the best of apparatus and arrangements; but it will be very small, if proper equipment is selected.

Proper oil-handling equipment will consist of tank cars or steel barrels for shipping and steel tanks or barrels for storage, together with pipe lines, pumps, etc., for distribution. The quantity of apparatus required depends upon conditions. Where the quantity of oil handled and the distance is considerable, economy requires pipe lines and pumps, since they save handling, expedite conveying and prevent losses.

The ordinary method of filling oil cans, or oilers, is a source of loss, on account of the quantity spilled each time and the frequency with which the oilers need refilling. With a pump and funnel there is almost a certainty of overflowing the oiler; and while some oil runs back into the reservoir, another and considerable portion remains to be wiped off with waste, thus forming a complete loss. The portion that runs back into the reservoir is a source of inefficiency, since it collects dust and dirt, thus contaminating the oil and providing future bearing trouble.

This source of loss can be prevented by the use of a tank with a pump that automatically prevents overflowing by "bypassing" the oil to the reservoir after a definite amount is in the oiler. Such equipment, while more expensive than that ordinarily used, justifies the extra cost.

Handling of Lubricating Oils

In the case of lubricating oils there is usually a considerable loss connected with the oiling of machinery, on account of the careless manner of filling oil holes and oil cups. It is not uncommon to allow them to overflow, regardless of the fact that such an excess serves no purpose except to increase the oil consumption. Poorly fitted bearings permit the oil to waste away, saturating the floor and everything else near-by. Such a condition is wasteful, not only in the matter of oil, but of belting and other equipment that it ruins, besides creating disagreeable surroundings for the workmen. This wasted oil also causes dust and dirt to collect, causing more rapid wear of the machinery. Sometimes the workmen are allowed to clean their hands with oil, in spite of the fact that a suitable soap is cheaper and more satisfactory.

Economies may often be effected by a careful study of the cutting fluids. Not infrequently, equally good results are secured with a water solution of some cutting compound, as compared with oil, since for many purposes it possesses sufficient lubricating properties and, of course, is much more cooling. Any substitution, however, should not be made without a thorough knowledge of the situation and after careful experiments, since a great deal of harm may be done by premature changes, not only to the product, but also by creating prejudice against any improvement. On the other hand, a more expensive fluid may be more economical, on account of decreased tool wear, as well as of the wear of the machine, and an improved product. As a case in point, I have in mind a number of turret lathes that had been running on soda water solution, as a cutting fluid, costing about 1c. per gal. After this solution had been in use for some time, it was found that the machinery had deteriorated considerably, owing to wear caused by soda being deposited on the moving parts. This soda acted as an abrasive, bringing about the rapid impairment of the machinery and increasing the difficulty of handling. A cutting-compound solution costing about 2½c. per gal. was substituted, the wear decreased, and the finish of the product improved. Sometimes it is necessary to go even farther and use a high-grade cutting oil, as is done in the case of automatic machines.

Extracting and Reclaiming Oils

There is a loss connected with machines using cutting oils, unless the oil is extracted from the chips. This saving will be worth while even in the case of such an inexpensive fluid as kerosene, since there will be at least 1 gal. of oil recoverable in 140 lb. of chips as they are found in the pan of the machine. A lathe working on 3-in. diameter steel will easily make 2,000 lb. of chips per day and will thus make possible the recovery of about $1.40 worth of oil. In the case of a regular cutting oil there will be several times as much oil in the chips, and the saving will then be considerably more, on account of the greater value of the fluid. The only machinery necessary is a plain centrifugal oil separator, which is comparatively inexpensive.

Many times there are wastes of tool steel that can be prevented by systematic study. A common mistake is to employ an improper grade of steel. This sometimes occurs because the grade chosen is more easily heat-treated than the more economical one, and money is thus continually being dissipated because of application in the wrong place. This loss is not entirely confined to the use of a too high-grade steel, but frequently to the use of too low a quality. A well-known example is high-speed steel for die parts, in place of less expensive carbon steel. What is true in the case just cited applies even with more simple tools. Sometimes tool steel is used for a machine part where a properly heat-treated piece of machine steel would give equal, if not superior, results.

Punches and Dies for a Door-Hanger Carriage

By Robert Mawson

SYNOPSIS—In this article are shown the punches and dies used on the first four operations in manufacturing the crossbar of a door-hanger carriage. Eight operations are required, of which those described in this article are piercing and blanking, embossing, piercing end holes and trimming.

The carriage is part of the equipment made by the McCabe Hanger Manufacturing Co., New York City, and is used on various types of door hangers. A view of an assembled carriage is given in Fig. 1. It is composed of the crossbar, the making of which is here described, four cones each having a set of balls, four wheels and the uniting rivets. The overall width of the assembled wheels is held to a limit of 0.005 in., which denotes the high-grade work obtained with these tools.

In manufacturing the crossbar plates the first operation is piercing and blanking. The tools for this operation are designed with stops that enable the steel strip, which has been previously cut to the correct width, to be fed against one of the stops. The punch, being forced down, pierces the first plate. The stop is then pulled out and the second stop pushed back. The punch is again forced down with the press and pierces the second plate.

The two stops are then drawn back, and the plate is pushed against the stop at the rear end of the die. The punch, forced down with the machine, cuts off the first blank that was pierced. The operation is then continued. One stroke of the machine thus pierces two blanks and cuts off another.

The next tools in the sequence are those for embossing. The plate is pushed against a stop, and the depressions are formed with the tools shown. The holes at the ends are pierced, and it will be noticed that one of them is made larger than the other. This enables the two plates to be assembled as will be described in a later article.

The last tool illustrated is for trimming the blank. The piece is fed under the stripper plate against a locating stop, and the punch, which is made with a similar contour to that desired for the plate, is fed down on the stock and the operation performed. By examining Figs. 6 and 8 on the opposite page it will be seen that the blank is rectangular in shape until this trimming operation is reached, when it is formed to a contour having rounded ends and a connecting web slightly narrower than the rounded ends.

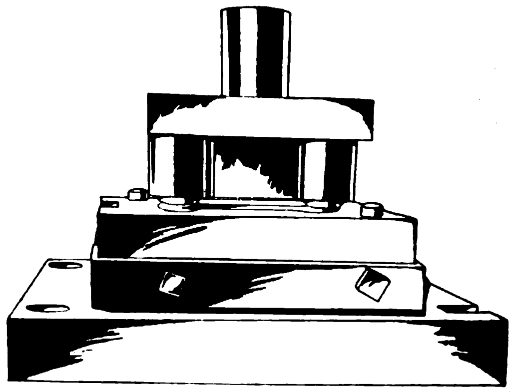

FIG. 9. TRIMMING PUNCH AND DIE

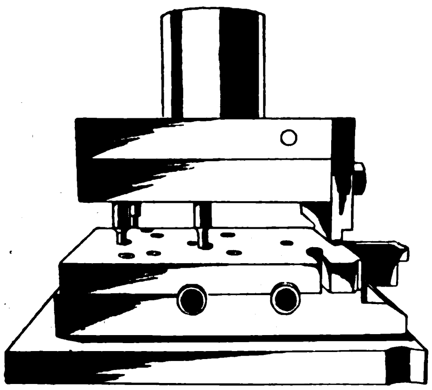

FIG. 3

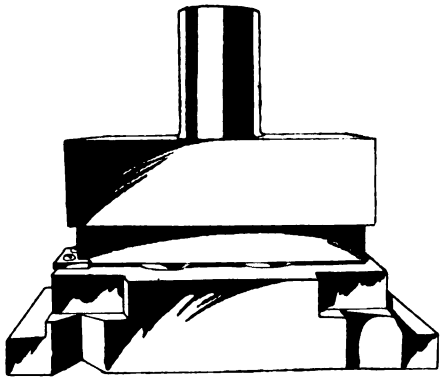

FIG. 5

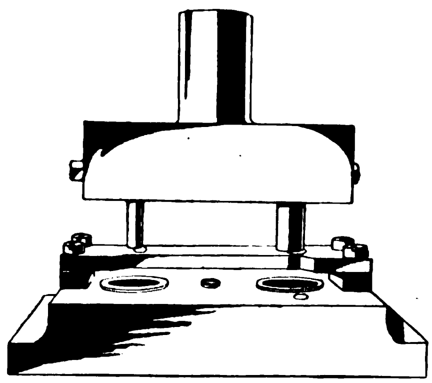

FIG. 7

PUNCHES AND DIES USED IN MANUFACTURING VARIOUS ELEMENTS OF A DOOR-HANGER CARRIAGE, WITH THE WORK SHOWN IN POSITION

FIGS. 3 AND 3-A

Operations—Piercing and cutting off blank, Fig. 2. The stock, which has been cut to width, is fed under the stripper and is first pierced. It is then fed to the next position, obtained by the second stop. The punch is caused to descend, and the second blank is pierced. The stock is pushed in again and the third blank pierced. The fourth position, determined by the stop at the rear, is obtained, and the punch, descending, cuts off the blank to length.

FIGS. 5 AND 5-A

Operation—Embossing the blank, as shown in Fig. 4. The blank is located against the strips at the end and the rear. The punch is then caused to descend, and the cup shape is embossed.

FIGS. 7 AND 7-A

Operation—Piercing end holes, as illustrated in Fig. 6. The blank is located in steel recesses, into which the embossed part fits. With the descent of the punch, the holes are pierced at each end through the center of the embossed recess.

FIGS. 9 AND 9-A

Operation—Trimming the blank to the contour seen in Fig. 8. The blank is pushed in from the end against the locating stop. The punch, which is made to the desired form, is forced down into the die, trimming the blank to the correct shape.

Grinding Wheel Selection

By Robert J. Spence

The occasional discovery of better combinations of grains for grinding wheels makes the revision of the grinding-wheel list from time to time practical, but not absolutely necessary. The old list of Norton wheels J, K, L and M, 24 combination, for ordinary machine-shop work, as used on Norton plain grinders, is just as efficacious today as it was 10 years ago.

In fact, in the small shop, where work to be ground comes to the grinder in small lots, it is not advisable to depart from the old list. A continuous changing from one wheel to another to satisfy grinding conditions to a minute degree loses more time in changing wheels and wear of wheel in re-truing than would be lost in the use of a wheel not in absolute harmony with the list employed by the automobile manufacturer who has a large variety of wheels. The old list was as follows:

Wheels for diameters under 4 in.: Soft steel—M, 24 combination alundum; hardened steel—K, 24 combination alundum; cast iron—K, 24 combination alundum; bronze —M, 24 combination alundum.

Wheels for diameters above 4 in.: Soft steel—L, 24 combination alundum; hardened steel—J, 24 combination alundum; cast iron—J, 24 combination alundum; bronze—L, 24 combination alundum.

However, by reason of the constantly increasing demand for greater output from grinders in the automobile industry and in munitions works a new list of grinding wheels has come into being. In this case each wheel has been selected to meet exact conditions and is used on the same machine on the same work day after day. Some of the larger plants even insist on having one man only do all the wheel truing in the entire grinding department. The new list follows:

Wheels for diameters under 4 in.: Soft steel—M, 24 combination alundum; hardened steel—K, 38 combination alundum; cast iron—30 K, crystolon; bronze—30 K, crystolon.

Wheels for diameters above 4 in.: Soft steel—L, 24 combination alundum; hardened steel—J, 38 combination alundum; cast iron—30 J, crystolon; bronze—30 K, crystolon.

In the rough-grinding of automobile crankshafts of soft material a 36 grade O alundum wheel is now used. Six years ago we were able to rough-grind the bearings of only two crankshafts before the wheel had to be retrued. The wheel then in use was the 24 combination O. Today, on shafts of similar material, with a 36 grade O wheel it is possible to rough-grind 10 shafts before re-truing the grinding wheel, and I have known operators to go as high as 75 crankshafts, where the wear on the grinding-wheel fillets was not excessive. Since it takes 110 revolutions of the cross-slide wheel to put the grinding wheel in position for truing and 110 revolutions to bring the grinding wheel back again to the cutting position, it can readily be seen that a great saving of time is effected by the latter wheel. In the finishing of these same crankshafts a 26-18 grade M wheel is now used in preference to the older 24 combination M.

In writing on grinding-wheel selection a person is generally tempted to de[illegible] number of grinding problems that have c[illegible]perience, and the result is that the reader is left in a state of confusion regarding the choice of the proper wheel. The more simple the matter can be made the better it is for all. Neither should an understandable list of grinding wheels for the machine shop contain a complicated assortment of articles that come under the jurisdiction of the pottery works, the optical-lens factory or the like.

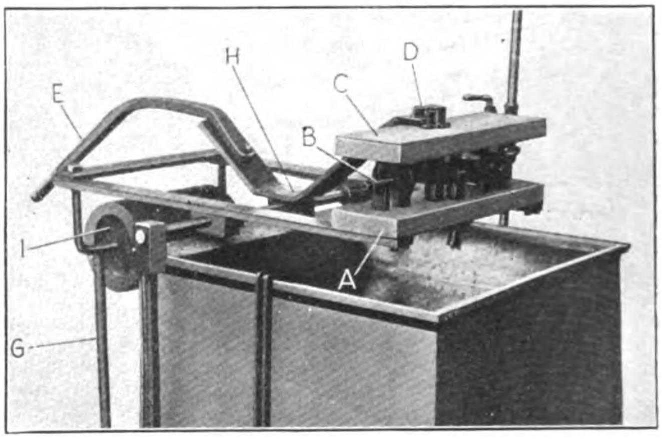
The lists of grinding wheels that I have designated are Norton grinding wheels that have given good service under ordinary conditions on Norton plain grinders.

A Dipping Fixture for Heat-Treating Crankshafts

By E. V. Thomas

All the crankshafts used by the Henderson Motorcycle Co., Detroit, Mich., are heat-treated by heating the crankshaft to a nice red and then quenching in an oil bath. To prevent distortion as much as possible, the crankshaft is held in a special dipping fixture, as shown.

The lower "jaw" *A* of this device has a number of V-blocks set into it, in which the shaft ends and crankpins fit nicely. The heated crankshaft is laid in these



CRANKSHAFT DIPPING FIXTURE

V-blocks as at *B*, and the upper jaw *C* is quickly brought down on it and locked by the taper pin *D*. The upper jaw is fitted with V-blocks to correspond to those on the lower, so that the crankshaft is held solidly between them.

The helper lifts the lever *E* and plunges the work beneath the oil. When the piece is sufficiently cool, the man ceases to push up on the lever, and the counterweight *F* helps to raise the work out of the oil. The weight is prevented from going down too far by means of forked supports *G*. When the taper locking pin is removed, the upper jaw may be lifted by pressing down on lever *E*, as it is hinged at *H*.

The High Polish of Russian Shells has been the subject of much discussion. One reason suggested when the shells were silver or nickel plated was that the plating acted as a resister against rust. And one of our rather sarcastic friends thought that so finished the shells looked better as souvenirs on the top of a grand piano in a drawing room. The subject may now be settled and further discussion cease. We have it from a high Russian authority that this fine finish and polish are to prevent pulling off some lint from the cotton gloves wore by the soldiers who load the guns. A rough surface on the shells would pull off some of this lint, which would fill up the clearance between the shell and the gun bore and impair the accuracy of the firing piece.

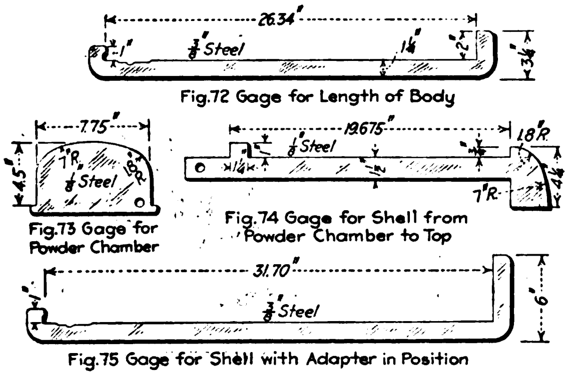
Manufacturing 12-In. Shrapnel--III*

By Robert Mawson

SYNOPSIS—The operations followed in machining the adapter, diaphragm, adapter bottom, adapter plug and powder tube. This article carries the manufacturing of the shell up to the final loading and shipment. The production time, fixtures and special methods employed are described in detail and fully illustrated.

For the final inspection the shell is first tested with the adapter out, the gage shown in Fig. 72 being used. The powder chamber is measured with the gage seen in Fig. 73, and the inside of the shell from the bottom of the powder chamber to the top of the adapter seat with the gage in Fig. 74.

The adapter is screwed down home by a clamp, Fig. 34. The gage illustrated in Fig. 75 tests the overall length of the shell, and the outside form is tested with the contour gage, Fig. 76. For the outside diameters



FIGS. 72 TO 75. LENGTH AND FORM GAGES

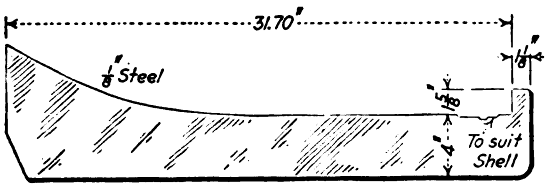


FIG. 76. OUTSIDE CONTOUR GAGE

the snap gages, Figs. 52, 54 and 77 (shown in Part II), and also the ring gages, Figs. 78, 79 and 80, are employed. The final gage for testing the shell is the profile form, Fig. 81.

In Fig. 82 is shown a handy truck that conveys the shells about the machine shop from the various machines to the testing department. In Fig. 83 are shown elements used on the shrapnel. At *A* is the rough-forged adapter as received at the factory, and at *B* is one finish-machined. A diaphragm is shown at *C*, an adapter bottom at *A*, adapter plug at *E*, powder tube at *F*, a number of the balls used in the shell at *G* and some powder pellets at *H*, the only missing elements being the powder and rosin. The manner in which they are placed in the shell will be described in another article.

The first operation in machining the adapter is forming the inside, facing the large end and machining the thread. Fig. 84 is a detail illustration of the adapter forging. For the first operation the rough forging is placed in the chuck, Fig. 85, which is held to the faceplate of the lathe with capscrews. The chuck jaws *A* are tightened against the forging by means of the setscrews *B*, thus holding the part securely. It will be observed that the jaws are operated independently, enabling the operator to hold the forging in the chuck so that it will be concentric.

The link, Fig. 37, is set up and operated in a similar manner to that described for machining the inside of the shell. As the tool carriage is fed forward with the adapter revolving, the link, drawing the carriage on an arc, machines the desired contour on the inside of the part.

The special bracket to hold the link is fitted to the side of the lathe bed, as in Fig. 86. An illustration

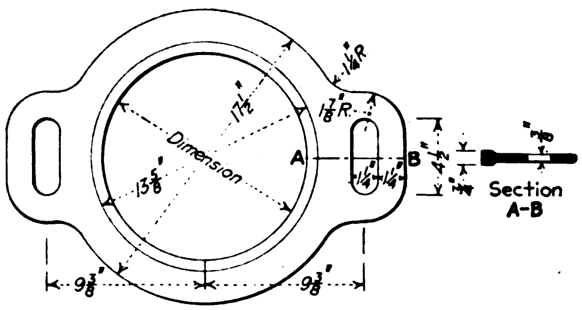

FIG. NO.	MAXIMUM	MINIMUM

of the set-up for performing the machining operation is shown in Fig. 87 and in diagrammatical form by Fig. 88. The gage for testing the machined contour is illustrated in Fig. 89.

The link is thrown out of contact, the shoulder of the large end is faced and the thread machined, using tools held in the tool carriage in the usual manner. The ring gage for testing the thread may be seen in Fig. 90. Fig. 91 shows the machine set-up for facing and cutting the thread.

The adapter is screwed into the chuck, Fig. 92, which is held on the faceplate of the lathe. The hole is drilled and tapped at the small end of the adapter, the tools

*Previous installments appeared on pages 537 and 581.

being held in the tool carriage of the lathe. The gage for testing the machined thread is shown in Fig. 93. The tool carriage is set over approximately 7¼ deg., and with an ordinary turning tool the beveled surface on the end is machined.

The gage for testing the overall length and contour at the end of the adapter and the manner in which it is used are illustrated in Fig. 94. Fig. 95 shows the lathe set-up for performing the machining operation, and this arrangement is also given in diagrammatical form by Fig. 96.

A detail of the finish-machined adapter may be seen in Fig. 97. The outside of the adapter is machined while it is in position on the shell, as was described on page 584. After the adapter has been completely machined, a hole is drilled for the fuse setscrew. The jig employed for this purpose is shown in Fig. 98.

The diaphragm is made from a steel forging, a detail of a finished piece being given in Fig. 99. The first operation, for which the forging is held in a universal-type chuck, is turning part of the outside and forming radius. The outside is first turned with the tool carriage thrown around approximately 4½ deg. The front edge is faced

with the tool carriage set squarely, the test gage being shown in Fig. 100. The radius tool, Fig. 101, is fastened in the tool carriage and the radius machined on the corner. The gage for testing this radius is shown in Fig. 102 and the gage for testing the entire contour in Fig. 103.

The diaphragm is then reversed and held again in the same chuck for the second operation—turning the rest of the outside, drilling and counterboring the hole.

The adapter bottom, Fig. 107, is made from 2-in. bar stock. It is held in a universal-type chuck and turned to size and the thread machined. An 0.43-in. hole is drilled through the center and then counterbored to 0.68 in. for 0.15 in. deep. A part is cut off 0.30 in. wide, thus making an adapter bottom. The counterboring and cutting-off operations are carried on alternately to make the parts. The lathe set-up for manufacturing the adapter bottoms is shown in Fig. 108 and in diagrammatical form by Fig. 109.

The gage for testing the thread may be seen in Fig. 110. The pin spanner wrench holes are drilled in the adapter bottom, using the jig in Fig. 111.

The plug is made from 3¾-in. bar stock, the first operation being turning the outside to 3½-in. diameter and forming the shoulder. The shouldered portion is

Light Coloring for Large Machine Tools

By J. C. Austin

I recently visited the pressroom of a large concern manufacturing sheet-metal parts. The presses and shearing machines were painted with very light-colored paint. It was indeed surprising to observe the effect and the absence of the depressing and rather awesome feeling one usually gets from heavy blackened machines ordinarily found in big pressrooms. If this is so noticeable and relieving to a passerby spending only a few moments in the factory, what must it mean to the operators and other persons working there eight or nine hours of the day?

One's surroundings and the things handled and worked with have so much to do with one's spirits and feelings and resultant efficiency that even a trifling item such as the color of paint on a machine tool is well worthy of attention in these days when much effort is being put forth to conserve all energies for useful work. It is not uncommon, of course, to see the inner walls of a shop painted white, so why not carry the idea a little farther and include at least some parts of the machines?

An additional effect, other than psychological, is of the "safety first" order, for it is not true that the light reflected from a white surface and the resulting shades and shadows render objects more discernible, so that operators are less likely to misjudge distances and get their fingers or hands in the way of moving parts?

Without some study I am not prepared to state jus[illegible] much more effort is required to keep clean [illegible]e light-colored machines than the darkly [illegible]s, but venture the statement that it is not [illegible]ight at first be supposed.

Automatic Machine for Making Radiator Cells

By Ethan Viall

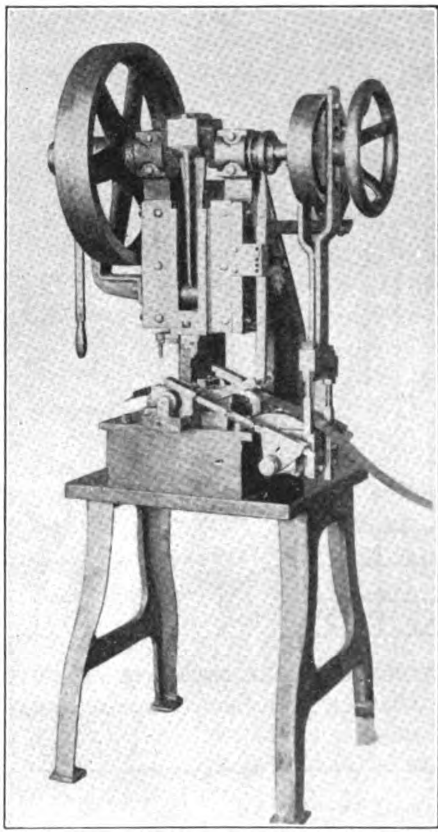
SYNOPSIS—The machine here described takes a flat strip of metal and automatically forms it into the complicated shape used in automobile radiators. Once set, the machine requires little attention on the part of the operator, the strip feeding in at one side and the formed cells coming out at the other. The low power consumption of a battery of these machines is remarkable.

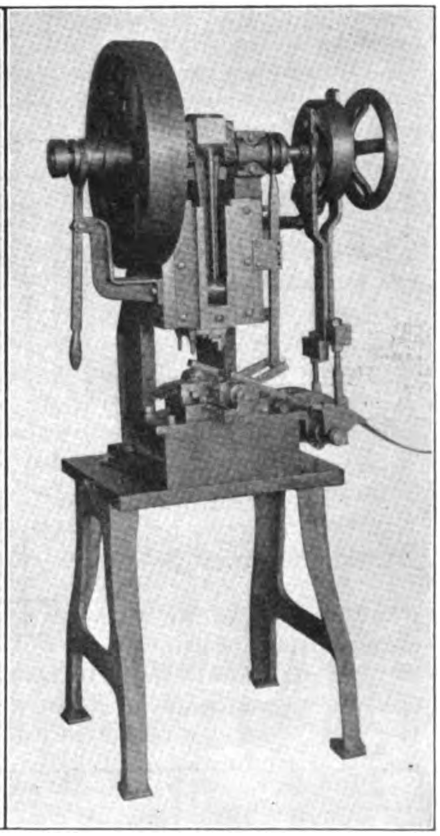
When one stops to consider the enormous number of automobiles produced in a year and the fact that each one, with the exception of the air-cooled type, has a radiator on it through which circulates the water that cools the motor, the question naturally occurs, How are these radiators made? That the copper cells are formed by automatic machinery is almost a foregone conclusion, since in no other way could such enormous quantities be produced cheap enough and good enough for commercial purposes. Several of the different machines employed have been described in these columns from time to time as they were perfected. The machine described in this article is remarkable, not only for the comparative simplicity of the mechanism used to produce a rather complicated form, but also for its ease of operation and low cost of upkeep. Moreover, it is in no wise an experiment, as two of the largest automobile factories have installed large batteries of these machine and some of them have been in use for over four years. It is enough to say that the first machine made is, in all points of essential construction, the same as those being made in the shop today.

Two views of one of these automatic cell-forming machines are shown in Figs. 1 and 2. This particular machine is set up for the production of a double row of copper cells each $\frac{5}{16}$ in. square, but by using different set-ups various sizes and shapes may be produced. The machines are made in pairs, to feed right and left, so that the formed cells will feed onto the same table. One operator runs two machines, and an electric-bell alarm gives notice as soon as the strip stock on a reel is run off.

On various kinds of work, copper strips 0.005 to 0.0055 in. thick and from 2 to $4\frac{1}{2}$ in. wide are used. The average speed of a machine is 70 r.p.m., and one will produce 2 ft. of formed cells per minute, using 14 ft. of strip stock. As the stock is almost as easily bent as so much paper, very little power is required; for instance, a 3-hp. motor runs 24 machines under working conditions. Each machine weighs complete about 850 lb. The City Machine and Tool Co., Toledo, Ohio, is the maker, and both the machines and the radiator cells were originally designed by K. M. Boblett, who has been radiator expert for several of the largest automobile factories in the country.

In order to be certain that the reader has a clear idea of the type of work produced, some of the cells will be shown and described before proceeding with a description of the working mechanism. At *A*, Fig. 3, is shown a section of a plain strip and a section of formed cells, just as they were removed from the machine. *B* gives an end view of the cells, and at *C* are some partly pulled apart, to show the arrangement. Another view is shown at *D*. From these illustrations it will be seen that the





FIGS. 1 AND 2. DIFFERENT ANGLE VIEWS OF AUTOMATIC RADIATOR-CELL FORMING MACHINE

cell groups are shaped somewhat like a figure 8, formed from the strip and repeatedly folded back against the cells ahead. Depressions are formed lengthwise on the outside of each pair of cells for the circulation of the cooling water.

The cell strips or groups are cut the proper length to fit the size of the radiator to be made and are then assembled into the radiator frame and soldered, a finished radiator in actual use being shown in Fig. 4 Several drawings of the different types of cells are seen in Fig. 5, and they will give a good idea of the arrangement of the various-shaped cells and also of the placing and shape of the water spaces.

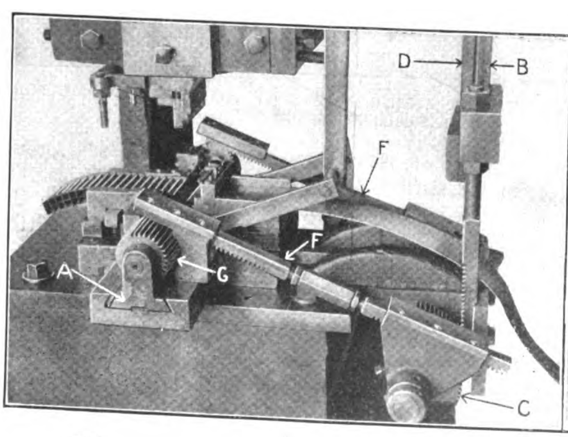

FIG. 6. POSITION OF PARTS WITH RAM UP

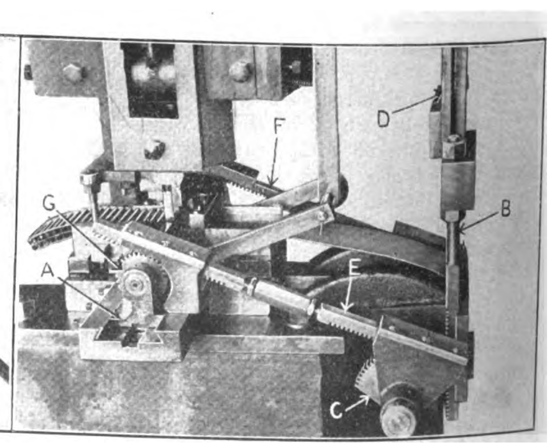

FIG. 7. CROSS-SLIDES IN, FINGERS PARTLY ROTATED

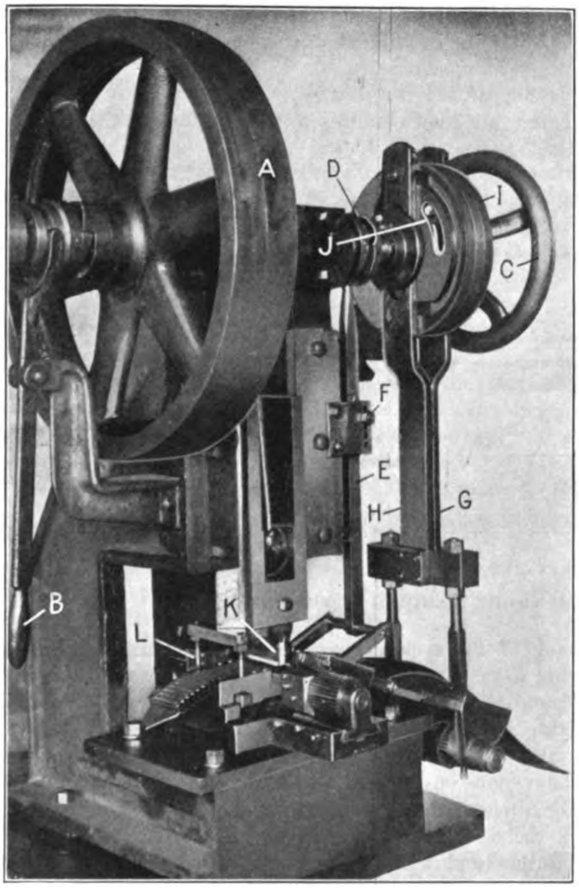

FIG. 8. CLOSE VIEW OF MAIN WORKING PARTS

A close-up view of one of the machines, Fig. 8, will serve to point out the main working parts. The combined drive pulley and flywheel, common to machines of this type, is shown at *A*. The clutch lever at *B* is in a convenient place to be reached easily by the operator. The handwheel *C* is used in setting or adjusting only. The cam *D* operates the feed-movement lever *E*. It will be noticed that this lever is fulcrumed in a block *F*, which has several holes in it in a vertical line. By placing the swiveling bolt in different holes the stroke of the lever may be varied to give several lengths of feed strokes.

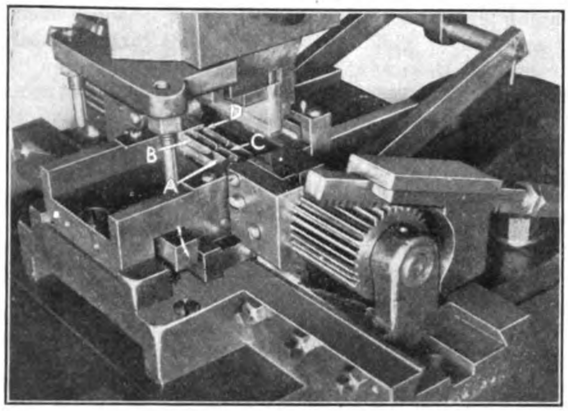

FIG. 11. MANDRELS IN AND CLOSE TOGETHER

The two slides *G* and *H* operate the in-and-out movement and the turning or folding movement of the forming mandrels. These slides are actuated by cams at *I*. Here a disk is keyed solidly to the drive shaft. On each side of this disk a cam disk is placed, being locked to the middle disk by screws through slots, as shown at *J*. By this means the cam disks can be accurately set and properly timed with the rest of the mechanism. The method of placing the slides themselves will be plainly seen by inspection. The press ram carries a forming punch *K* and the two die-raising pins *L*.

Proceeding now with further details of the forming mechanism, Fig. 6 shows the ram just starting down and the other parts in a corresponding position. The cell-forming is done by two sets of mandrels of four fingers each, run in from opposite sides and working simultaneously. Two fingers of each set are placed one above the other and have an out or an in movement only. The other two fingers of the set have an out or an in movement and also a rotary movement through an arc of 90 deg. The first two fingers are used simply to hold the work while the others form or fold the work against them.

Each set of mandrels is carried on the inner end of a slide *A*. These two slides are operated by a sliding plate working at right angles to them. This plate has two diagonal slots in it, in which rollers on the ends of the cross-slides work, so that as the plate is moved one way or the other the cross-slides are fed out or in. This

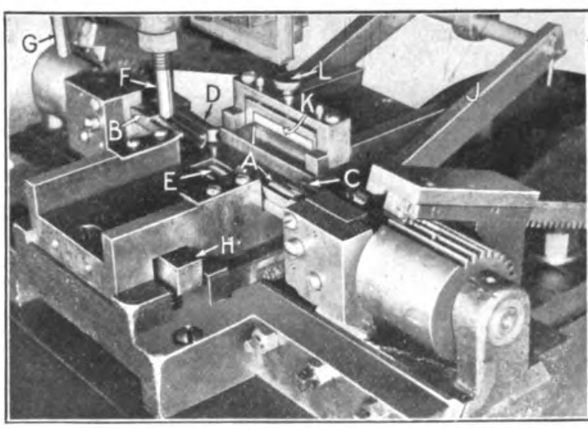

FIG. 9. MECHANISM WITH WORK REMOVED

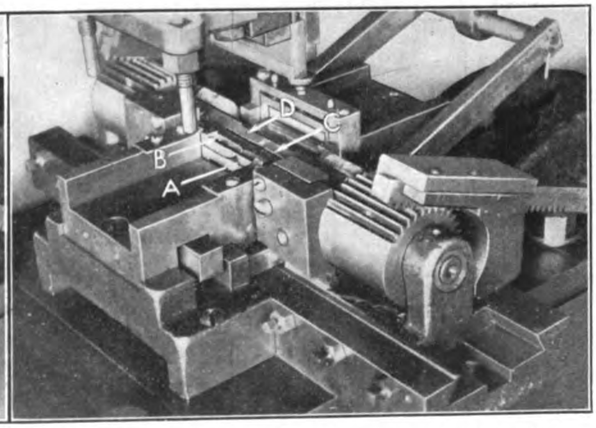

FIG. 10. MANDRELS IN AND PARTLY ROTATED

sliding plate, which works parallel to the stock movement, is operated by slide B from the outside cam previously described. Downward movement of this slide draws the two cross-slides inward. Movement is transmitted from the vertical slide by a rack on the lower end, which meshes with a gear segment on a cross-sleeve. A crank movement connects the sleeve and the sliding plate.

This action will be better understood by reference to Fig. 8. Here cross-slide A is shown drawn inward to the working position, and slide and rack B are moved downward. Care should be taken at this point not to confuse the gear segment C with the one operated by the rack referred to. As soon as the cross-slides are fed in, the vertical slide D commences to rise, which causes gear segments C on each end of the shaft to turn and move the racks E and F, so that the pinion segments G rotate through an arc of 90 deg., carrying the folding fingers through their rotary movement. It will be noticed that the long pinion segments allow the cross-slides to work freely out or in without interfering in any way with the rotary movement.

Some of the working parts, with the strip stock removed, are shown in Fig. 9, which illustrates the beginning of the cycle of movements. The mandrel fingers that have an out or an in movement only are shown at A and B in their respective slides. The others are shown lying on their sides at C and D. While the stock is being fed along, the lower form E, which makes the depressions on the under side of the cells, remains below the surface of the guiding channel, so as not to catch in the work. As the mandrels are moved into working position and the ram descends, however, this form is raised to contact with the work by means of the pins F and G, which strike both ends of the crossbar H and tilt the form upward.

The feeding of the stock is done by a small slide that works back and forth at I, being operated from the cam previously mentioned, through the yoke lever J. A roller K, tensioned by the thumb-screw L, presses the stock to the slide. Unless some means were provided to lock the stock as it was fed forward, the reciprocating movement of the feed slide would simply move the stock back and forth with it. This condition, however, is provided for by having the mandrels fed partly into the cells before the feed slide starts back.

The mandrel fingers, fed in to meet, and the fingers C and D, partly rotated, are shown in Fig. 10. The movement completed and all fingers together are shown in Fig. 11. The entire cycle of bending and forming

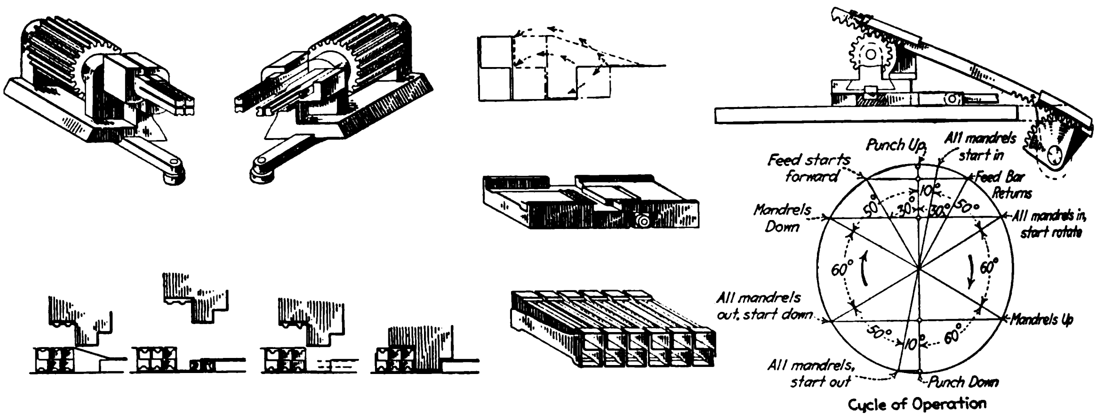

FIG. 12. DETAILS OF PUNCH AND MANDREL BENDING MOVEMENTS

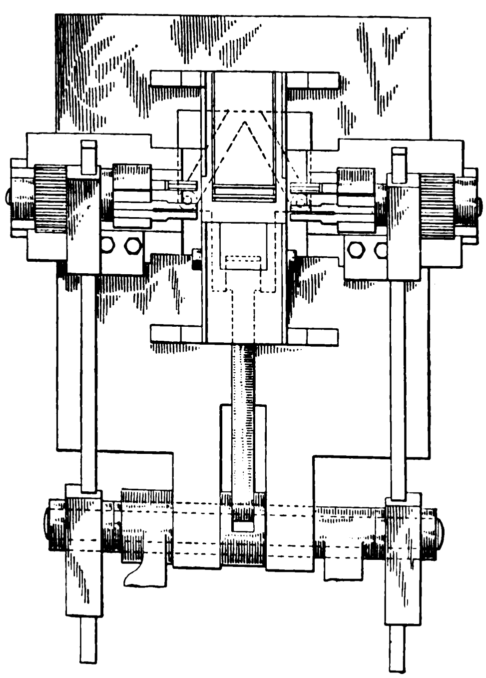

FIG. 13. DETAILS OF SLIDE POSITION AND ACTION

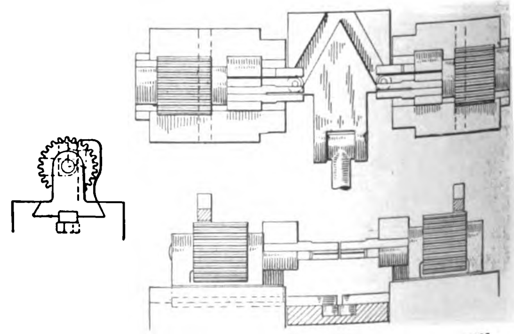

FIG. 14. DETAILS OF CROSS-SLIDE OPERATION

operations, the action of the punch carried in the ram and the mandrel-finger movements will be easily understood by reference to Fig. 12, which needs little explanation other than that afforded by the illustration itself.

Interesting Cross-Slide Movements

A plan view of the various slides is given in Fig. 13, and the method of moving the cross-slides out or in is plainly shown in Fig. 14. These drawings, taken together with the photographs and description, will give a clear idea of the entire mechanical action and formation of the radiator cells.

The precision with which the machine works will be appreciated when one considers that stock 0.005 in. in thickness is very thin material to be formed into such an intricate shape without tearing or buckling in any way. The finished product must be water-tight at 20 lb. pressure. These machines have handled stock only 0.003 in. thick, when making aëroplane radiators. It does not draw or stretch the metal in any way, but simply wraps it into the desired shape. Soap water is used as a lubricant and is applied to both sides of the stock as it is fed between two felt rolls.

Turning the Inside Edge of a Scale Case

By E. V. Thomas

An awkward piece to hold is shown in Fig. 1. It is a case for an automatic scale. The operation is turning of the inside edge or flange, which is done on a vertical turret lathe in the shop of the Caille Perfection Motor Co., Detroit, Mich. The method of holding the casting is illustrated in Fig. 2. The jaws *A*, *B* and *C* are stationary, and the casting fits over the specially shaped ends. The rubber-covered post *D* is used as a driver only, to prevent slippage during the cut. The casting is held down on the jaws by the spider *E*, which is tightened down by the screw *F*, the ends of the spider arms catching the inside bottom flange of the casting, as shown in Fig. 1. The turning is done after the case has been enameled, so that any method of outside holding is out of the question. In addition, by this method of holding it on the inside, centering is greatly simplified.

Precision Gage-Making Work

By Gustave A. Remacle

One of the commonest forms of gage is the snap gage. In spite of its simple construction, care and skill are necessary in its making. There are a number of different methods of making a snap gage, differing according to the dimensions of the measuring points and toolroom facilities.

In making a gage such as is shown in Fig. 1, the slots may be milled, leaving 0.003 or 0.004 in. for grinding on either side of the slot. Lately we have been annealing the stock after roughing the slots and stamping on all the required figures or names, for the gages have a tendency to warp, owing to the stamping. After hardening, the gage is ground on both faces and on all the edges.

If the familiar Brown & Sharpe surface grinder is to be used for grinding the slot or opening to size, the gage should be clamped to an angle plate and set in position so that the face of the gage is square with the face of the wheel. When being ground, the gage should be in a position directly under the center of the wheel. If the grinder is equipped with a magnetic chuck, parallels should be placed around the angle plate so that there will be little opportunity for the set-up to shift during the operation.

The wheel used should be thin enough to enter the slot without touching the sides, and it must be dressed so that it grinds only at the corner. One side of the slot is then ground until a smooth, clean surface is obtained. If a wheel of the saucer type is used, it must be reversed on the spindle for the second side and redressed enough to have it running true at the cutting edge. If a straight wheel is dressed as shown in Fig. 3, it will do the job without reversing. It can readily be seen that, after one side of the slot has been ground to a finish, the gage must not be shifted from its position on either the angle plate or the table of the machine.

The grinding operation is performed by entering the wheel into the slot, feeding the work against the wheel and then raising and lowering the wheel. The table of the machine may be moved so that the gage is removed from the wheel when the operator wishes to measure the slot. As lapping is a very slow process, a minimum amount of stock should be left for removal in this

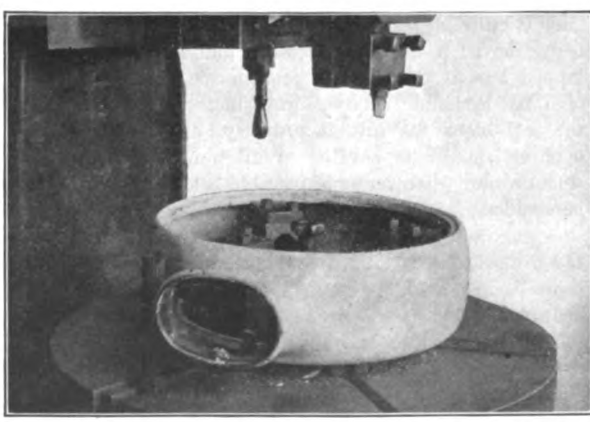

FIG. 1. TURNING INSIDE EDGE OR FLANGE OF AN AUTOMATIC SCALE CASE

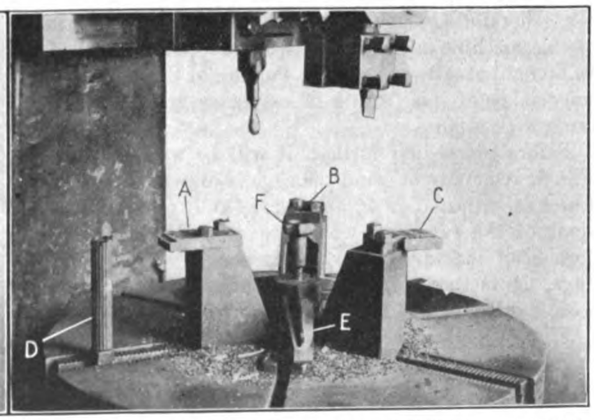

FIG. 2. DETAILS OF THE HOLDING FIXTURE FOR THE VERTICAL TURRET LATHE

manner. Therefore, all end play in the spindle of the machine should be removed, to facilitate a good grinding job. This is accomplished by clamping a spring against the end of the spindle, as shown in Fig. 5.

If the operator wishes to play safe when grinding out the gage, he should determine just how much stock remains to be removed, by measuring the slot with a smaller test block and feeler gages. When the gage is almost to size, a test block, Fig. 2, is used to give accuracy. As may be seen, there are two sizes on this piece, one being 0.002 smaller than the other. All the measuring surfaces of this test block are carefully lapped to size, as the accuracy of the finished snap gage will depend upon the accuracy of the test block. If the gage has been ground as described, a good grinding job will be the result, and the 0.0002 in. allowed for lapping will be sufficient to finish-lap the opening to the correct size.

Most cutter-grinding machines are well adapted for grinding gages such as the snap gage of Fig. 1. In fact, if the spindle is in good condition and the other parts are in fair shape, a machine of this type is the best suited for general snap-gage grinding. The one best feature of this machine is that the line of travel of the table can be brought exactly in line with the face of the wheel. The importance of this feature in snap-gage grinding will be dealt with later.

Before proceeding farther, it will be well to describe Fig. 6. One way to grind the gage is to move the gage or wheel as indicated at *A*; another, as at *B*. If the dimensions of the gage and wheel are such that the cutting corners of the wheel clear the corners *A*, Fig. 7, of the gage, the method *A*, Fig. 6, should be preferred. Otherwise, method *B* will have to be resorted to.

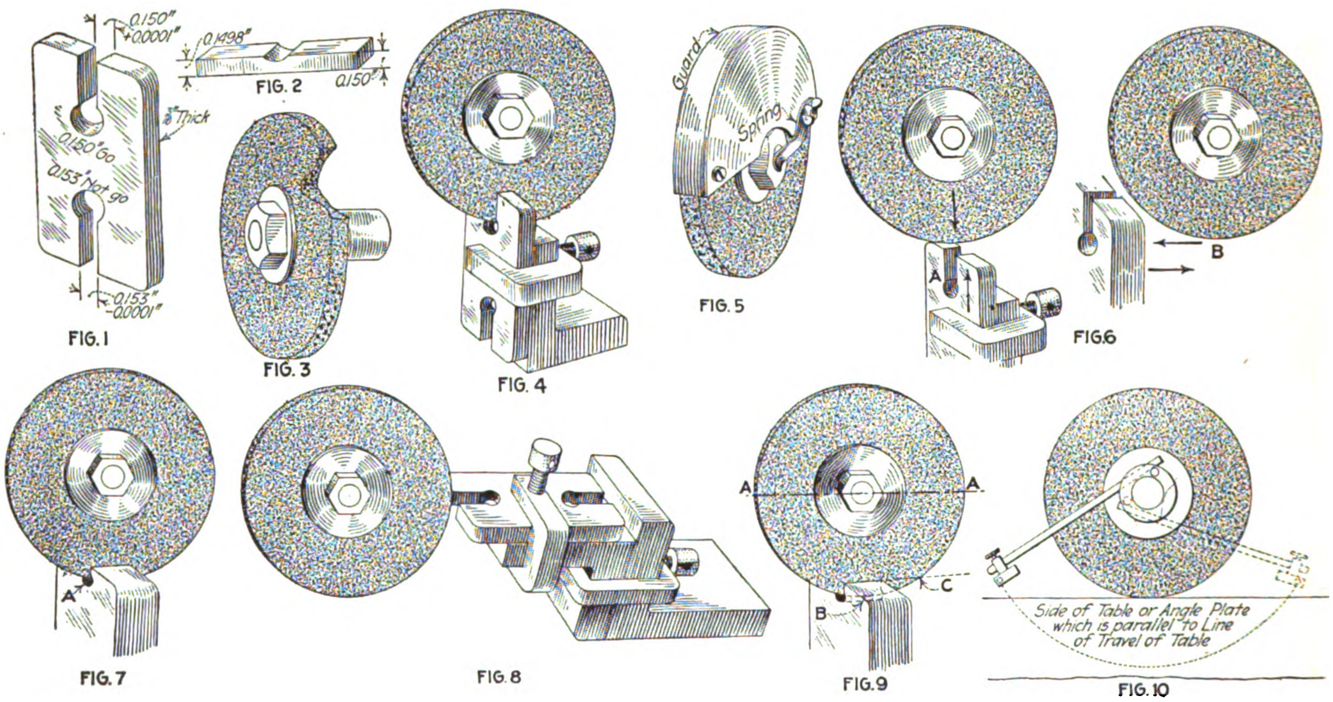
Fig. 8 shows a set-up for grinding gages on a cutter grinder. This is the most convenient manner of grinding small slots I have ever used, with the exception of a machine constructed especially for the purpose.

When it is imperative to grind the gage in the manner shown at *B*, Fig. 6, it should be ascertained whether the face of the wheel is in line with the line of travel of the table of the machine. If the wheel is not in line, the greatest error will be found at point *A*, Fig. 9, the error gradually decreasing to zero at point *B*. Hence, as the top of the gage comes in contact with the wheel at point *C* while the bottom of the slot in the gage comes in contact with the wheel only at point *B*, the top of the slot will be ground larger than the bottom. If a cutter-grinding machine is used for such grinding, the table may be adjusted with an indicator, as shown in Fig. 10.

If good grinding results have been obtained, 0.0001 in. on either side of the slot will be sufficient for lapping. If poor results have been obtained in the grinding—that is, if the sides of the slot are rough or not parallel—a correspondingly greater amount of lapping will have to be done. As lapping is slow work, the very best grinding results should be aimed at.

The gages, after grinding, are lapped to fit the test block, by means of small steel or cast-iron lapping blocks that have been ground somewhat smaller than the slot and charged with fine diamond dust. If the opening in the gage is quite large, a lap may be held in the vise, the gage being moved to and fro by hand; but most gages can be lapped best if the gage is held in the vise and the lap operated by hand. The opening should be lapped so that the test block fits into it properly. Both sides of the opening should be parallel at all points, very flat and smooth, and wherever it is possible round corners should be avoided.

A gage with an opening only $\frac{1}{16}$ in. in width requires the utmost skill if lapped by hand, and any slots smaller than $\frac{1}{16}$ in. should be lapped in a machine. At present we are making some snap gages with an opening of only 0.0325 in. in width and are doing the work on a special grinding device. After grinding with a small, fine wheel, the [illegible] replaced by a copper disk charged with [illegible] gage occupying an undisturbed position [illegible] at there is no opportunity for the slight-[illegible]



METHODS AND DETAILS FOR GRINDING SHOP GAGES

Chart for Ratios for Speeds in Geometric Progression

By A. Lewis Jenkins*

SYNOPSIS—An analysis of the problem of obtaining geometric progression for the speeds of cone-type machine tools. Ratios found in practice are given. An alignment chart provides an easy means for determining the ratios of any common type of cone drive.

It is generally conceded that the spindle speeds on machine tools should be in geometric series, and at the present time it would be unwise for a builder of machine tools to advertise his machines as having speeds in arithmetical, harmonic or cubic parabola series or in a geometric series that overlapped.

An investigation of the speeds of over 500 machine tools shows that the machines having speeds in geometric series are decidedly in the minority. If the speeds on these machines were presented to a mathematician having no knowledge of machine tools, with the request that he determine the series in which they are supposed to be, he would undoubtedly report that there is no law or series that expresses their arrangement even approximately and that they may be arranged in almost any way within certain limits. This peculiar condition has undoubtedly been brought about through attempts to introduce other considerations, such as large back-gear ratios, high belt speeds, large ranges of speeds and large steps on the cones.

In most cases a compromise of these considerations may be effected in such a way as to give a geometric series without greatly affecting the speed values. In order to do this, however, it is necessary to know how the speeds are related to the geometric series.

Considering a perfectly general case of speeds in geometrical progression, obtained by mechanisms consisting of a pair of stepped cones, back gears and one or more countershaft speeds such as are used on machine tools, let

p = Number of steps on cone pulley;
b = Number of back-gear changes;
c = Number of countershaft speeds;
A = First or slowest spindle speed, in revolutions per minute;
L = Last or fastest spindle speed, in revolutions per minute;

$N_1, N_2 \ldots N_c - 1, N_c$ = Countershaft speeds (N_1 the slowest and N_c the fastest);

$W_1, W_2, W_3 \ldots W_b - 1, W_b$ = Back-gear ratios affecting a decrease in spindle speeds by being in gear (W_1 the smallest and W_b the largest, their values being greater than unity);

r = Constant multiplier in the geometric series of spindle speeds, or the geometric ratio;

$U_1, U_2, U_3 \ldots U_p - 1, U_p$ = Cone-pulley ratios (U_1 the greatest and affecting the highest spindle speed);

*Associate professor of mechanical engineering, University of Cincinnati.

$A, B, C \ldots$ = Diameters of steps of the counter shaft or driving cone (A the largest);

$Z, X, Y \ldots$ = Diameters of the steps of the follower or cone on the machine (Z the largest);

T = Total number of spindle speeds.

Spindle and Countershaft Speeds; Geometric Ratio

The total number of spindle speeds is given by the equation

$$T = pc\,(b + 1)$$

As a matter of fact, a perfectly general formula for the number of spindle speeds would naturally consider a machine that has no back gear, or "drives direct," as having a back gear equal to unity, such a consideration being applicable to gear boxes and geared heads. In this case the expression for the total number of speeds is written $T = pcb$. But since a back gear is commonly considered as a combination of gears for decreasing the spindle speeds and since the terms first, second and third are used to designate the relative reductions they produce, it is considered desirable to follow the well-established practice of calling the one giving the least reduction and highest spindle speed the "first back-gear ratio."

The value of the geometric ratio for any number of countershaft speeds, steps on the cone and back-gear ratios may be found by the equation

$$r = \left(\frac{L}{A}\right)^{\frac{1}{pc\,(b+1)-1}}$$

On the assumption that the consecutive spindle speeds are obtained by employing all the countershaft speeds before shifting the belt or changing the back-gear ratio, the countershaft speeds are in the following geometric series:

$$\begin{aligned} N_1 &= N_1 & N_c - 3 &= N_1 r^{(c-4)} \\ N_2 &= N_1 r & N_c - 2 &= N_1 r^{(c-3)} \\ N_3 &= N_1 r^2 & N_c - 1 &= N_1 r^{(c-2)} \\ N_4 &= N_1 r & N_c &= N_1 r^{(c-1)} \end{aligned}$$

The ratio of any two successive countershaft speeds must be equal to the constant multiplier, in order to have the spindle speeds in geometrical progression.

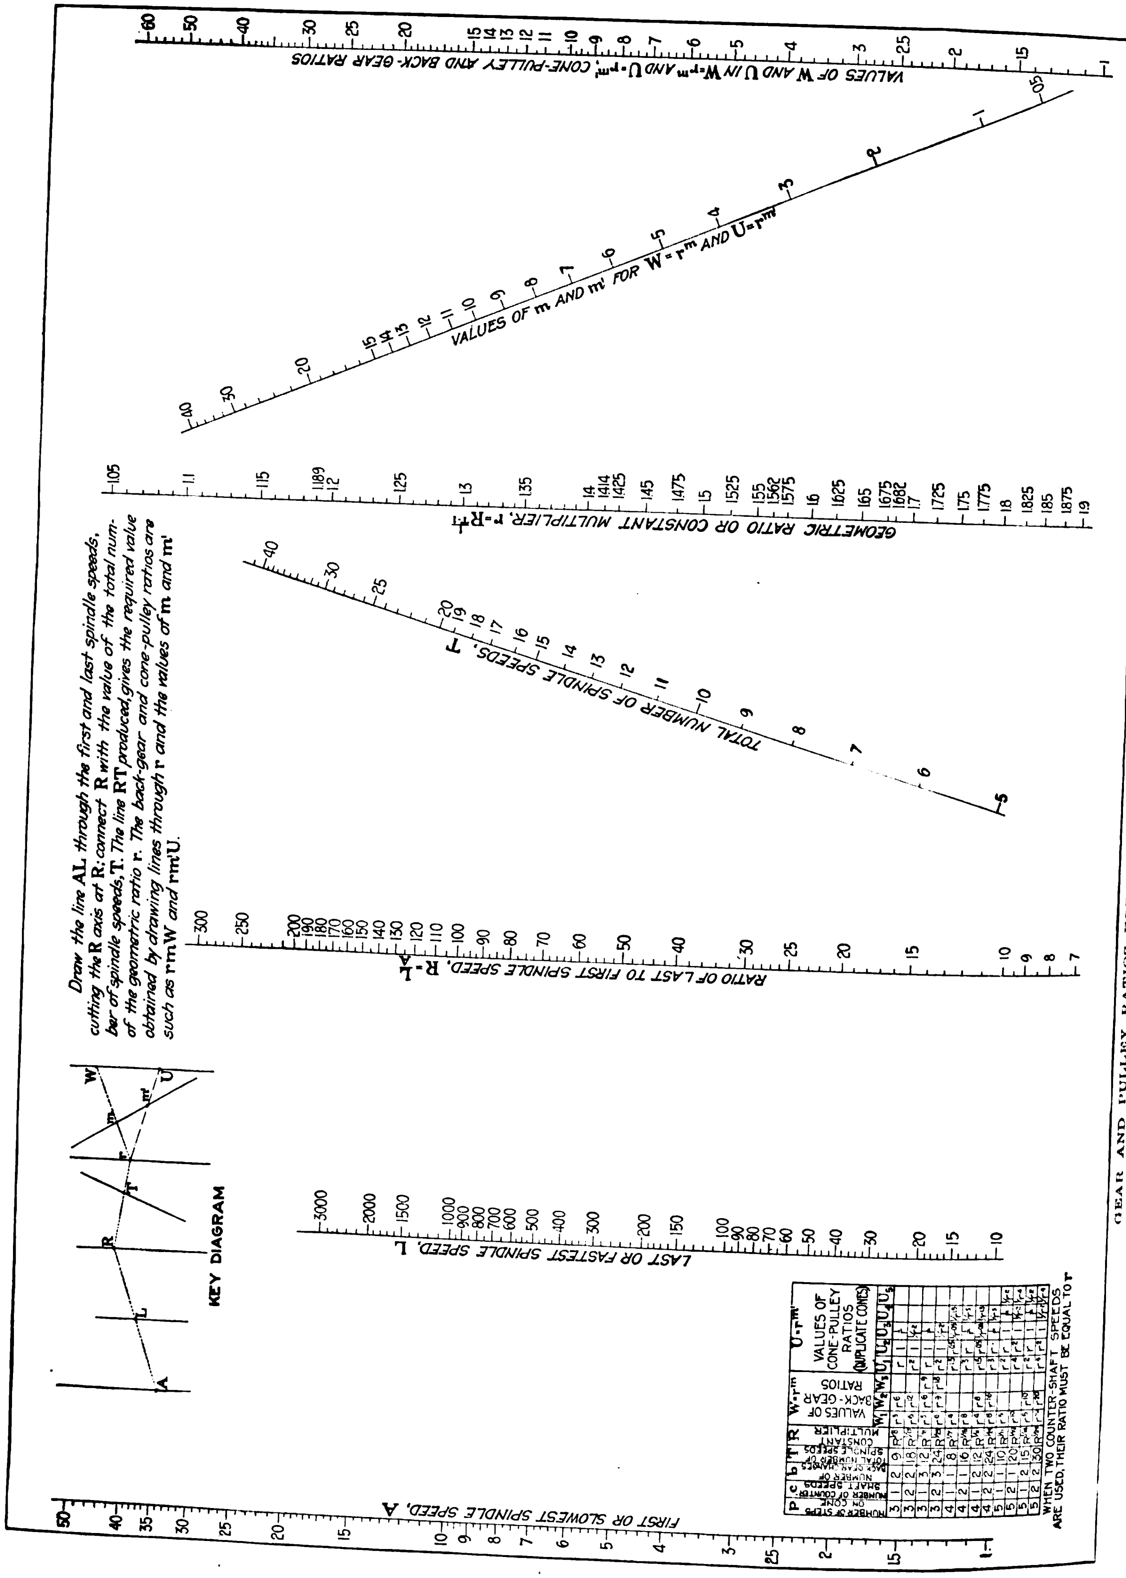
Taking the values of the back-gear ratios that reduce the spindle speeds as being greater than unity gives

$$\begin{aligned} W_1 &= r^{pc} & W_b - 2 &= r^{pc\,(b-2)} \\ W_2 &= r^{2pc} & W_b - 1 &= r^{pc\,(b-1)} \\ W_3 &= r^{3pc} & W_b &= r^{pcb} \end{aligned}$$

$a, b, c, d \ldots$ denote the diameters of the steps on the driver, a being the largest.

$z, y, x, w \ldots$ denote the diameters of the steps on the follower, z being the largest.

$U_1, U_2, U_3 \ldots U_p$ are the ratios of the cone-pulley diameters and are equal to $\frac{a}{v}, \frac{b}{w}, \frac{c}{x} \ldots$, U_1 being the largest and U_p the smallest.



GEAR AND PULLEY RATIOS FOR SPINDLE SPEEDS IN GEOMETRIC PROGRESSION

If N denotes the highest speed of a five-step cone pulley, regardless of the relative sizes of the cones, the lowest speed of the follower is

$$A = NU_5 = NU_p$$

and the highest speed of the follower is

$$L = NU_1 = NU_p r^{p-1} \qquad \text{or } U_1 = U_p r^{p-1}$$

which is true for any number of steps. If there are c countershaft speeds,

$$U_1 = U_p r^{c(p-1)}$$

This equation may be written

$$U_1 \div U_p = r^{c(p-1)}$$

and similarly, the other ratios are

$$U_2 \div U_{p-1} = r^{c(p-3)} \qquad U_3 \div U_{p-2} = r^{c(p-5)}$$

$$U_p \div U_1 = r^{c[p-(2p-1)]}$$

These equations represent ratios of the cone-pulley ratios, and in order to determine the value of any one cone-pulley ratio it is necessary to make some such assumption as

$$U_p U_1 = t^2$$

where $t = N \div N_1$ in the equation for the highest speed,

$$L = NU_1 = U_1 t N_1$$

or that value by which all the cone-pulley ratios must be divided when the countershaft speed is changed without changing the spindle speeds. It is easily seen that, if the countershaft speed on an ordinary lathe be doubled, the diameters of the countershaft cones must be reduced to half their size, if the spindle speeds remain unchanged. It is an important fact that the cone pulleys do not necessarily have to be duplicates in order to give the desired ratios or to maintain a constant length of belt; hence, from the foregoing equations

$$\frac{U_1}{U_p} = \frac{U_1}{\frac{t^2}{U_1}} = \frac{U_1^2}{t^2}$$

and

$$\frac{U_2}{U_{p-1}} = \frac{U_2}{t^2} = \frac{U_2^2}{t^2} \qquad \frac{U_3}{U_{p-2}} = \frac{U_3^2}{t^2}$$

By substituting,

$$\frac{U_1^2}{t^2} = \frac{U_1}{U_p} = r^{c(p-1)} \qquad \text{or } U_1 = tr^{c\frac{(p-1)}{2}}$$

and similarly,

$$U_2 = tr^{c\frac{(p-3)}{2}} \qquad U_{p-2} = tr^{c\frac{(5-p)}{2}}$$

$$U_3 = tr^{c\frac{(p-5)}{2}} \qquad U_{p-1} = tr^{c\frac{(3-p)}{2}}$$

$$U_4 = tr^{c\frac{(p-7)}{2}} \qquad U_p = tr^{c\frac{(1-p)}{2}}$$

In the equation for the slowest spindle speed

$$A = NU_p = Nt = r^{c(1-p)}$$

the actual countershaft speed, $N_1 = Nt$, may be given any desired value by selecting the proper value of t. By making $t = 1$, $N_1 = N$, and the cone pulleys practically become duplicates.

In connection with this last statement it should be remembered that duplicate cones have their diameters in arithmetical progression, and they will not give speeds in an exact geometrical progression; the error, however, is so small that it may be neglected except in very unusual cases.

The table on the alignment chart shows the number of spindle speeds; values of r in terms of the fastest and slowest spindle speeds; the back-gear ratios and the cone-pulley ratios in terms of r for all cases usually met in the construction of machine tools.

An investigation of about 400 lathes shows that it is average American practice to have a constant geometric ratio, based on the ratio of the highest-lowest speed, for each type of lathe, whereas it is English practice (Nicolson and Smith) not to have the geometric ratio the same for any two machines, unless by mere accident.

The average values of r, based on the ratios of the highest and lowest speeds, for lathes built in America are as follows:

Type of Machine	Average Value of r
Three-step cone, double back gear, 9 speeds	1.5
Three-step cone, double back gear, 18 speeds	1.22
Four-step cone, single back gear, 8 speeds	1.69
Four-step cone, single back gear, 16 speeds	1.3
Five-step cone, single back gear, 10 speeds	1.58
Five-step cone, single back gear, 20 speeds	1.26
All-geared head, 8 speeds	1.58
All-geared head, 12 speeds	1.36
All-geared head, 16 speeds	1.26
All-geared head, 18 speeds	1.23

Taking the average of these values of r for 8, 9 and 10 speeds gives 1.58, and for 16, 18 and 20 speeds gives 1.25.

For radial drilling machines having 20 spindle speeds the values of r vary from 1.27 to 1.35, the average being about 1.3. The value of r for vertical drilling machines having 8 spindle speeds varies with the size of the machine and is equal to $r = 0.9675S^{1/7}$ where S = size of machine which gives 1.49 for a 20-in. machine and 1.61 for a 36-in. machine. A constant ratio of 1.44 has been proposed for vertical drilling machines having 10 spindle speeds.

The result of having a constant geometric ratio for all machines would be an ideal condition from the standpoint of time setters who make special slide-rules and charts for machines. Carl G. Barth proposed the ratios of $\sqrt{2} = (2)^{1/2} = 1.414$ and $\sqrt[4]{2} = (2)^{1/4} = 1.189$ for all machines. These are considerably less than the values of 1.58 and 1.25 obtained by taking an average of average values used in the various types of lathes. Values of 1.25 and $(1.25)^2 = 1.56$ are easily remembered and come nearer to representing the present practice on lathes than the values suggested by Mr. Barth.

It would be in accord with Mr. Barth's idea to use $(2)^{3/4} = 1.682$ when $\sqrt{2}$ is not large enough to cover the required range and $\sqrt[8]{2} = (2)^{1/8} = 1.0905$ when $\sqrt[4]{2}$ is too large. There is apparently no very good reason why one of the values 1.0905, 1.189, 1.414 and 1.682 should not be used in designing any machine tool.

It should be observed that the values of the ratios of the countershaft speeds, cone pulleys and back gears depend only upon the value of r, which varies with the ratio of the highest and lowest spindle speeds for a given mechanism and is independent of the values of the countershaft speeds. Hence, if a machine is designed with speeds in a geometric series having a constant multiplier equal to r, its speeds will always be in a geometric series having that same value of r, regardless of the countershaft speed, provided the ratio of the countershaft speeds is kept equal to r.

The alignment chart, together with the table shown in Fig. 1, offers a very easy means of determining the values

of the geometric ratio and the gear and pulley ratios of practically any cone-type machine tool and may also be applied to some mechanisms used in the all-geared types. The method of using the chart is shown in the solutions of the following problems which are taken from lathe practice. The first gives the limiting speeds for a machine having a four-step cone and single back gear. The values for the various ratios are the quantities to be found. The second gives the highest spindle speed on a five-step cone single back-gear machine, having two countershaft speeds and asks for the pulley ratios and the value of the lowest spindle speeds.

Two Illustrative Problems

Problem 1—The highest and lowest speeds on a four-step cone single back-geared lathe having two countershaft speeds are 260 and 7; what should be the values of the cone-pulley and back-gear ratios and the ratio of the countershaft speeds? From the table on the chart it is seen that the back-gear ratio for this machine is $W = r^8$, the cone-pulley ratios are r^3, r, $\frac{1}{r}$ and $\frac{1}{r^3}$, and the total number of spindle speeds is $T = 16$. To use the chart, draw a line connecting 7 on the A axis with 360 on the L axis, cutting the R axis at 51.4. Then through this value of R draw a line through $T = 16$, and this will cut the r axis at 1.3, giving the geometric ratio. A line produced through $r = 1.3$ and $m = 8$ gives $W = 8.15$, which is the back-gear ratio; through $m = 3$ gives 2.2 for the first cone-pulley ratio, and through $m = 1$ gives 1.3 for the second cone-pulley ratio. Hence, the cone-pulley ratios are 2.2, 1.3, $\frac{1}{1.3}$ and $\frac{1}{2.2}$. The ratio of the two countershaft speeds is $r = 1.3$.

Problem 2—The highest spindle speed on a five-step cone single back-geared machine having two countershaft speeds is 430, and the back-geared ratio is 10.1; what are the pulley ratios and the value of the lowest spindle speed? From the table it is seen that the back-gear ratio is r^{10}, the cone-pulley ratios are r^4, r^2, 1, $\frac{1}{r^2}$ and $\frac{1}{r^4}$, and $T = 20$. Through $W = 10.1$ draw a line through $m = 10$, giving $r = 1.26$. Then through this value of r draw lines through $m = 4$ and $m = 2$, giving values of $U = 2.52$ and 1.59; or the cone-pulley ratios are 2.252, 1.59, 1, $\frac{1}{1.59}$ and $\frac{1}{2.52}$. Then through this value of $r = 1.26$ draw a line through $T = 20$, cutting the R axis at 81. A line through this value of R and $L = 430$ cuts the A axis at 5.3, the desired value for the slowest spindle speed.

Problem 3—On a three-step cone double back-geared machine having two countershaft speeds the first cone-pulley ratio is 1.49 and the highest spindle speed is 313; what are the lowest spindle speed and the back-gear ratios? It is seen from the table that the first cone-pulley ratio for this machine is r^2, the back gear ratios are r^6 and r^{12}, and $T = 18$. Through $U = 1.49$ and $m = 2$ draw a line cutting the r axis at 1.22. Then through this value of r and $m = 6$ and $m = 12$ draw lines cutting the W axis, giving 3.29 and 10.9 for the back-gear ratios. Through $r = 1.22$ and $T = 18$ draw a line cutting the R axis at 29.5; then through this point and $L = 313$ draw a line cutting at $A = 10.6$, which is the desired value of the slowest spindle speed.

The Best Way To Make Cores and Prints

By J. J. Eyre.

One of the necessary evils of the pattern shop when the hole to be cored is below parting line of mold is the making of tail prints and core boxes.

Pattern makers should appreciate the necessity of allowing plenty of taper to the face as well as the sides of the tail prints, which insures better work in the core room and foundry, and consequently a better casting. It allows the core to drop freely into place without scraping the sand into the bottom of the mold, and also does away with the "fin" back of the hole, caused by clearance being allowed or by the molder filing the teat of the core, as is frequently done.

It is common practice to make the core box as shown in Figs. 1 and 2. Both methods are costly and have their faults. Fig. 1 illustrates the core parted through the

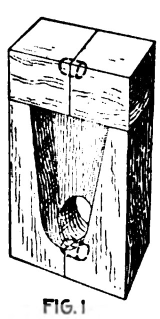


FIG. 1

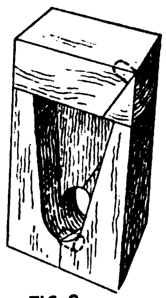

FIG. 2

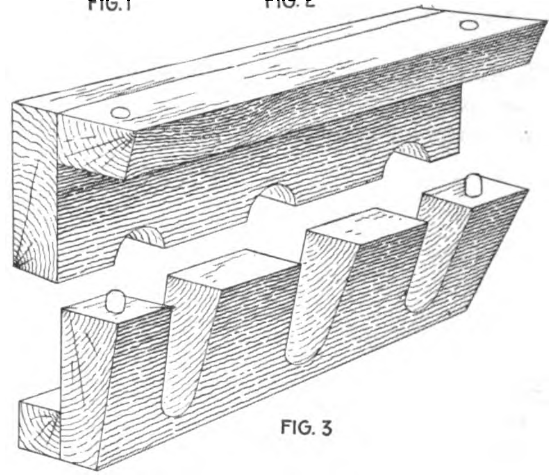

FIG. 3

METHOD OF MAKING CORE PRINTS

center, when it is apt to break down unless the greatest care is used by the core maker. The method of making the joint shown in Fig. 2 exacts more care and time in the pattern shop, and unless special attention is given, it is likely to stick in the square or closed corner of the box. With both methods the core box is choked with sand in the joint of the box, making the core oversize, which is likely to crush the mold when placing the core in position.

In Fig. 3 is shown a much simpler form of construction. I have used this type of box for wood and metal molds for a good many years and find it gives better satisfaction in the core room, besides being much cheaper to make.

It has a further advantage over the methods illustrated in Figs. 1 and 2 in that it can be made up for multiple cores, as shown in the illustration, for any number of cores.

Dies for Making a Pressed-Brass Hame Ball

BY ERNEST A. WALTERS

SYNOPSIS—The work described herewith includes blanking, cupping, drawing and bulging dies used in turning out a regular standard product—a hame ball for draft-horse harness. The details of the bulging die, or "fluid punch," are particularly interesting, as they show how bulging dies can be worked rapidly and maintain a supply of the bulging liquid.

The production of a pressed-brass hame ball, as shown, necessitates four press operations, including both drawing and bulging. The drawing dies produce a brass shell, 1$\frac{3}{16}$ in. in diameter by 4 in. deep, which goes through an annealing furnace and is then put through the bulging operation of the "fluid punch" type, which is not commonly known, producing a finished brass hame ball, as shown.

A set of first-class dies is also shown. They are so designed that it is possible to replace parts quickly and without much cost. In the first operation a cup *A*, Fig. 1, is blanked and drawn on a double-action press, which gives greater satisfaction than a single-action press. The

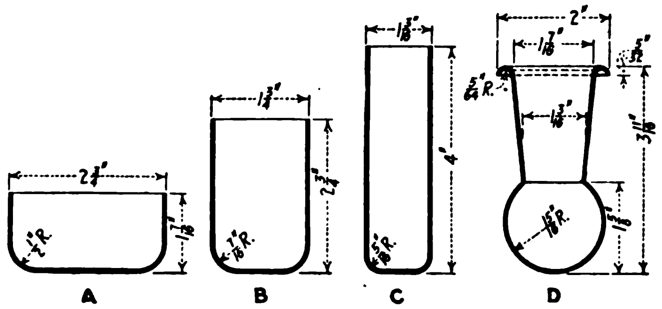

FIG. 1. HAME BALL, 16 GAGE BRASS

double-action press makes it possible to run continuously on the sheet, the shells being pushed through the draw die and dropping into a receptacle beneath, whence they are automatically conveyed to the belt press. Here they are drawn to 1¾-in. diameter as *B* drops through, and are again automatically conveyed to the following operation, where they are reduced to 1$\frac{3}{16}$-in. diameter, as *C*. They are then annealed, to prevent the shells from breaking or splitting while being bulged on the fluid die, which is supplied with lard oil automatically through a pump and the proper supply gaged by an overflow pipe, shown at *H*, Fig. 5.

In Fig. 2 are shown the blanking and cupping dies and the punches. The blanking punch *A*, made of hardened tool steel, is screwed to the cast-iron punch holder *B* by screws *C*.

The blanking die *D* is made of hardened tool steel, the cupping die *F* of high-speed steel, highly polished. The dies *D* and *F* are seated in the cast-iron bolster plate *E* and held in place by the stripper and side gages *G*, which in turn are held securely by fillister-head screws *H*.

The stripper plates *I* release the shell from the punch *K*. They have a horizontal motion of $\frac{3}{16}$ in. and receive the proper tension by small springs *S*. A small pin gage *J* spaces the blanks.

The drawing-punch point *K* is made of high-speed steel and screwed to the machine-steel punch *L*. A small hole drilled in the center continues through the punch,

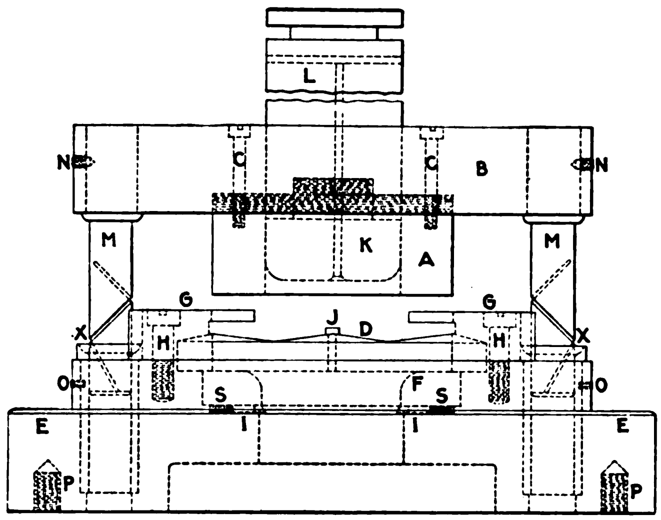

FIG. 2. BLANKING AND CUPPING DIES

to prevent a vacuum and allow the shell to strip easily.

Guide pins *MM* are made of hardened tool steel and secured by headless screws *N*. The guide pins are 0.002 in. smaller in diameter than the bronze bushings *X* and are lubricated with machine oil mixed with white lead, which is placed in a recess at *X*.

The bushing *X* is secured by headless screws *OO*. The holes *PP* are tapped underneath the bolster plate. This

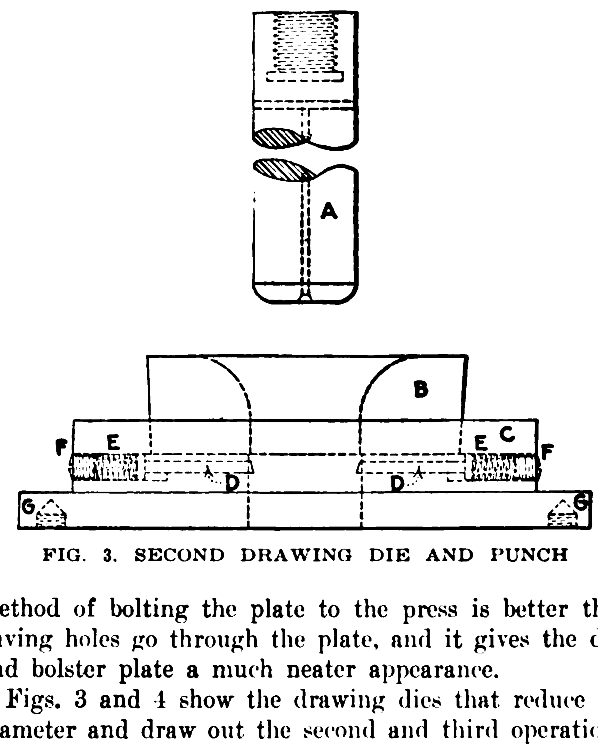

FIG. 3. SECOND DRAWING DIE AND PUNCH

method of bolting the plate to the press is better than having holes go through the plate, and it gives the dies and bolster plate a much neater appearance.

Figs. 3 and 4 show the drawing dies that reduce the diameter and draw out the second and third operations. The punch *A* and the dies *B* are made of high-speed steel

highly polished and very durable, as compared with ordinary tool steel.

The inserted die *B*, Figs. 3 and 4, are cheap and lasting, as compared with a large solid die, because it can be shrunk and brought back to size a number of times. It can also be replaced in a few seconds when necessary and does not hold up production on the succeeding operations while making a change.

The ring dies *B* are set in the bolster plate *C* and do not require to be held, as the stripper pins *DD* strip the shell from punch *A* on its return, making it impossible for the shell to unseat the die.

The stripper pins *DD* are made of tool steel and hardened at the ends *X*. They receive the proper tension from springs *E*. The setscrews *F* hold springs *E* in position and regulate the necessary tension. The holes *G* are tapped to secure the bolster plate to the press bed.

Fig. 5 shows the bulging die and punch with shell in position and reservoir filled with oil ready for the descent of the punch to bulge the taper and finish the ball. The punch *A* is made of hardened tool steel, while *B* is the bolster plate which seats the dies. These are

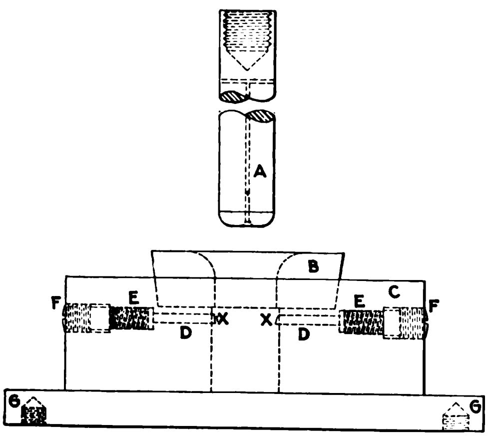

FIG. 4. THIRD DRAWING DIE AND PUNCH

made of hardened tool steel, consisting of two halves *CC*, which in operation are opened and closed by handle and screw *DD*. Both halves are counterbored to receive four springs *E* that spread the dies and keep them open while removing and placing the shell *F*, shown in place to be opened and bulged.

The oil is supplied by an automatic pump and enters through the pipe at *G*. The overflow pipe *H* expels the surplus oil and acts as a gage in keeping the reservoir from overflowing. It is important that the overflow pipe be ½ in. above the shell level, in order to keep enough oil in the reservoir instantly to fill the shell *F* when it is dropped into position.

The punch *A* has a ¾-in. threaded hole through the center to allow pressure adjustment by the threaded plugs *JJ* and rubber washer *K*. This must be 0.005 in. smaller than the inside of the shells. This operation opens and wires over the flange and at the same time bulges out a perfect ball on the end.

Good judgment and care must be exercised in both adjusting the press and in the oil-displacement space in the punch. This space is secured by adjusting the plugs *JJ* in order to get the proper effect on the ball. The pressure is equally distributed on the dies *CC* by the hardened block *I* when closed by screw and handle *DD*.

When the shell is in place, it will be noticed that the hollows of the dies are full of oil. As this must be expelled, the oil channels *XX* are provided and must be as small as possible in order not to leave any depres-

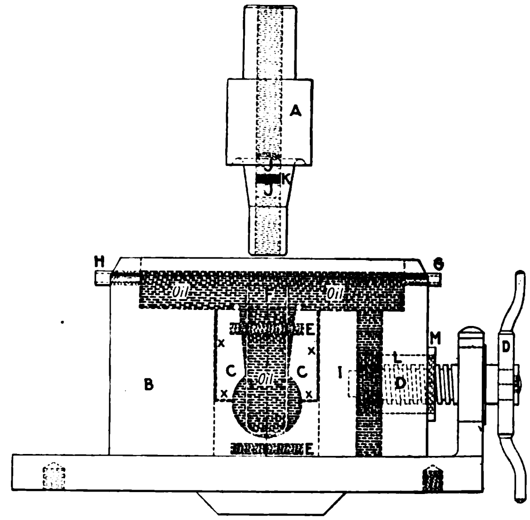

FIG. 5. BULGING AND OPENING DIE AND PUNCH

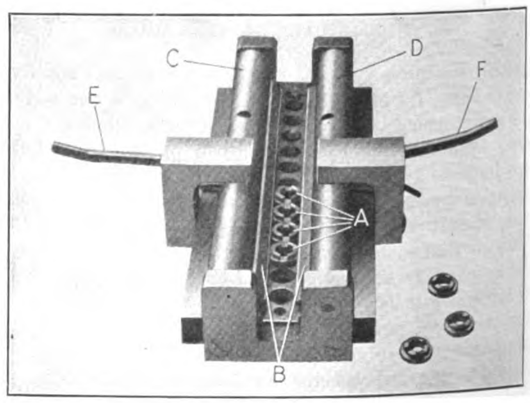
sion on the finished ball. The bronze bushings *L* and *M* and the nut can quickly be replaced when it becomes necessary. The tapped holes *OO* are to secure the bolster plate to the press.

Multiple Milling Jig

By E. A. Thanton

The idler stud washers on Henderson motorcycles are first drilled and turned; then they have a ⅛-in. slot milled across the top. Some of the slotted washers may



A MULTIPLE MILLING JIG

be seen at the right in the accompanying illustration. They are slotted in lots of 12 in the jig shown.

The washers are slipped into the channel, as at *A*. The clamping jaws *B* just catch the shoulders of the washers. These jaws are operated by eccentric rolls *C* and *D*, which are turned by the handles *E* and *F*. As soon as the lot is slotted, the washers are pushed out and the jig refilled by shoving washers in from one end.

Furnace and Oil Burner Plans

By Louis D. Peik

A large furnace equipped with oil burners and with the proper combustion and draft for annealing steel castings economically was for some time a problem with us in several ways. A large positive blower furnishing the air for the burners caused no end of repair expenses, and the steel stack was usually red hot and a smoke nuisance.

The furnace was 20 ft. long, 13 ft. wide and 9 ft. high from the car to the roof arch. Remodeling was carried out with good results, as in Fig. 1, which shows a cross-section of the annealing furnace after it was changed, and equipped with new home-made burners.

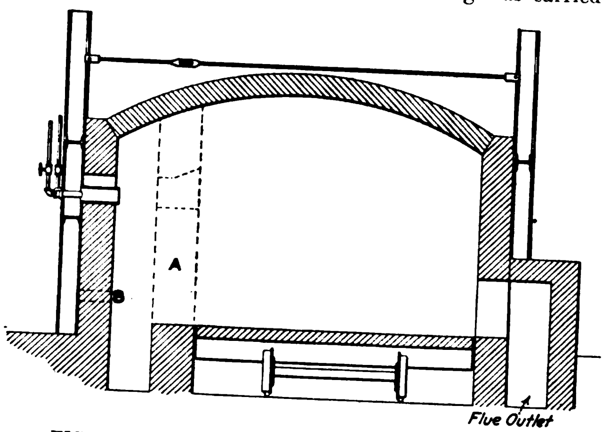


FIG. 1. ANNEALING FURNACE AS REMODELED

The original construction included the wall *A* and air-take holes *B*, comprising the combustion chamber.

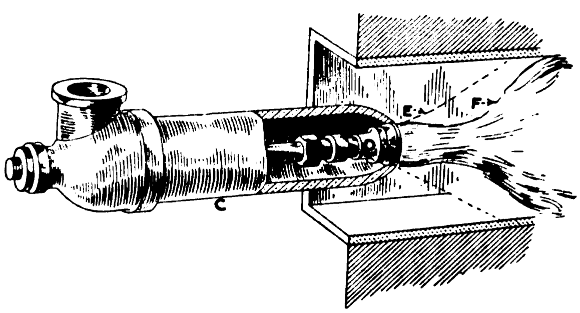

FIG. 2. ACTION OF THE BURNER

A burner was devised, as is shown in Fig. 2, made up almost entirely of standard fittings and gas pipe. The pipe *C* was heated and drawn somewhat to a point, leaving a hole just large enough to pass through it the nozzle *D*. The nozzle is a water-hose garden sprayer and can be bought for 20c.; the rest of the parts are standard fittings. The complete burner, fitted with valves and oil strainer, is shown in Fig. 3.

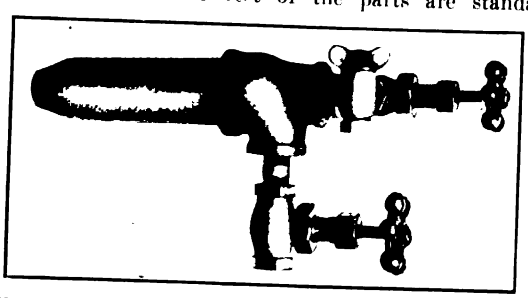

FIG. 3. BURNER WITH VALVES AND OIL STRAINER

Fig. 2 gives a good idea of the spray. Before the steam is turned on, the oil sprays in the direction *E*, shown in dotted lines. The steam passes out over the nozzle, mixes with the oil and in a very fine vapor or gas takes the course shown by *F*. The injector effect draws in enough air to produce perfect combustion in the furnace without any additional air supply.

It might appear that the burner side of the furnace will be colder than the outlet side, owing to the travel of the heat, but our experience with a furnace of this size does not find this to be the case. Conditions would be more nearly ideal, however, if the flue outlets were placed on both sides of the furnace. Under their changed condition our stack barely gets warm, and the smoke is hardly perceptible. In addition to this the blower was shut down and steam used instead. There is also a marked saving in fuel oil. Fig. 4 shows a cross-section of a proposed heating furnace for melting alloys with fuel oil. It is built in tunnel shape, so as to give a coiling motion to the flames.

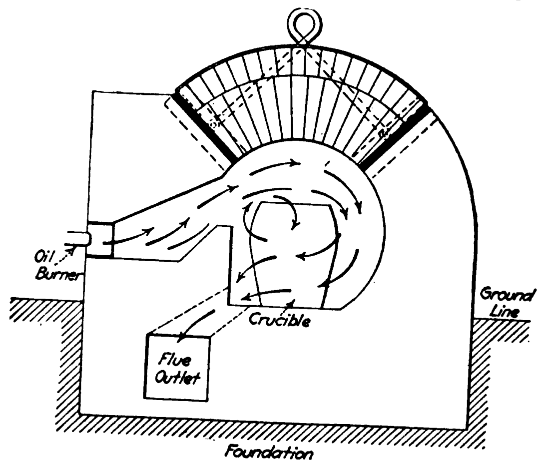

FIG. 4. FURNACE FOR MELTING ALLOYS

It might be of interest to many who have furnace problems to know something in regard to the proper size of flue outlets. After considerable experimenting with three different kinds of furnaces, I find that 1 per cent. of the volume in cubic feet of the furnace expressed in square feet gives the proper total area of flue outlet. For example, take a furnace 5x6x2 ft., to have two flue outlets: $5 \times 6 \times 2 = 60$ cu.ft.; 1 per cent. of $60 = 0.6$ sq.ft.; $0.6 \times 144 = 86.4$; $86.4 \div 2 = 43.2$ sq.in. Therefore the size of each opening is 6x7 in., nearly.

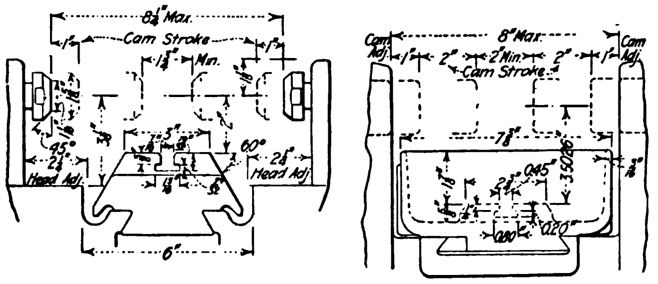
Spline-Milling Fixtures

By W. S. Wright

The spline miller has been used quite extensively in the past to spline keyways, to hog away metal to be finished later by another operation and for cutting through slots. With the rush of gun work a new field of usefulness has been opened up for this type of machine. It will do a vast amount of work with practically no attention, for one man of the unskilled class can handle several machines without inconvenience, as a machine once started will run until its operation is completed and then stop. Each

cutter may not remove as much stock as an end mill; but as each machine is two spindled, the results of a day's run are quite satisfactory. The cutter used is called a fish-tail cutter, being made with two, three or four teeth.

The table moves as any miller table, only it is accelerated by different means and passes back and forth



FIGS. 1 AND 2. DIAGRAMS OF STROKES OF TWO SPLINE MILLERS

between the two spindles. The distance from the center line of the cutters and the top of the table is constant and cannot be changed.

Capacity diagrams of these machines, of Pratt & Whitney make, are shown in Figs. 1 and 2. Fig. 1 is for the smaller machine, in which the standard collet takes a straight-shanked cutter $\frac{1}{4}$ in. in diameter, although $\frac{5}{16}$-in. cutters may be used. The entire head of this machine is adjustable $2\frac{1}{4}$ in., and the table cam stroke is 1 in. for each spindle, making a total movement of 2 in. The table travel is 2 in.

The larger machine, shown in diagram in Fig. 2, has an adjustment of 1 in., by means of moving the cam on its shaft, and has a 2-in. cam stroke for each spindle. This machine takes straight-shank cutters $\frac{1}{4}$ and $\frac{7}{16}$ in. in diameter. The table travel is 4 in.

In Figs. 3 and 5 are shown two styles of spline-milling fixtures, which are typical designs for these machines. Considering Fig. 3, the base *A* is of cast iron. Upon it is mounted a stationary jaw *B*, which is screwed, doweled and tongued to the base. Under this jaw and in a slot in the base is a machine-steel slide *D*, upon which is mounted a swivel jaw *C* held on the slide by means of a shoulder screw *H*. All these parts, except the base, are made of machinery steel and are carbonized, hardened and ground. With the high cost of tool steel it would be out of the question to make these parts of that material.

The jaws are closed by means of a cam *E*, mounted on a stud *F* in the iron base *A*. The long end of the slide is held down by passing under the stationary jaw *B*, and the head end of the slide is forced downward as well as forward by the action of the cam in closing.

On the side of the slide is screwed a plate *G*, in which is a rectangular opening. Driven into the side of the cam handle *E* is a pin *K*. As it is desired to open the jaws to remove the work, this pin bears against the back side of the opening in the plate *G* and pulls the slide back or toward the operator, thus allowing the work to be removed. In the bottom of the base is planed a slot of the same width as the slot in the miller table, and two keys *J* are screwed in place.

Fig. 4 shows the part upon which the cuts for both slots are made. The slot cut in the fixture, Fig. 3, is the small one marked *X*, while the cut marked *Y* is the one taken in the fixture of Fig. 5. The work in each case is positioned by the lug at the right of the cut *Y*.

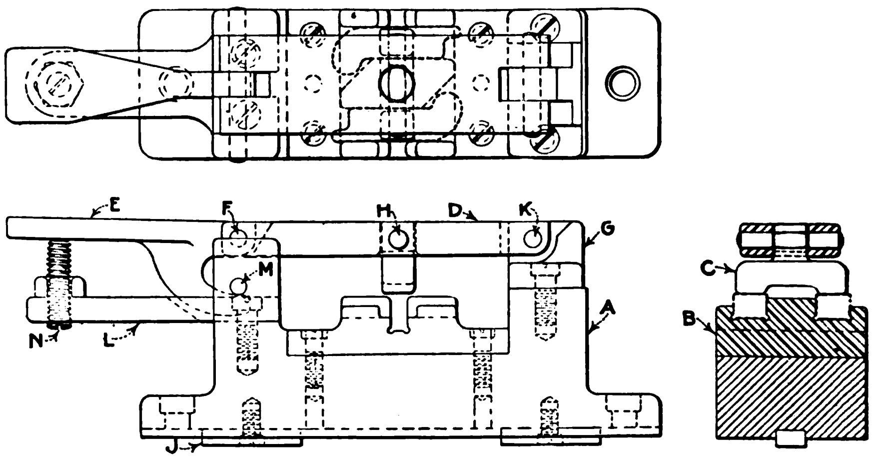


FIG. 5. ANOTHER SPLINE-MILLING FIXTURE

When work can be held in a horizontal position and not vertical, as in Fig. 3, a fixture of the type shown in Fig. 5 may be used. In this fixture upon the base *A* is screwed and doweled the machine-steel block *B*, which is a bedding and locating block for the work.

The work is held down on this plate by means of a swivel clamp *C*, hung in the leaf *D*. The leaf is swiveled on the pin *K* on a machine-steel block *G*, which is screwed to *A*. Clamping the work is done by a binder handle *E*, which is hung on the pin *F* in the leaf and binds under the pin *M* in the base. The block *G* is cut at a 45-deg. angle, as shown, to prevent the leaf from being thrown back on the table of the machine. The binder *E* is a forging. The casting is planed from $\frac{1}{32}$ to $\frac{1}{64}$ in. below the bottom of the leaf, when in the position to hold a piece of maximum size and to allow the leaf to close tight on a piece of minimum size. As considerable pressure may be put on the handle *E*, a stop handle *L* is provided with screw and nut *N*. This fixture is keyed to the machine table in the same manner as the one of Fig. 3, and each is held in place by T-nuts and fillister-head screws. While conditions may require fixtures of different construction, these convey the general idea.

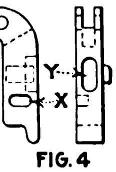

FIG. 4

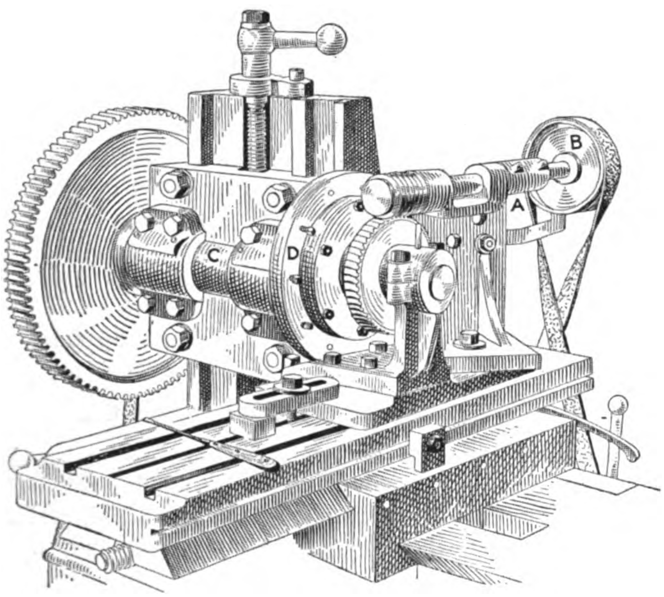
FIGS. 3 AND 4. A SPLINE-MILLING JOB AND ITS FIXTURE

Letters from Practical Men

A Continuous Milling Fixture

The continuous milling rig shown herewith was set upon a Brainerd miller to help out on a rush order. The work to be done was the surfacing of irregular-shaped cast-iron pieces that were already ground on one side. The two faces had to be parallel within ± 0.0005 in.

There was at hand a fixture that, with a little changing, was well adapted to the work. A pair of heavy bearings, mounted on a base, carried a 1½-in. worm-driven shaft, on which a faceplate was swung. This faceplate was provided with a locating stop for the work and a screw



A CONTINUOUS MILLING FIXTURE

to draw each piece flat against the faceplate, a tapped hole already in the pieces being convenient for this operation. Removing the worm shaft from its former position, it was fastened to an angle plate as at *A*, so that a belt drive could be obtained from the regular feed. To do this a pulley was screwed to the worm gear on the back of the machine in line with the pulley *B* in the upper worm shaft. The usual feed changes were thus obtained and applied to the faceplate. Removal of the pinion on the screw allowed the table feed worm gear to revolve without moving the table.

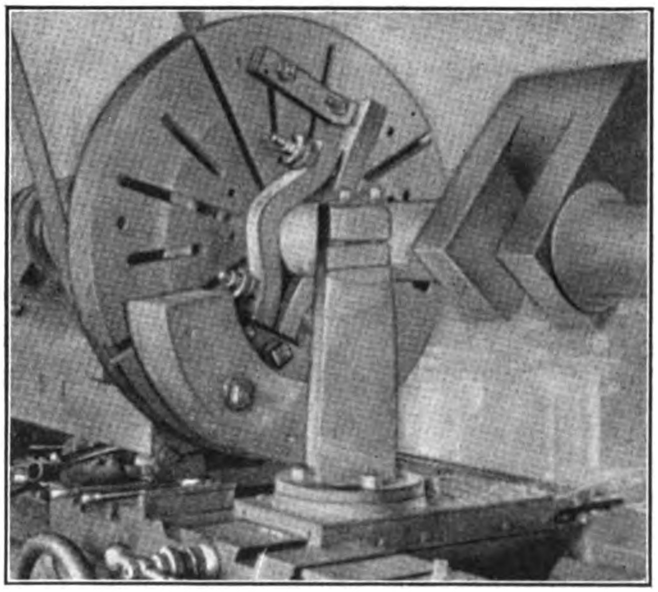
An end mill carried in the spindle *C* completed the outfit. The production was 450 pieces per day—all within the prescribed limits. To insure perfect work, the saddle was moved up, the feed put on and the working surface of the faceplate *D* dressed off lightly by the end mill before any pieces were run. A screwdriver was the only tool the operator needed to attach the pieces to the faceplate. The screws used to hold them may be seen on the outer ring.

Incidentally, the illustration shows a source of danger—guarded in this instance—which to the writer's belief the safety inspectors have overlooked. There are any number of this type of miller in use, all powerfully geared and all made with a big driving gear in the spindle. The gear has six arms, the spaces between which when revolving forming as dangerous a trap as could be found. If by any chance an arm were thrust through one of the openings, the mildest possible result would be a broken limb. The writer has protected the machine shown and others by disks of ⅜-in. boards cut out on the bandsaw and held on the gear by wood screws passing through the boards themselves, one disk being on each side of the arm. DONALD A. HAMPSON.

Middletown, N. Y.

Extended Tool Post for Crankshaft Turning

For turning large crankshafts the extended tool holder shown in the illustration has proved very suitable. The regular tool slide has been removed and the upright, which is a steel casting, bolted in its place. This, of



TOOL POST FOR CRANKSHAFT TURNING

course, may be swiveled so as to use it with either the right or the left hand. Near the upper end a slot has been planed, and a hardened-steel circular piece has been provided beneath the tool, enabling it to be set at any angle necessary. Two setscrews are used for clamping.

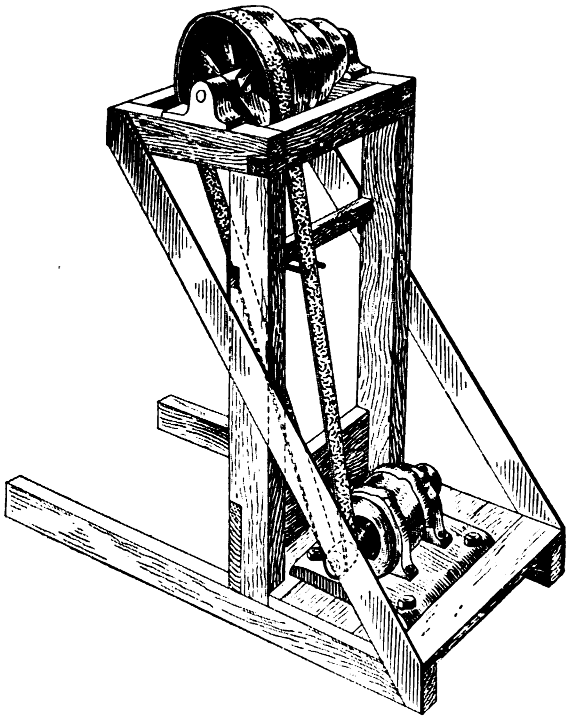
Lima, Ohio. D. S. MANN.

Portable Power Plant and Countershaft

The illustration shows a portable countershaft built for use in the finishing operations on hand screw machines. The base is of the same width and height as the standard elevating truck platform, with extensions of sufficient length to straddle the leg of the lathe at the spindle end and take the belt pull. A 3-hp. motor is mounted

on the base and belted to a countershaft, with tight and loose pulleys and cone on the upper framework. The power wires are supported over the erecting floor by small ropes and weights and are long enough to allow the machine to be moved anywhere on the floor. They are attached to the frame, with a double-throw switch on the side nearest the operator.

The machines were assembled by the progressive system, in rows of ten each. When the end one was completed, the countershaft was moved up to it, the belt attached, sliding the countershaft back until the requisite belt pull was applied. The screw machine was run in the reverse direction while the spindle nose was ground to the correct taper, owing to the fact that our internal grinder ran anticlockwise. The turret holes were then drilled, bored with a single-point tool and reamed. The tools



THE PORTABLE COUNTERSHAFT AND POWER PLANT

for this operation were held in the automatic chuck collet, thus insuring absolute alignment of the turret holes with the spindle. The belt was then taken off and the countershaft moved to the next machine in line.

The countershaft was easily handled by one man and saved a great deal of time and confusion that would otherwise have been required in moving machines to the line shaft and back again. H. B. McCray.

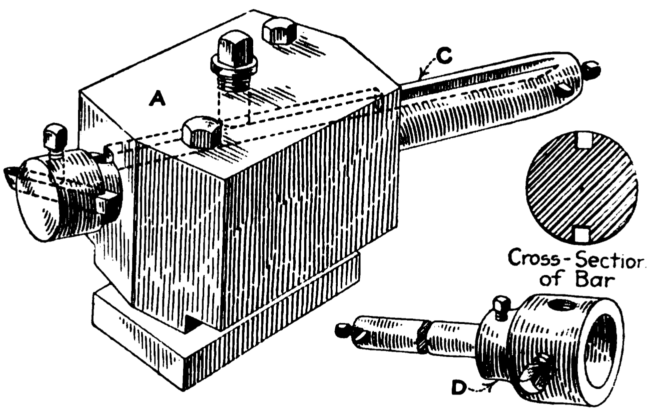
Charles City, Iowa.

A Boring Bar

The accompanying drawing shows a boring bar that has been found very useful for short heavy engine-lathe work. While it is a bar, its construction permits it to be used for numerous turning and facing jobs as well.

The cast-iron block *A* is bolted to the carriage after being planed to fit the tool-post slot and is bored in place. A keyway is cut in the top of the bore and a hardened key fitted to it. The key is made slightly loose, so that it may be removed easily. When in use, i... held in place by a substantial setscrew in the b...

The bar has a keyway in each side, which permits it to be turned over for inside or outside work. The tool slot is cut at an angle of about 45 deg., for the purpose of getting into corners. Forged bits of ¾-in. steel are used, and the bar is about 3 in. in diameter or may be heavier, if required. Braces may also be provided for



A BORING BAR ADAPTED FOR HEAVY LATHE WORK

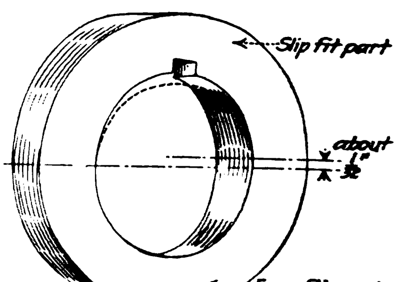
the back end of the bar and attached to the rear end of the carriage to prevent springing.

A socket *D*, which slips over the end of the bar and is held in place by a setscrew, makes it unnecessary to remove the bar for boring small holes. Bars of various lengths to suit the work being done may be used in the small end of the socket. Other sockets or caps may be made to slip over the end of the bar, for holding thread chasers and forming tools of different kinds.

Los Angeles, Calif. F. L. Bowler.

Fitting Tube-Mill Gears

The tube mills in a certain portland-cement works are gear driven. The gear and pinion on the intermediate shaft are subjected to tremendous stresses and vibration. To be sure that they would not come loose, we used to bore them out a force fit and press them on the shaft in the shop. When the gear was worn out or broken, the whole shaft, which weighed over 3,000 lb., had to be taken out and moved to the shop, the gear pressed off and a new one pressed on, which took considerable time. We tried to hold them on with a slip fit, but in time they always worked loose, no matter how well the key was fitted, spoiling not only the gear, but sometimes the shaft as well. So we tried a system which, because we did not know any other name for it, we called the two-diameter fit. The gear was bored out a force fit as usual, but allowing more for the fit. The shafts were 6 in. in diameter and we allowed eight thousandths. Then the gear was moved over in the chuck about $\frac{1}{32}$ in. and another cut taken. We allowed the tool to touch just half of the diameter of the first hole. This second bore was ...y slip fit on the 6-in. shaft. The keyway was then ...he middle of the larger-sized bore. To assemble,



FITTING TUBE-MILL GEARS

the gear was slipped on the shaft to the required point and the taper key driven, drawing the force-fit bore against the shaft.

When the gear was to be changed, the key was drifted out. A few blows from a sledge were sufficient to knock the gear down onto the slip-fit part of the bore, and it was easily slipped off the shaft and a new one put on.

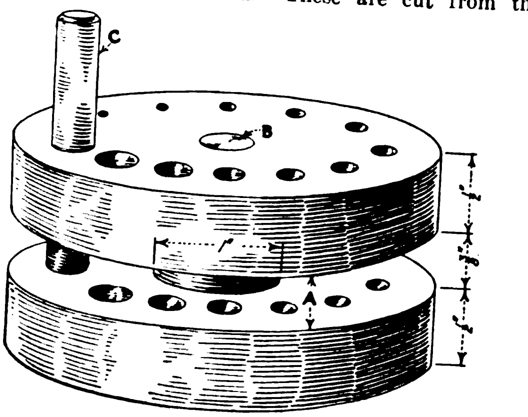
Although these drives are subjected to great stresses and vibration, we never had one come loose. As far as we could judge, this method of holding was just as secure as the force fits.

Seattle, Wash. E. W. WRIGLEY.

Handy Punch and Die Block

Herewith is shown a sketch of a very handy punch and die for a mechanic's tool kit. It may be used to punch sheet metal of any kind.

The series of holes is drilled straight through both flanges and is made to take the punches *C*, made from standard sizes of drill rod. These are cut from the



A HANDY PUNCH AND DIE BLOCK

rods and the ends hardened. Either of the surfaces *A* may be used as the die. When both are dull, they may easily be renewed by grinding on an arbor inserted in the hole *B*.

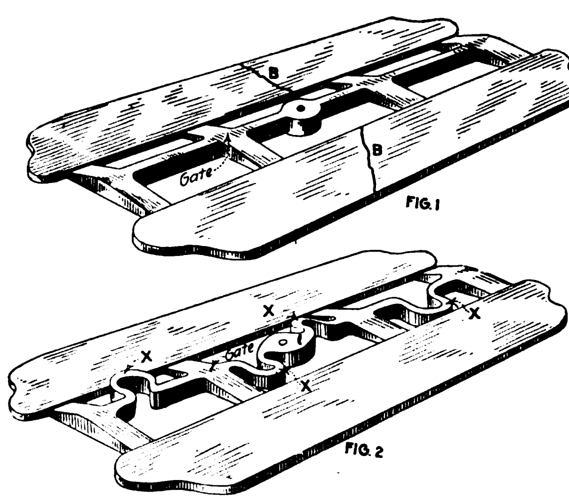
It is understood of course that the whole die block is to be hardened. HAROLD E. GREENE.

Ilion, N. Y.

Preventing Shrinkage Cracks

Considerable difficulty was experienced by a malleable-iron foundry in producing long thin castings such as shown in Fig. 1. The difficulty was to prevent them from cracking through the points indicated by *B*, while cooling in the mold. The trouble was overcome by employing an extra man during the pouring period, to dump the molds immediately after being shifted and to break the castings off the gate before cooling. After several years of production by this method the foundry head took the matter of making alterations on the gating, to overcome the extra expense involved.

The pattern department came to the conclusion that the cracking was due to the castings being much lighter in cross-section than the gate, causing unequal contraction, which was successfully overcome by the use of a bent gate, Fig. 2. The contraction breaks this at the points marked *X* and saves the castings.



PREVENTING SHRINKAGE CRACKS

The foundry is now producing the castings in large quantities at moderate cost and doing away with the expense of the extra man. STEPHEN BONA.

Union City, Conn.

Relation Between Drafting Room and Factory

Issuing drawings to the factory and keeping the factory supplied with uptodate prints are matters of no little importance. It often happens that, after blueprints have been sent to the shops and even after apparatus has been manufactured from them, the engineer will change the design, so that the prints in the factory become obsolete.

In some large factories, when changed prints are sent to the manufacturing departments daily, a bulletin is also issued and sent along, giving the drawing numbers affected, describing the changes, stating the requisition and job numbers and giving the disposition of material in process of manufacture. Where patterns and tools are involved, this bulletin will state, "Patterns changed" or "Tools changed." The production man, seeing this, will at once issue orders to change the patterns or tools and will state whether production is to be held up on present apparatus or whether it may go on and the change work in automatically.

This bulletin is sent to all manufacturing departments and should accompany the blueprints of that issue. Pattern shop, foundry, screw-machine, tool and machine-assembly departments are automatically notified at once. Each and every foreman is thus acquainted with the situation and is watching for his new or changed orders from the production department.

The clerk in the factory, on receiving these new prints and bulletins, will call in all the old prints of the previous issue, which should be scrapped. He should keep a record of all prints charged out and make sure that each man in the department holding an old print is supplied with a new one covering the latest changes. Some factory foremen in trying to cut down their "overhead" will neglect to have their blueprint files properly looked after, although this is a big mistake. It may happen that hundreds of dollars will be thrown away by making

up, according to an old drawing, parts that will be useless for the new construction.

The bulletin issued on new and changed drawings should be kept on record for at least five years, for possible reference. It is the chart on which the whole manufacturing work hinges. By living up to it and doing strictly what it states the factory foreman or superintendent will eliminate all his troubles with the engineering and drafting departments. It may happen that the bulletin is wrong, but this is the fault of the engineer and not of the factory man.

It may be found sometimes that the bulletin may not have as many drawings recorded as there actually are on change. The factory clerk is in a good position to discover this, as he is the checker. By notifying the drafting department a supplementary sheet is sent through, covering the missing numbers.

To sum up the whole situation: The drafting-department daily bulletin notifies the factory of new and changed drawings, calls attention to pattern and tool changes, tells of disposition of material in course of construction, notifies the production and cost departments of all changes on apparatus being built and, lastly, is a silent superintendent of the whole manufacturing department.

Pittsfield, Mass. JOHN INKERMAN.

Chuck Wrench Provided With Renewable End

Having had much trouble with chuck wrenches which operate screws with female openings, I devised a wrench that successfully does away with the annoyance caused by twisting off the square end that enters the chuck screw.

The body of the wrench is made as large as practical, to give the necessary metal around a square broached hole in the end. A small hole is drilled entirely through the shank. The wrench ends are made of standard cold-drawn square stock driven in the broached hole. In case the end is twisted off, the cross-handle is removed, and the broken end is driven out with a drift through the small hole in the wrench body. A new piece is driven in, and the wrench is as good as new.

Brazil, Ind. FRANK G. SENTER.

Inspection of Castings

The inspection of castings is a subject on which very little has been written and at the same time one which should interest all mechanics. A casting is something more than a lump of metal taken out of the sand. It is oftentimes the foundation for a lot of expensive work. If defective, the further expense of machining it should be stopped, if possible.

The inspection of large castings is interesting, as each casting, even if off the same pattern, will check differently. To decide whether or not to use a defective casting, before any machine work has been done, will often tax the judgment of the most experienced of inspectors. To facilitate the inspection of castings and to standardize it, I have worked out the following specification and find it very satisfactory:

All castings must check reasonably close to the dimensions on the drawings, all variations to be noted and reported when necessary, an allowance being made for the required amount of material for finishing all parts that require machining.

Castings should be free from all defects—such as shrinkage cracks, sand-, shrink- or blow-holes, warped or twisted surfaces, lumps, fins or burnt sand—that affect the strength or appearance.

All castings must be cleaned thoroughly. This means that no extra work will be necessary in order to use the castings, that all lumps and fins must be chipped off flush with the surface of the castings and that all sand, chaplet plates, cleaning jacks, nails and core rods must be removed from fillets and cored pockets or holes. Exceptions will be made from these rules, in the following cases:

Castings used for a rough class of work will pass as O.K. with a foundry finish suitable for this particular class of work. Minor defects, unless present in large numbers, that do not affect the strength or appearance of the castings will pass as O.K. Castings that have shrinkage cracks, shrink-, sand- or blow-holes located at such points that they will not affect the strength of the casting will pass as O.K., provided that the filling of the defective spot or spots is done at the expense of the foundry. Castings that have had defective spots filled or welded without first having obtained permission of the inspector will be subject to rejection. Permission to patch a defect will only be given after inquiry has been made regarding the extent of the defect.

Castings that have been welded or burned on at points that are to be finished must be soft enough at such points to be readily machined. If too hard, the castings will be subject to rejection.

Castings that develop defects after machine work has been done will be subject to rejection or will be filled or welded at the expense of the foundry.

Castings that have warped or twisted surfaces that do not affect the use of the casting or cause extra work in machining will pass as O.K. W. H. NOURSE.

Portland, Ore.

Wanted--Data on Shell Practice

There seems to be such a variety of methods used when machining the shells that the practice followed by our readers is worth recording.

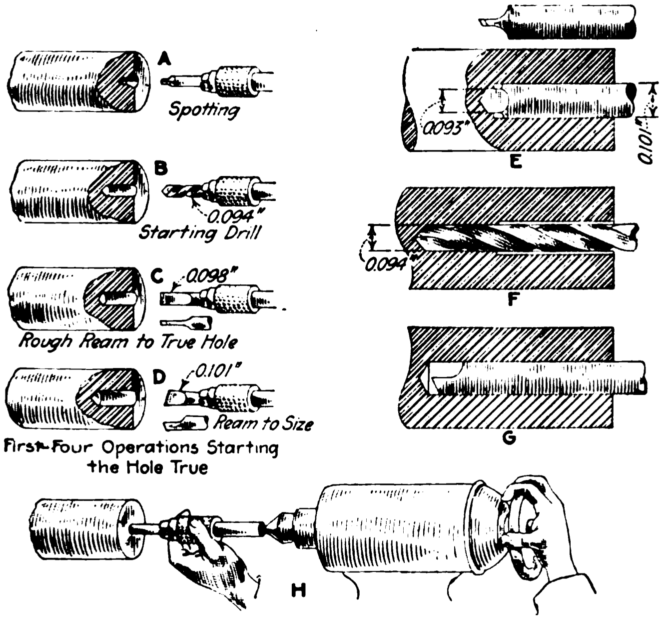
In some firms we find that low-carbon steel is used for the machining tools, some using them dry, others with a cutting lubricant. Other concerns are utilizing high-speed tools, either dry or with cutting fluid. Will our readers engaged on this class of work kindly send us what is their practice, which to be of value should contain the following data: Chemical analysis of steel being machined, surface speed at which it is machined, feed and depth of cut being taken, nature of steel used for the machining tool, whether dry, or if using a cutting fluid, its nature. A compilation of such information would be of great value, as it deals with an interesting, live subject.

Also of value would be the following information: Operation and machine tool used, physical properties of steel machined. If heat-treated, what is the treatment? Is steel from bar or forged? Of what type is the cutting tool? Information on threading is especially wanted.

Discussion of Previous Question

Drilling Long, Small Holes

The article by A. R. Robertson on page 241 of the *American Machinist* proved of interest to me, as I have several times faced the same problem. Just a few months ago a number of spindles were required that called for a long, small hole of the kind referred to. These spindles are used on a special machine, and six are required for each set. The outside diameter is a little less than $\frac{1}{2}$ in. and the length is 6 in. A 0.101-in. hole is drilled and reamed from end to end and is required to run true with



DRILLING LONG, SMALL HOLES

the outside and to be as near straight as it can reasonably be made. The hole size limits are 0.001 in. over and nothing under. The specifications called for machinery steel, and the pieces were to be cyanided on each end when completed.

The steel had already been cut off, but on taking up the job I returned it to the stockroom and had cold-rolled steel furnished instead, allowing about $\frac{1}{8}$ in. to turn off. The pieces were then rough-turned to within $\frac{1}{32}$ in. of size and well annealed. The reason for using the cold-rolled steel is that machinery steel is often stringy and uneven in grain, while cold-rolled is smooth and easy to work. This is a material aid in keeping the hole going straight. The roughing off and careful annealing are for the purpose of disposing of the rolling or drawing stresses in the steel, which would otherwise be likely to make the piece crooked later on.

The hole is drilled in a bench lathe. First, one end of each piece is trued off on the diameter for $\frac{3}{8}$ in. back, making the size uniform for the lot. Then this end is back-rested, the other end being held in the draw-in chuck. The illustrations from *A* to *D* show how the work is spotted with a center drill, drilled about $\frac{5}{16}$ with a 0.094 twist drill and rough-reamed with a short two-lip tool made of drill rod. These tools are all caught short in the chuck, which is held in the tail spindle, thus insuring a true start. The finish-reaming should not be done with too short a reamer, for a slight lack of alignment will give a large hole at the start, which will not help matters. We are now ready to proceed.

Three different tools are used, shown from *E* to *G*—a spotter, a drill and a cannon reamer—and two lengths of each, $3\frac{1}{2}$ and $6\frac{1}{2}$ in. All are made from drill rod, with the exception of the drill. These tools are used in rotation, as the hole is put through by stages.

The chuck, however, is no longer held in the tail spindle, but the center hole in the shank is placed against the tail center. Therefore, the operator, lightly holding the chuck as shown at *H*, is quickly aware of any undue resistance encountered by the tools and lets the chuck run around, thus avoiding breaking a drill in the hole.

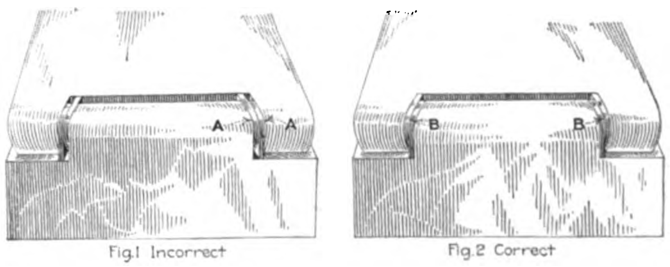
The first tool is the spotter. Its body fits the hole just reamed, and the point, ground the same as the drill, spots the bottom just enough to give the drill a true start. Then comes the drill, which is a regular twist drill sweated in a drill-rod shank. It is cleaned and oiled by withdrawing and dipping in an oil cup wherever it pulls hard. After about $\frac{3}{8}$ in. or a little more has been drilled, the hole is reamed with a cannon reamer, and so on through the piece. This follow-up method will keep the hole going nice and straight. On these pieces 6 in. long, drilled from the one end, there were none running out more than four or five thousandths at the back end.

The correspondent mentions grinding the drill out of center. I have used this plan for getting through hard bronze or high-speed steel, but it does not seem that a very straight job would result. ARTHUR W. SUITER.

Woonsocket, R. I.

Wearing Plates for Jigs

The wear plates for jigs, described by B. Maxim on page 200, are excellent, but the illustration is rather misleading. It is no doubt an error in draftsmanship, but the hardened wear plates are shown anchored in such



WEARING PLATES FOR JIGS

a fashion as to lose their usefulness, as the plates and casting rub at *A*, Fig. 1.

No doubt, Mr. Maxim's idea is, as in Fig. 2, to have the wear come on the plates at *B*. A comparison of the two sketches will show the difference.

Luton, England. P. J. TOMPKINS.

Heavy Projectile Turret Lathes

SYNOPSIS—The heavy turret lathes described in this article were made expressly for work on the smaller sizes of projectiles. The range of speeds and feeds is ample for this class of work, yet care has been taken to avoid complication.

In designing and making the turret lathes here shown the Hill Pump Co., Anderson, Ind., first intended building them for its own use only, but later decided to place them on the open market. The nature of the company's factory work and the ownership of an ample foundry gave it especial facilities for manufacturing these machines. Two sizes are made at present, known as No. 3 and No. 6.

The main idea has been to produce strong, accurate and easily operated lathes for machining the smaller sizes of explosive shells. The comparative simplicity of design and the absence of complications add to the security from breakage under severe working conditions. The use of a large number of these machines in its own shops has enabled the company to test out the various features.

The bed is of the box-pattern type, wide, deep and reinforced with cross-ribs. It rests on a large oil pan supported on pedestal legs that form large oil chambers. The headstock totally incloses the spindle and the main gears. It contains a large oil reservoir for chain lubrication to the spindle and back-gear shaft bearings. The latter are all fitted with heavy renewable bronze bushings. A glass gage on the front of the headstock enables the operator to see that sufficient oil is kept in the reservoir at all times.

The spindle is of high-carbon steel, hollow and accurately ground to size. All gears are accurately cut and are made of steel, with the exception of a bronze worm-wheel in the apron. The flat turret is of large diameter, gibbed at the outer edge and very heavy. All its parts are carefully fitted and scraped into position. It is arranged for six tool holders, which are tongued and fitted to slots in the turret and are held firmly in their respective positions by a pin set under the cutting tool and by hardened and ground bushings into which the pin fits The turret apron is of the shrouded box style, arranged for longitudinal power feed, with a single automatic stop. The oil pump is of the gear type and supplies oil or other lubricant to the cutting tool through an automatic distributor only when the tool is in working position.

Except in certain dimensions and in the method of operating the chucks, the No. 3 and the No. 6 lathes

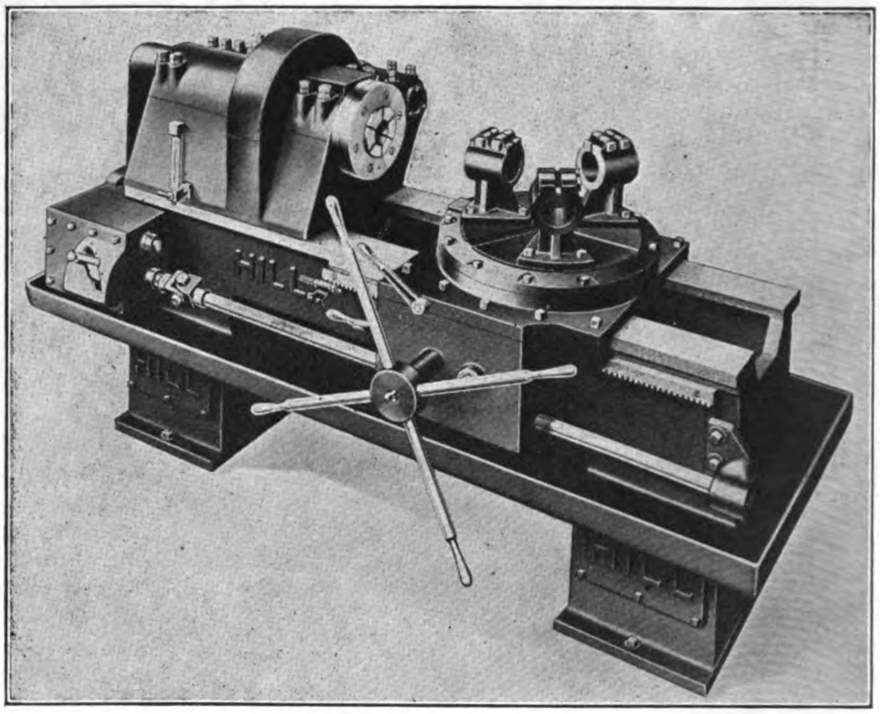


FIG. 1. EXTRA-HEAVY PROJECTILE TURRET LATHE

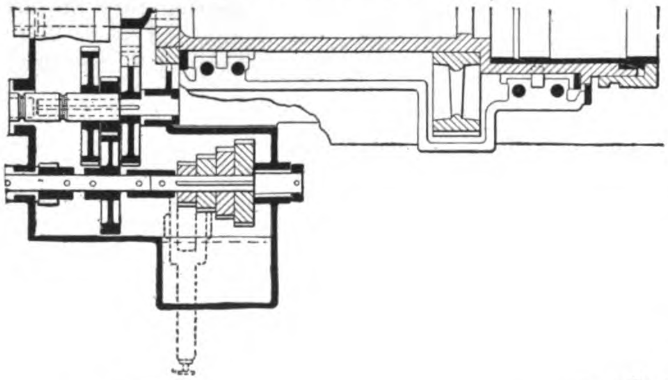

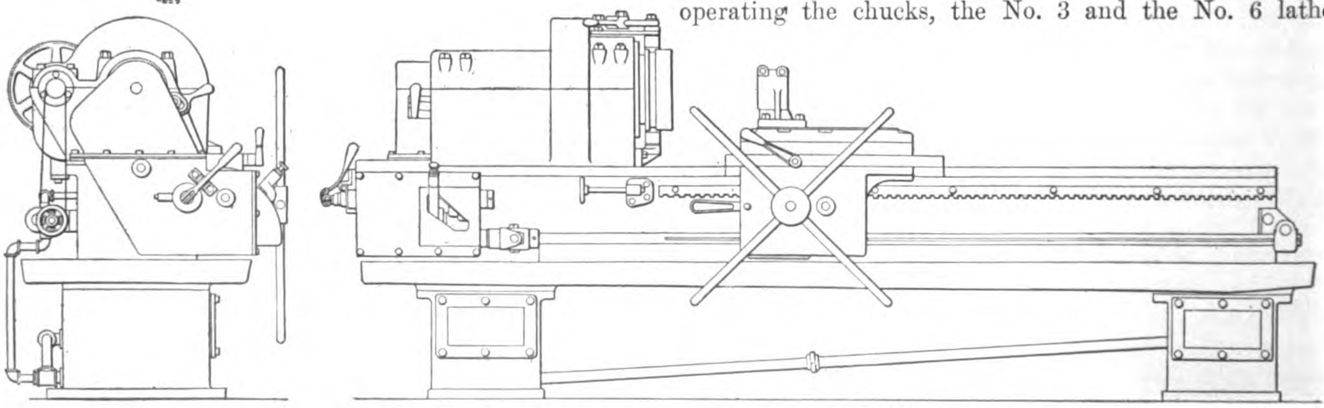

FIG. 2. DETAILS OF NO. 6 HEAVY PROJECTILE TURRET LATHE

closely resemble each other. The No. 3 may be seen in Fig. 1 and in detail in Fig. 3. These two illustrations show how the self-centering draw-in chuck is operated by a handwheel at the back. Fig. 2 gives details of the No. 6 machine. Here the handwheel is dispensed with, and the chuck is operated by means of a toggle-lever action mounted over the front bearing within easy reach of the operator.

The driving power is supplied to each machine through a single pulley on the back-gear shaft, which is 12 in. in diameter and has an 8-in. face. Eight changes of feed are available through quick-change gears, which are 0.015, 0.020, 0.025, 0.030, 0.045, 0.060, 0.075 and 0.090 in. per revolution. The regular equipment includes self-centering draw-in chuck with hardened jaws. Special tools or holding fixtures are supplied on order. The following are important dimensions of the two sizes of machines:

For the No. 3 machine—swing over bed, 22 in.; from face of chuck to turret tool socket, 27 in.; longitudinal movement of carriage, 25 in.; height from floor to center of spindle, 40 in.; length of bed, 6 ft.; ratio of driving gear from back-gear shaft to spindle, 4.13; face of gears, 3 in.; bore of spindle, 3½ to 4½ in.; overall length of spindle in bearings, 25 in.; front spindle bearing, 5¾ in. in diameter by 6 in. long; rear spindle bearing, 5½ in. in diameter by 5 in. long; diameter of turret, 18 in.; floor space for machine, 2 ft. 6 in. by 7 ft. 6 in.; cubic measure boxed, 8 ft. 6 in. by 5 ft. 6 in. by 4 ft. 6 in.; net crated weight, about 6,000 lb.; net boxed weight, about 6,500 lb.

For the No. 6 size—swing over bed, 22 in.; from face of chuck to tool socket, 48 in.; longitudinal movement of carriage, 48 in.; height from floor to center of spindle, 40 in.; length of bed, 9 ft.; back-gear ratio, 4.13; face of gears, 3 in.; bore of spindle, 3½ to 4½ in.; overall length of spindle in bearings, 25 in.; front spindle bearing, 9⅜ in. in diameter by 6 in. long; rear spindle bearing, 5½ in. in diameter by 5 in. long; floor space, 10 ft. 6 in. by 2 ft. 6 in.; cubic measure boxed, 11 ft. 6 in. by 5 ft. 6 in. by 4 ft. 6 in.; net weight crated, about 8,000 lb.; net weight boxed, about 8,500 lb.

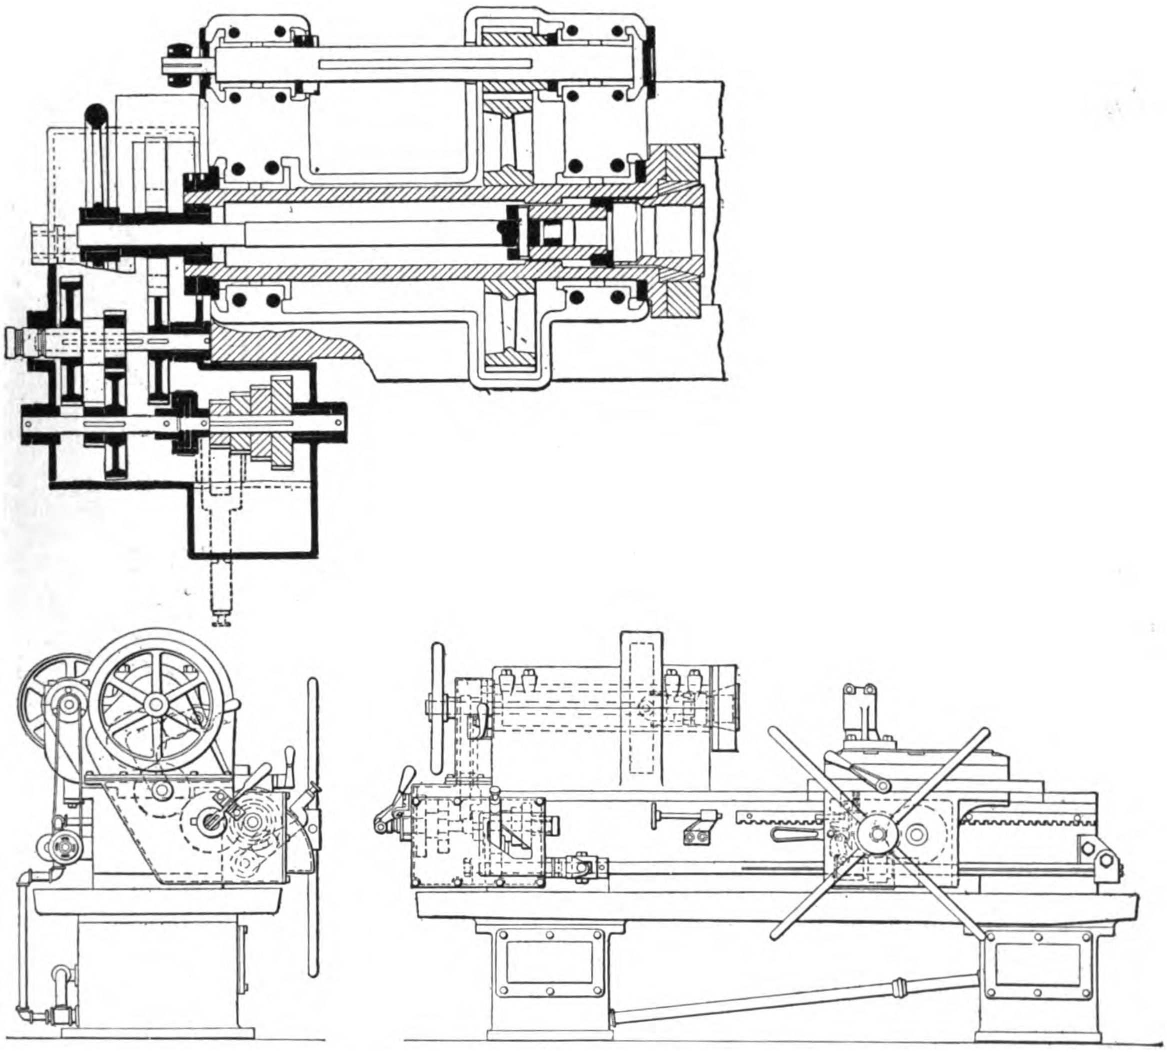

FIG. 3. DETAILS OF NO. 3 HEAVY PROJECTILE TURRET LATHE

Whale Oil for Cheap Cutting Compound

A Canadian concern manufacturing 18-pounder high-explosive shells makes inquiry for a recipe for a good cutting compound that could be made from whale oil.

The extensive use of lard oil in this plant has led to what is considered excessive cost for cutting compound, and the plentiful supply of whale oil has suggested the possibilities of economy through the utilization of this grade of oil.

DISTRIBUTION OF MACHINE SHOPS IN SOUTH AMERICA IS SHOWN BY THE DOTS

Editorials

A supply of indexes for Vol. 43, July-December, 1915, is still available.

Those desiring copies should make prompt application.

Machine Shops in South America

Comments on South American business conditions in general have appeared in these columns during the past few weeks. This discussion is the first of several that will give accurate statistics and facts in regard to the machine shops of that great southern continent—their equipment, workmen and executives. The information is drawn from records prepared on the spot by Duncan N. Hood, the special representative of the *American Machinist* who has just returned from an 18 months' journey, going down the west and returning along the east coast.

The reason for referring to this as a coast journey is realized at once by glancing at the map on page 652. On that map are plotted the machine shops of South America. It will be observed that they are strung along the coast line, with the exception of a cross-continent belt stretching from Chile across the upper part of Argentina.

The total number of machine shops indicated on the map is 461, divided among the various countries as follows: Panama, 3; Colombia, 12; Ecuador, 21; Peru, 45; Bolivia, 21; Chile, 69; Argentina, 95; Paraguay, 5; Uruguay, 15; Brazil, 147; the Guianas, 9; Venezuela, 19. During Mr. Hood's recent trip he visited 70 per cent. by number of all these shops and obtained detailed information in regard to their work, equipment and personnel. In this group are included all the large shops of South America. Those not visited are the smaller ones in remote or inaccessible locations.

A familiar way to estimate the importance of the machinery building and repairing in a given locality is to tabulate the shops according to the number of men employed. Grouping the South American shops in this way gives the following classification: Number of shops employing up to 20 men each, 368; from 21 to 50 men each, 52; from 51 to 150 men each, 18; from 151 men up, 23.

Another classification that is of interest is one that arranges the shops according to the kind of work done. As will be expected, the two important items in such a grouping of South American machine shops are general repairs and railroad repairs. The complete classification is as follows: Railroad repairs, 88; shipbuilding and ship repairs 31; general repairing, 225; light-machinery building, including engines, 26; street-railroad repairs, 57; mining-machinery repairs, 34.

What these figures mean in terms of possible increase in the number of machine shops in South America can be gathered by a comparison with United States statistics. In South America there is in round numbers one machine shop for every 100,000 persons. In the United States there is one shop for every 5,000 persons. The ratio is 20:1. Hundreds of shops will be built and equipped as the great southern continent follows the path of development that this country has traversed during the last 75 years. What a tremendous prospect!

Protest Against Committing U. S. to Metric System

The leading editorial on page 563 in the issue of two weeks ago pointed out an attempt to commit the United States to the metric system in the conference for uniform laws recently held at Buenos Aires, Argentina. On page 609 of last week's issue a copy of the cablegram of protest sent by the National Association of Manufacturers was printed. Other protests were sent, and the *American Machinist* can now state definitely that at least eight such cablegrams were forwarded to Secretary of the Treasury McAdoo prior to the opening of the sessions of the conference in South America.

At this writing we do not know what action, if any, was taken. It is inconceivable, however, that anything detrimental to the great manufacturing and commercial interests of the United States could have been done in view of the standing and importance of the associations and firms that registered their protests.

Manufacture of Munitions in Navy Yards

The impression one receives in going through a United States navy yard is that it is greatly overequipped. The appearance of some of the yards is worse than others in this respect, but they all look lonesome in spots. The reasons for this condition are many and involved; but whatever the reasons, there is this justification—in wartime there would be work for every machine and every square foot of space.

The new idea in cost keeping—that the cost of work should not be assessed for idle equipment—has led those who have thoroughly apprehended it to make changes in their business and manufacturing policies so as to take on work that can be handled in connection with their regular work and that will employ equipment which would otherwise be idle. This policy tends to stabilize the working force and permit general economies of practice, as well as to increase revenue.

Applying this reasoning to the navy yards, it would appear to be profitable for the yards to take up manufacturing work to keep busy this idle equipment, and what more appropriate side line is there than munitions? Why, for example, would it not be well for a forging press to be busy making shells when it is not occupied by its regular jobbing employment? Moreover, the introduction of work of this kind generally in the yards

would go a long way toward solving the problem that has for years been before the Navy Department—of developing a sort of "coal and ice business." The yards are always very short of work when the fleet is in southern waters, and the workmen and general organizations suffer thereby.

There is another and more important factor to be considered in this connection. Manufacturers who went in for war orders are pretty generally agreed that their great difficulty in getting started lay in finding men who knew how to make munitions. Optimistic persons took contracts and then looked to see how to make the goods. Not but what we had plenty of men who could find out how. When an emergency turns up, we want plenty of men who know what to do. Also, we want to know just what equipment is needed for each line of goods—machines, jigs and fixtures, gages, etc.

Through the engineers of the country the Government is seeking to make preparations for the prompt mobilization of industry, in case of war, for the production of war material in immense quantities. Let the Government start now to manufacture men, in the navy yards and arsenals, who will know how to make this material, with the view of distributing them among the producing units of mobilized industry when the occasion arrives. They should take with them detailed plans and specifications for the material necessary to the production of munitions and for the details of the manufacturing processes and of inspection. These men should be of the kind that can explain matters clearly and show other men how to do things; they should be high-grade, intelligent machinists, of the sort that makes good inspectors.

The navy yards would then stop munition manufacture and turn to the work for which they are intended, tackling it with large, well-trained forces, excellent equipment in working order and complete, well-oiled organizations.

This proposition is sensible and practicable. It will cost nothing, it will undoubtedly lead to substantial economies, and the Navy Department has the power to adopt it, right now.

The Broad View in Adjusting Complaints

A proper sense of proportion is essential to success in any field of endeavor. Lengthy correspondence resulting from deficiency in this faculty is one of the most prolific wastes of energy in the industrial establishment, particularly as it takes up the time of the better-paid members of the organization. Not that the written word can be dispensed with—it is the very life of modern business—but it should be confined to essentials. Too frequently correspondence concerns itself with the elaboration of the obvious, on the one hand, or the discussion of that which is relatively of no importance, on the other hand.

Wastes of time and energy in the latter direction are especially prolific in connection with adjusting complaints made by customers concerning their purchases. An example came to our attention recently, which is typical of this failing. A purchaser found a fitting misplaced on a new lathe and made a claim on the manufacturer for the cost of shifting it, as the machine could not be operated satisfactorily otherwise. The manufacturer replied at considerable length, to the effect that such a mistake could not have been made at his factory; it must have been the result of faulty assembling. The customer pointed out that the fitting was secured by dowels and was found in place when the machine arrived. This ruled out the possibility of error in erecting. The manufacturer in reply questioned the extent of the misplacement. The customer, to satisfy the manufacturer, submitted further proof of his contention. After several more letters the manufacturer grudgingly gave his consent to a deduction of $5 from the bill, to correct the error.

The correspondence probably cost the purchaser more than $5 in loss of time and temper. However, as he felt that he was in the right, he naturally would not drop the matter until he had obtained satisfaction from the manufacturer. To be sure, he had nothing much to gain by making his point, but that purchaser can never be expected to accept an unsatisfactory delivery without a protest.

The case of the manufacturer was quite different and showed considerably greater lack of vision in extending the controversy. No matter what the merits of the purchaser's complaint may have been, the manufacturer had nothing to gain by carrying on a lengthy argument with his customer. His sense of proportion was deficient. When a customer reports in a $1,000 machine a defect that can be corrected for $5, it is, in the first place, a certainty that the customer is honest in his complaint, even if he is mistaken. This consideration alone should lead the manufacturer to accede to requests for minor adjustments. The manufacturer who does not quibble over complaints at once acquires merit in the eyes of his customer. But even when the manufacturer feels that a complaint is unwarranted as to fact and questionable as to intention his sense of proportion should still show him that the expense of lengthy correspondence will be more than the cost of a trivial correction.

Wanted--A Lighting Gage

When we begin to have state laws or commission rules in regard to the lighting of factories, there will be specifications for the minimum amount of both day lighting and artificial lighting that must be provided. How is the foreman in charge of a room or a department to know when the daylight is insufficient and it is time to snap the switch and put on the artificial light? It is evident that some sort of lighting gage must be provided.

This matter has already been made a subject of discussion among illuminating engineers, with the suggestion that there must be developed either a simple, portable and inexpensive stationary lighting gage or, as they call it, a photometer. It should be so arranged that a glance at a dial or some other part would indicate to the foreman whether or not the intensity of illumination is equal to the minimum requirement. The use of such an instrument would put the matter of illumination on the basis of knowledge and not in the swamp of guesswork.

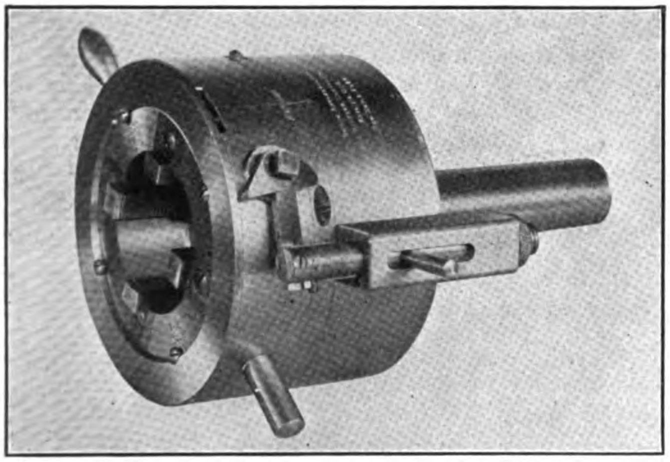
Here is possibly a fruitful field for the use of some mechanical ingenuity in developing a successful, inexpensive photometer. If it can be made cheaply enough, one should be provided for every department of every shop.

Shop Equipment News

Self-Opening Die Head with Floating Die

In the design of the die head shown, known as the Boehm automatic die, the Rickert-Shafer Co., Erie, Penn., has aimed to provide a die head that will cut a truly parallel thread and that will possess a positive opening mechanism.

The chasers have a radial movement and are directly backed up by the cam ring throughout their entire length and width. They slide between hardened and ground chaser guides and are carried by hardened and ground carriers. The chaser carriers have a groove milled in the outer end to take the positive-opening cam, which is a face cam milled on the under side of the cam ring. The cam ring is locked in the closed position by two hardened locking pins, which slide in hardened bushings and lock against hardened plugs. These locking pins are



SELF-OPENING DIE HEAD
Made in eight sizes ranging from $\frac{3}{8}$-in. to $2\frac{1}{2}$-in. capacity, either with or without float

entirely independent in action from the rest of the die, thus allowing the die head to come to the back position before closing. The die head is driven by three hardened rollers, which are located at the extreme outside of the shank head, in order to eliminate as much torsional strain as possible.

The floating die has a lateral float of from $\frac{1}{8}$ to $\frac{1}{4}$ in., according to the size of the die, and is provided with an adjusting ring by means of which all the float may be taken up and the die made to cut the threads as short as $\frac{3}{32}$ in. By means of this float any error in the camming of automatic or screw automatic machines is taken up by the die head. When it is used in hand machines, the operator by watching the float can tell whether he is forcing the die or letting it drag. This will prevent his spoiling work and also opening the die before the proper length of thread is cut.

The taper attachment is adjustable, so that one set of cams is able to handle all practical tapers. The swivel cam is graduated for tapers from $\frac{1}{4}$ to $1\frac{1}{2}$ in.

Oxyacetylene Welding and Cutting Torches

The Oxyacetylene Torch Co., Greenfield, Mass., has recently placed on the market a line of welding and cutting torches, two views of which are shown in Fig. 1. The upper torch is of the plain type, and the lower illustration a roller attachment. This device is useful to guide the torch over metal in performing cutting operations, so as to retain the correct distance of the torch from the plate. The lower design also shows a loop connection by which the operation may be performed with only a single tank of oxygen.

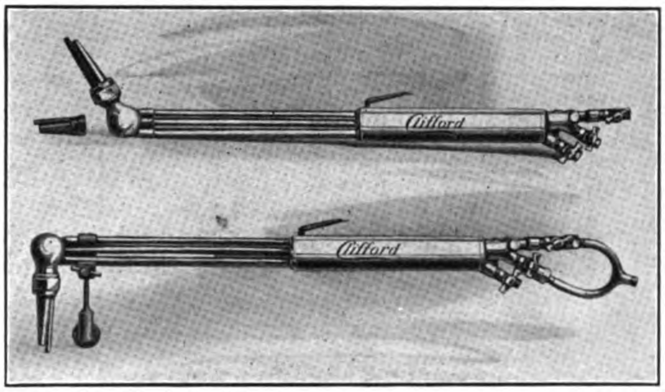


FIG. 1. TWO TYPES OF CUTTING TORCH

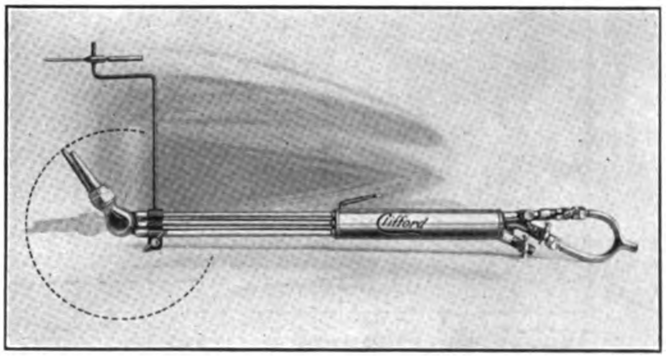

FIG. 2. CUTTING TORCH EQUIPPED WITH RADIUS ATTACHMENT

Another view of the cutting torch is given in Fig. 2. This illustration shows a radius attachment for use in cutting circles of various diameters.

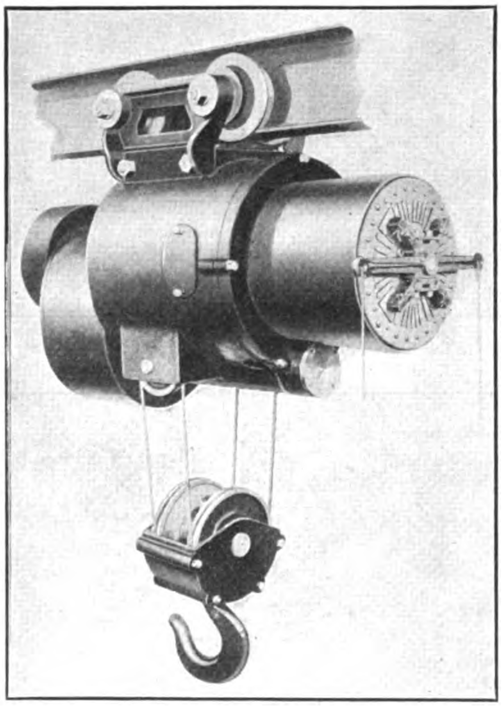
The novel and interesting feature of the welding and cutting torches here described is the universal head, by which the head and thus the flame may be swung on an arc up to 270 deg. while the flame is burning. The advantage of this feature is apparent, as it allows the welder to swing around the flame to suit various positions as desired, such as up, down, straight or round a corner. In this way difficult welding operations are made simple. The various welding tips have self-contained mixing chambers, thus enabling the proper gas mixture to be obtained for each size.

Electric Shop Hoist

The frame of the electric hoist shown is made of cast iron, cylindrical in form and so constructed as entirely to inclose the operating units. Easy access for inspection is provided through a number of openings with easily removable covers.

The portion of the frame containing the gearing and mechanical brake is operated from the drum and motor by a cast partition and is packed with transmission grease. The drum is provided with suspension lugs for attaching to a trolley or other type of mounting.

The hoist is equipped with roller bearings, and owing to the comparatively slow movement, the drum bearings are bronze bushed. Cut spur gearing is used throughout. The drum is of cast iron, grooved to receive the full amount of rope for the given lift without overlapping. The drum gear is fastened to the end of the drum and not to its shaft. The drum replaces the motor frame and revolves around the motor armature, by which construction a more compact hoist is secured and a higher lift made possible. In replacing the motor frame, the drum is of unusually large diameter, being 40 to 45 times the diameter of the hoisting rope used.



ELECTRIC SHOP HOIST

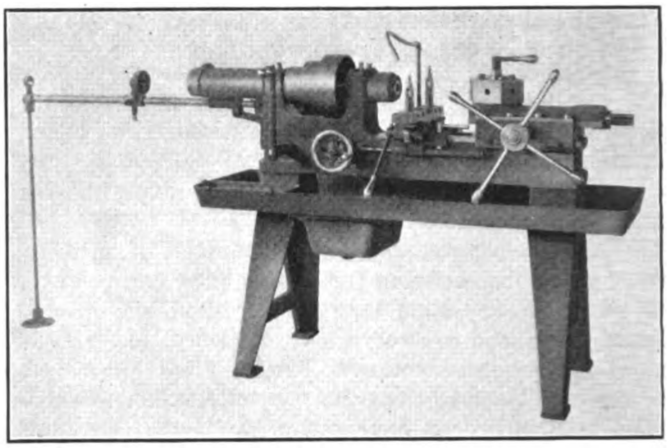
The hoist is equipped with a mechanical-load brake, which automatically stops and holds the load when the motor is stopped and is released only by revolving the motor in the lowering direction. It is of the friction disk type and is contained in the same inclosure as the gearing. A solenoid-operated brake capable of holding the full load attached to the hoist armature shaft is provided. It will instantly stop the motor when the current is cut off. The hoist can be equipped with standard series wound motor for direct current and standard motor for alternating current. Either rheostatic or single-speed control can be furnished.

This type of hoist is a recent product of the Economy Engineeri[illegible] Co., Willoughby, Ohio, and is made in capaci[illegible] from 1,000 to 10,000 lb.

Hand Screw Machine

The illustration shows a plain-head hand screw machine recently developed by the Charles Stecher Co., Chicago, Ill.

The machine is similar to that shown on page 700, Vol. 43, with the addition of power feed to the turret.



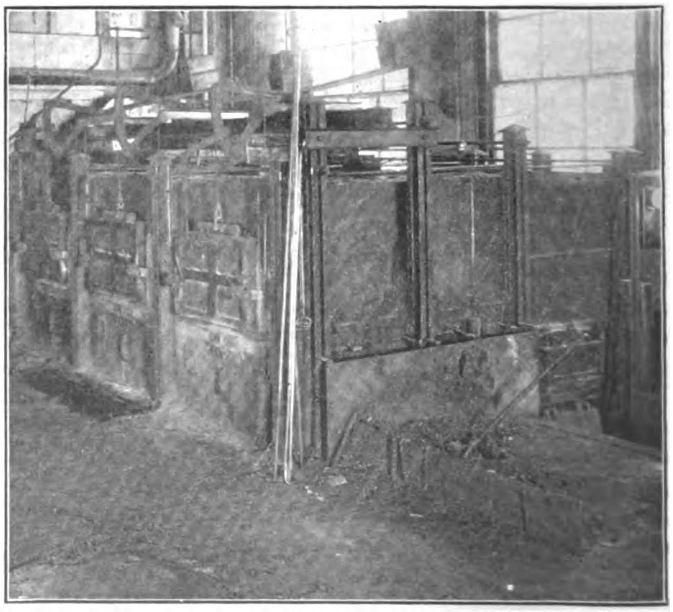
PLAIN-HEAD HAND SCREW MACHINE

Wire-feed capacity, $1\frac{5}{16}$-in. round, $\frac{15}{16}$-in. square and $1\frac{1}{8}$-in. hexagon bars; hole in spindle, $1\frac{5}{8}$ in.; swing over bed, 14 in.; diameter of holes in turret, $1\frac{1}{4}$ in.; length that can be turned, 7 in.; greatest distance from end of spindle to turret, 17 in.; width of belt, 3 in.

The arrangement of the power feed is such that the tools are fed positively the same distance each time. This is accomplished by an arrangement of the friction in the power-feed rod. The friction permits the rod to slip when the tools have reached the positive stop and can be easily seen by the operator, who trips the feed. The gears are entirely inclosed and run in oil.

Combined Three-Oven Furnace

The design of the heat-treating furnace shown is based on the research work of Alfred Smallwood, Birmingham, England. The American rights for the manufacture of this furnace have been secured by the American Incandescent Heat Co., Delta Building, Boston, Mass.



COMBINED THREE-OVEN FURNACE

In the design and construction of this type of furnace it is claimed radical departures have been introduced to take care of the often neglected factors of the purity of the gases generated by the burning material and the action of these gases on the metal.

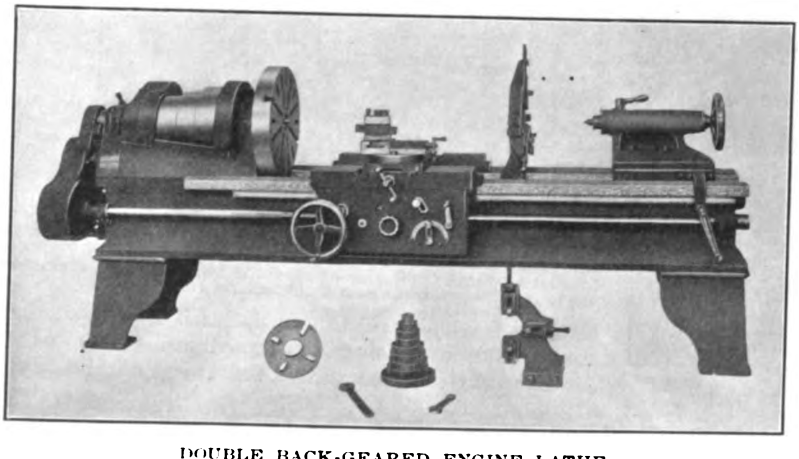
The furnace is planned for the scientific heat-treatment of steel, copper and alloys. It is made to use coal, oil or gas as fuel, ordinary bituminous coal, either hand fired or fired by mechanical stokers, with natural draft, commanding the maker's preference. A system of controlling dampers is said to provide a high degree of uniformity of temperature in the heating chambers, and in addition an extended secondary combustion is maintained to a length considered sufficient to insure a pure reducing flame at the point at which the gas enters the heating chamber.

With the construction employed it is possible to operate from one to five independent heating chambers on one firebox, with a different temperature in each chamber, if desired. The claim for low maintenance cost is based on the existence of low gas temperatures in this type of furnace, the use of standard-size brick, and large heat-storage area. The heating chamber is completely surrounded by canals through which the gas passes before leaving the furnace, providing a rapid and even heat absorption.

Heavy-Duty Engine Lathe

The dominant aim in the design of the lathe shown was a sufficiently heavy proportioning of parts to enable the rapid removal of stock.

The machine is double back geared and is built along conventional lines. To maintain alignment of the lead screw, the pads of the lead-screw bearings have grooves, into which the bearings fit. The lead screw is $3/4$ in. in diameter, Acme thread, four threads per inch, splined to provide for driving the feed mechanism. The threads of the lead screw are engaged only when cutting threads. The tailstock is of the cutaway type and can be set over $1\frac{1}{4}$ in. for taper turning.



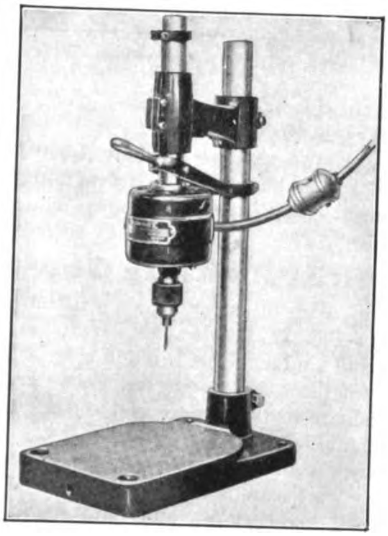
DOUBLE BACK-GEARED ENGINE LATHE

Swing over bed, $22\frac{1}{4}$ in.; swing overcarriage, $14\frac{3}{4}$ in.; hole in spindle, $1\frac{3}{8}$ in.; diameters of driving cones, 14, 12 and 10 in.; width of belt, 4 in.; distance between centers, 8 ft.; bed, 36 in.

The machine is made in a variety of bed sizes, ranging from 8 to 14 ft., by the Davenport Locomotive Works, Davenport, Iowa.

High-Speed Electric Sensitive Drilling Machine

The motor-driven sensitive drilling machine shown is equipped with ball bearings and is rendered sensitive by the use of a special coil-spring mechanism located in the column. The simple construction is apparent.



MOTOR-DRIVEN SENSITIVE DRILLING MACHINE

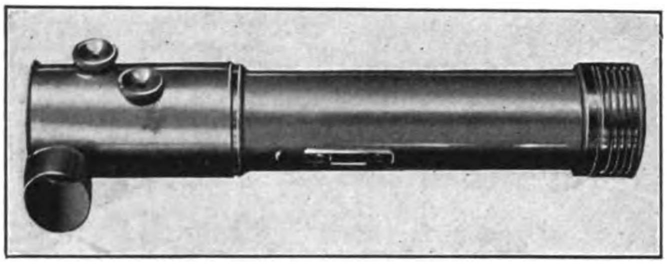
Capacity in steel, 0 to $\frac{3}{32}$ in.; in brass, aluminum and wood 0 to $13/64$ in.; vertical adjustment of spindle, 2 in.; height over all, 18 in.

The motor and bracket can be readily raised or lowered on the main column. The motor overhangs sufficiently to permit drilling in the center of a 6-in. circle. This machine is a recent product of the Wisconsin Electric Co., Racine, Wis.

Eye Color-Pyrometer

The instrument shown is designed to measure directly the temperature of a piece under heat-treatment. With this instrument the color of the heated body is exactly duplicated, and at the same time the temperature is indicated on an accurately calibrated scale. The operation of the instrument is extremely simple. It is focused on the piece in the furnace and is then adjusted until the color of the work is duplicated in the instrument, when the temperature can be read on the calibrated scale. It is claimed that the temperature readings with this instrument are within 1 to 2 per cent., regardless of the furnace temperature, and that an operator who is color blind can utilize it; for although he cannot distinguish color as red, orange, blue, etc., he can still duplicate the intensity, on which principle the instrument operates.

While this form of pyrometer was designed for the more precise temperature measurement of high-grade steels under treatment, it can also be used for taking the temperatures of heated bodies either within or without a furnace, so that it is adapted to measuring the



EYE COLOR-PYROMETER

temperatures of ingots, billets, rails, plate, structural shapes, forgings, castings, etc.

It is made in two ranges—1,000 to 1,800 and 1,800 to 2,300 deg. F.—and represents a recent product of the Gibb Instrument Co., Pittsburgh, Penn.

Mechanical Pickling Conveyors

The accompanying illustrations show a conveyor made by the Chain Belt Co., Milwaukee, Wis., carrying cartridge cases and similar goods through a series of rinsing and pickling baths for removing all grease and oily deposits that adhere to the surface of the work during the process of manufacture.

The conveyor consists of two strands of roller chain belt, between which are attached steel bars whose ends are bent up at right angles and have semicircular recesses punched in them to suit the diameter of the work to be handled. The recesses in the bars are so disposed that the tubes lie slightly on an incline and automatically drain off the water or pickling fluid as the work leaves the bath and thereby saves time in draining off.

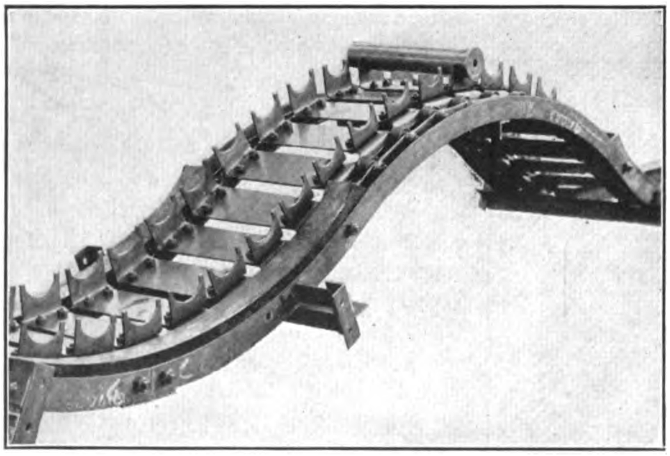


FIG. 1. CONVEYOR REMOVED FROM TANKS

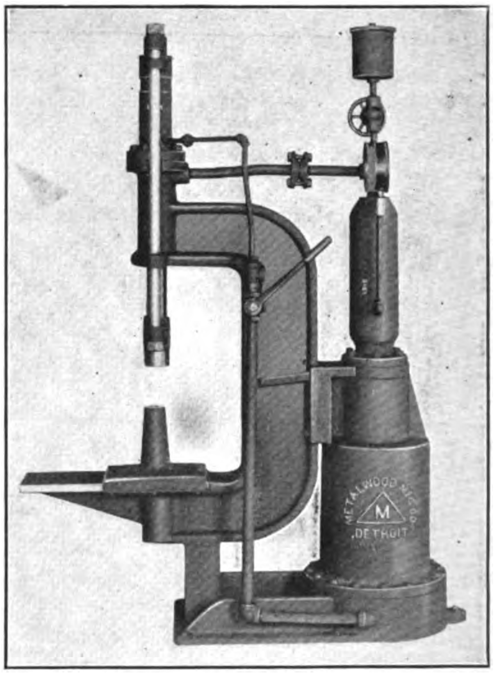
The upper trackage consists of steel angle irons bent into a series of curves to suit the length and depth of the tank and the time which it may be desired to hold the work in the various baths. Hold-down guides are provided at the curves. The trackage is entirely a self-contained unit and is constructed so that it can be removed, as in Fig. 1, or placed without disturbing the tanks or their fittings. The return run of the conveyor is carried on straight angle-iron tracks below the tanks.

The conveyor, shown in Fig. 2, is 34 ft. from center of head shaft to center of take-up shaft and is motor driven by spur gearing connected to the head shaft. The apparatus was designed to receive the work at one end and automatically discharge it at the delivery end after passing through the baths at the rate of 1,200 cases per hour when traveling at a speed of 10 ft. per minute.

Quick-Acting Press

The special feature of the hydro-pneumatic press shown is its quick action, 10 full strokes per minute being possi-



QUICK-ACTING HYDRO-PNEUMATIC PRESS
Capacity, 10 tons; diameter of ram, 3 in.; stroke, 6 in.; distance from ram to platen, 20 in.

ble while developing the full rated capacity. With shorter strokes and less tonnage the speed can of course be correspondingly increased to take advantage of conditions.

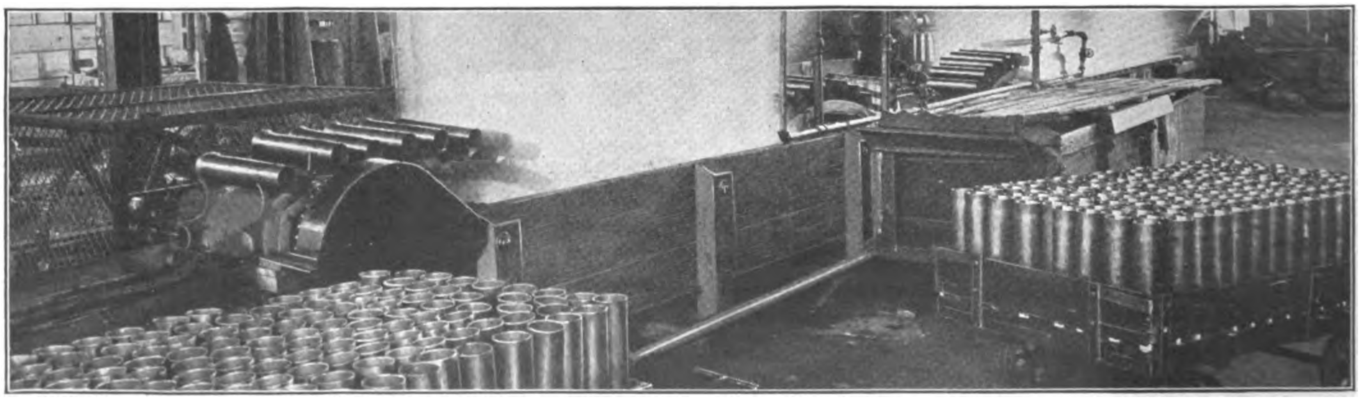


FIG. 2. CONVEYOR IN OPERATION IN SHELL PICKLING BATH

While intended primarily for flanging or upsetting in the assembly of parts, modifications in the design of the sliding fixture or the interchange of several fixtures makes it adapted for a wide variety of operations.

This press is a recent addition to the line made by the Metalwood Manufacturing Co., Detroit, Mich.

PERSONALS

Thomas K. Egan, for several years superintendent of manufacturing of the Dexter Folder Co., Pearl River, N. Y., has accepted the position of plant superintendent of the Brown Cotton Gin Co., New London, Conn.

J. C. Drumm, for a number of years associated with the Carnegie Steel Co. in engineering work, has joined the Scientific Materials Co., Pittsburgh, Penn., where he will be in charge of the efficiency-instrument department.

Wilmot Fleming, of the Fleming Engineering Co., Philadelphia, Penn., has been retained as the superintendent of the machine shop of the Pennsylvania Forge Co. which recently took over the equipment and business of the Fleming company.

J. B. Doan, for many years vice-president and general manager of the American Tool Works Co., Cincinnati, Ohio, has been elected president to fill the vacancy caused by the death of Franklin Alter. Robert S. Alter has become vice-president and foreign manager and Henry Luers, treasurer.

BUSINESS ITEMS

The offices of J. J. McCabe will be moved on Apr. 16 from 30 Church St. to the 18th floor Singer Bldg., 149 Broadway, N. Y. City. The warehouses remain in the same location, 10th and Brunswick Sts., Jersey City, N. J.

The Steel Products Engineering Co., Springfield, Ohio, has taken over the business of the Springfield branch of the Gem City Machine Co., and in addition to doubling the toolroom equipment has added a department for manufacturing.

Owing to rapid expansion in its special and contract machine business the C. H. Cowdrey Machine Works, Fitchburg, Mass., have completed a new addition three stories high and 235 ft. long by 85 ft. wide. The building is of the latest approved mill construction and with the additional equipment now in the course of installation greatly increased facilities will be available.

INQUIRY FOR MUNITION MACHINERY

A communication received from F. R. Ratcliffe, acting manager, Small Arms Factory, Department of Defense, Lithgow, Australia, indicates that the Australian military authorities will soon be in the market for additional machines and special equipment for small-arms and other munition factories.

FORTHCOMING MEETINGS

American Society of Mechanical Engineers. Spring meeting, April 11-14, New Orleans, La., Calvin W. Rice, secretary, 29 West 39th St., New York, N. Y.

National Metal Trades Association. Annual meeting, Apr. 27-28, New York, N. Y., Hotel Astor. H. D. Sayre, secretary, Peoples Gas Building, Chicago, Ill.

American Society for Testing Materials. Annual meeting June 27 to July 1, 1916, Hotel Traymore, Atlantic City, N. J. Edgar Warburg, secretary, University of Pennsylvania, Philadelphia, Penn.

American Society of Mechanical Engineers. Monthly meeting first Tuesday. Calvin W. Rice, secretary, 29 West Thirty-ninth St., New York City.

Boston Branch National Metal Trades Association. Monthly meeting on first Wednesday of each month, Young's Hotel. W. W. Poole, secretary, 40 Central St., Boston, Mass.

Providence Association of Mechanical Engineers. Monthly meeting fourth Wednesday each month. J. A. Brooks, secretary, Brown University, Providence, R. I.

New England Foundrymen's Association. Regular meeting second Wednesday of each month. Exchange Club, Boston, Mass. Fred F. Stockwell, 205 Broadway, Cambridgeport, Mass.

Engineers' Society of Western Pennsylvania. Monthly meeting third Tuesday; section meeting, first Tuesday. Elmer K. Hiles, secretary, Oliver Building, Pittsburgh, Penn.

Rochester Society of Technical Draftsmen. Monthly meeting, last Thursday. O. L. Angevine, Jr., secretary, 857 Genesee St., Rochester, N. Y.

Superintendents' and Foremen's Club of Cleveland. Monthly meeting third Saturday. Philip Frankel, secretary, 310 New England Building, Cleveland, Ohio.

Western Society of Engineers, Chicago, Ill. Regular meeting first Wednesday evening of each month, excepting July and August. J. H. Warder, secretary, 1735 Monadnock Block, Chicago, Ill.

Philadelphia Foundrymen's Association. Meetings first Wednesday of each month. Manufacturers' Club, Philadelphia, Penn. Howard Evans, secretary, Pier 45 North, Philadelphia, Penn.

Technical League of America. Regular meeting second Friday of each month. Oscar S. Teale, secretary, 35 Broadway, New York, N. Y.

STATEMENT OF THE OWNERSHIP, MANAGEMENT, ETC., REQUIRED BY THE ACT OF CONGRESS OF AUGUST 24, 1912,

of American Machinist, published weekly at New York, N. Y., for April 1, 1916.

State of New York } ss.
County of New York }

Before me, a Notary Public in and for the State and County aforesaid, personally appeared Chester W. Dibble, who, having been duly sworn according to law, deposes and says that he is the Vice-President of Hill Publishing Co., publisher of American Machinist, and that the following is, to the best of his knowledge and belief, a true statement of the ownership, management, etc., of the aforesaid publication for the date shown in the above caption, required by the Act of August 24, 1912, embodied in section 443, Postal Laws and Regulations, printed on the reverse of this form, to wit:

1. That the names and addresses of the publisher, editor, managing editor, and business manager are:

Publisher, Hill Publishing Company, 10th Ave. at 36th St., New York, N. Y.
Editor, Leon P. Alford, 10th Ave. at 36th St., New York, N. Y.
Managing Editor, Fred H. Colvin, 10th Ave. at 36th St., New York, N. Y.
Business Manager, Mason Britton, 10th Ave. at 36th St., New York, N. Y.

2. That the owners are:

Hill Publishing Company, 10th Ave. at 36th St., New York, N. Y.
Owners of 1% or more of Stock Issued.
Estate of John A. Hill, 10th Ave. at 36th St., New York.
Arthur J. Baldwin, 10th Ave. at 36th St., New York.
Fred R. Low, 10th Ave. at 36th St., New York, N. Y.
John McGhie, 10th Ave. at 36th St., New York, N. Y.
Fred S. Weatherby, 1600 Beacon St., Brookline, Mass.
Frederick A. Halsey, 356 W. 120th St., New York, N. Y.
G. Eugene Sly, 50 Union Sq., New York, N. Y.
Frederick W. Gross, 215 E. 11th St., Erie, Pa.
Alfred E. Kornfeld, 10th Ave. at 36th St., New York, N. Y.
Emma B. Hill, 80 Munn Ave., East Orange, N. J.

The balance of the stock issued (less than 1% each) is owned by 68 employees, 3 ex-employees, and 13 others who are wives, daughters or relatives of employees.

3. That the known bondholders, mortgagees and other security holders owning or holding 1 per cent. or more of total amount of bonds, mortgages or other securities are: Mortgage on building, Dime Savings Bank, Brooklyn, N. Y.

4. That the two paragraphs next above, giving the names of the owners, stockholders and security holders contain not only the list of stockholders and security holders as they appear upon the books of the company, but also, in cases where the stockholder or security holder appears upon the books of the company as trustee or in any other fiduciary relation, the name of the person or corporation for whom such trustee is acting, is given; also that the said two paragraphs contain statements embracing affiant's full knowledge and belief as to the circumstances and conditions under which stockholders and security holders who do not appear upon the books of the company as trustees, hold stock and securities in a capacity other than that of a bona fide owner; and this affiant has no reason to believe that any other person, association or corporation has any interest direct or indirect in the said stock, bonds or other securities than as so stated by him.

CHESTER W. DIBBLE,
Vice-President Hill Publishing Co.

Sworn to and subscribed before me this 31st day of March, 1916.

[Seal.] RICHARD L. MURPHY.
(My commission expires March 30, 1917.)

Prices--Materials and Supplies

IRON AND STEEL

Pig Iron—Quotations were current as follows at the points indicated:

	Apr. 7, 1916	One Month Ago	One Year Ago
No. 2 Southern Foundry, Birmingham	$15.00	$15.00	$9.00
No. 2 X Northern foundry, New York	20.50	19.75	14.25
No. 2 Northern foundry, Chicago	19.00	18.50	13.00
Bessemer, Pittsburgh	21.95	21.45	14.55
Basic, Pittsburgh	19.20	19.20	13.45
No. 2 X, Philadelphia	20.50	20.00	14.25
No. 2, Valley	18.50	18.50	12.75
No. 2, Southern Cincinnati	17.90	17.90	12.15
Basic, Eastern Penn	21.00	19.50	13.50
Gray forge, Pittsburgh	18.70	18.45	13.45

Steel Shapes—The following base prices in cents per pound are for angles 3 in. by ¼ in. and larger and tees 3 in. and larger from jobbers' warehouse at the places named:

	New York				
	Apr. 7, 1916	One Month Ago	One Year Ago	Cleveland	Chicago
Steel angles, base	3.10	2.95	1.85	3.25	3.10
Steel T's, base	3.15	2.95	1.90	3.25	3.10
Machinery steel (bessemer)	3.10	2.95	1.80	3.25	3.10

Steel Sheets—The following are the prices in cents per pound from jobbers' warehouse at the places named:

	New York				
	Apr. 7, 1916	One Month Ago	One Year Ago	Cleveland	Chicago
No. 28 black	3.50	3.50	2.60	2.95	3.20
No. 26 black	3.40	3.40	2.50	2.85	3.10
Nos. 22 and 24 black	3.35	3.35	2.45	2.80	3.05
Nos. 18 and 20 black	3.30	3.30	2.40	2.75	3.00
No. 16 blue annealed	4.30	3.75	2.35	3.00	3.45
No. 14 blue annealed	4.20	3.70	2.25	3.60	3.35
No. 12 blue annealed	4.15	3.65	2.20	3.55	3.30
No. 28 galvanized	5.65	5.65	4.00	5.50	5.50
No. 26 galvanized	5.35	5.35	3.75	5.20	5.20
No. 24 galvanized	5.20	5.20	3.55	5.05	5.05

Standard Pipe—The following table shows the comparison in discounts, together with the net prices in cents per foot:

	Black		Galvanized	
	Apr. 7, 1916	One Yr. Ago	Apr. 7, 1916	One Yr. Ago
¾ to 2 in. steel butt welded	72%	80%	53½%	69½%
2½ to 6 in. steel lap welded	71%	79%	52½%	68½%
Diameter, In.				
¾	3.12	2.30	5.35	3.51
1	3.91	3.40	7.91	5.19
1¼	6.44	4.60	10.70	7.02
1½	7.70	5.50	12.79	8.39
2	10.36	7.40	17.21	11.29
2½	16.97	12.29	27.79	18.43
3	22.19	16.07	36.34	24.10
4	31.61	22.89	51.78	34.34
5	43.12	31.08	68.30	46.62
6	55.68	40.32	91.20	60.48

Bar Iron—Prices are as follows in cents per pound at the places named:

	Apr. 7, 1916	One Month Ago
Pittsburgh, mill	2.45	2.40
New York	2.70	2.60
Warehouse, New York	3.10	2.90
Warehouse, Cleveland	3.25	2.25@2.50
Warehouse, Chicago	3.10	2.90

Cold Drawn Steel Shafting—From warehouse to consumers requiring fair-size lots, the following quotations hold:

New York	15% above list price
Cleveland	20% above list price
Chicago	List price

Boiler Tubes—From Pittsburgh, the following are the less-carload basing discounts for lap-welded boiler tubes:

1¾ and 2 in.	51%	3½ to 4½ in.	60%
2¼ in.	48%	5 and 6 in.	53%
2½ and 2¾	54%	7 to 13 in.	50%
3 and 3¼	59%		

These discounts apply to standard gages and to even gages not more than 4 gages heavier than standard. For long tubes charge 10% net extra as follows: 1¾ in. size over 18 ft. and not exceeding 22 ft.; 2 to 3 in. sizes over 22 ft. and not exceeding 24 ft.; 3¼ to 13 in. sizes over 22 ft. and not exceeding 25 ft.

High Speed Tool Steel containing from 10 to 18% tungsten sells as follows per pound in New York:

Billets .... $2.35 Bars $3.00

Swedish (Norway) Iron—This material per 100 lb. sells as follows f.o.b. places named:

New York			
Today	One Year Ago	Cleveland	Chicago
$4.75	$3.25	$5.05	$4.10

In coils an advance of 50c. is usually charged.

METALS

Miscellaneous Metals—The present quotations in cents per pound, with a comparison of practically a month and year ago, are as follows:

	New York		
	Apr. 7, 1916	One Month Ago	One Year Ago
Copper, electrolytic (carload lots)	27.50	27.25	16.50
Tin	53.00	55.00	53.00
Lead	8.50	6.75	4.25
Spelter	18.50	19.50	11.00
ST. LOUIS			
Lead	8.50	6.75	....
Spelter	18.50	18.00	....

At the places named, the following prices in cents per pound prevail:

	New York				
	Apr. 7, 1916	One Month Ago	One Year Ago	Cleveland	Chicago
Copper sheets, base	35.50	35.00	21.00	34.50	34.50
Copper wire (carload lots)	35.50	35.00	16.60	34.50	37.00
Brass rods, base	41.50	37.00	16.35	36.00	37.00
Brass pipe, base	44.50	41.00	19.10	43.00	45.00
Brass sheets	40.50	37.00	16.25	36.00	37.00
Solder ½ and ½ (case lots)	32.25	31.00	33.50	35.50	31.25

Old Metals—The following are the dealers' purchasing prices in cents per pound:

	New York		
	Apr. 7, 1916	One Year Ago	Cleveland
Copper, heavy and crucible	23.00	23.00	22.00
Copper, heavy and wire	22.00	22.00	21.00
Copper, light and bottoms	19.00	19.00	18.00
Lead, heavy	6.50	5.25	6.50
Lead, tea	6.00	4.75	5.50
Brass, heavy	14.00	14.00	18.00
Brass, light	12.00	12.00	12.00
No. 1 yellow rod brass turnings	15.00	14.00	16.25
Zinc	13.00	14.00	14.50

Monel Metal—The following are the prices in cents per pound for mill lengths 8 ft. and over:

WEST OF THE MISSISSIPPI

Press reports state that H. W. Graham and associates, Chillicothe, Mo., plan to equip a plant for the manufacture of tractors. Estimated cost, $100,000.

Press reports state that a garage and machine shop will be established at Kansas City, Mo., by L. L. Brown. About $4,000 worth of machinery will be required.

Plans are being prepared by J. C. Braecklein, Arch., Massachusetts Bldg., Kansas City, Mo., for a machine shop for Henry Lappe, Corliss, Kan. Estimated cost, $3,000.

The Panama Rubber Co., St. Louis, Mo., will install equipment in its plant for the manufacture of motor accessories.

The Robinson Fire Apparatus Manufacturing Co., St. Louis, Mo., will install equipment in its plant for the manufacture of heavy duty trucks and tractors.

Plans are being prepared for a 1-story boiler factory for the McCayne Investment Co., 15th and Dodge St., Omaha, Neb. Estimated cost, $4,000. R. Everett, 106 North 15th St., Arch.

Press reports state that the Studebaker Corporation New York, N. Y., plans to install about $50,000 worth of machinery in its proposed assembling plant at Dallas, Tex. Noted Feb. 10 and Mar. 2.

The Phoenix Iron and Steel Co., Galveston, Tex., recently incorporated, plans to construct a plant.

Ford & Roberts, Ada, Okla., will construct a machine shop.

WESTERN STATES

Charles Snyder and I. C. Thompson plans to construct a garage and machine shop at Buhl, Idaho.

The Beaver State Motor Co. is constructing the second unit to its plant at Gresham, Ore. Noted Jan. 6.

The S. Lowengart Estate has been granted a permit for the construction of a 2-story garage at Park and Couch St., Portland, Ore. Estimated cost, $28,000.

The contract has been awarded for an addition to the plant of the Globe Iron Works, Tacoma, Wash., which will be occupied by Pacific Boiler Co., Seattle.

Bausch & Founch plans to construct a 75x180-ft. garage and machine shop on E St., San Bernardino, Calif. Estimated cost, $20,000.

The Ford Motor Co. has awarded the contract for the construction of a 5-story addition to its assembling plant at Treat Ave. and 21st St., San Francisco, Calif. J. B. Lund is Mgr. Noted Dec. 23.

Plans are being prepared for the construction of a 1-story addition to the automobile repair shop of I. C. Noble on Bush St., San Francisco, Calif.

CANADA

Plans are being prepared by W. C. Cowan, 200 Victoria St., Berlin, Ont., for the construction of a factory at Berlin for the Canadian Regal Motor Co., Ltd., 433 King St. Estimated cost, $18,000.

Plans are being prepared for the construction of a garage at Brantford, Ont., for C. J. Mitchell, 55 Darling St., Brantford. Estimated cost, $20,000.

The Steel Co. of Canada, Hamilton, Ont., will construct an addition to its plant at Hamilton. Estimated cost, $24,000. Robert Hobson is Mgr.

Fire recently damaged the munition plant of B. Bell & Son Co., Ltd., at St. George, Ont. Loss, $10,000.

The National Equipment Co., Ltd., manufacturer of gasoline engines, pumps, etc., is constructing a tank shop at Toronto, Ont., and will install new machinery.

The Canadian Brush Machinery Co., Ltd., plans to establish a plant at Walkerville, Ont.

The Ford Motor Co. of Canada will build a 4-story assembling plant at 5th Ave. and Fir St., Vancouver, B. C. W. G. Patrick is Local Mgr.

GENERAL MANUFACTURING

NEW ENGLAND STATES

Bids are being received for the construction of a 3-story woolen mill for the Troy Blanket Co., Troy, N. H.

The United Fruit Co., Board of Trade Bldg., Boston, Mass., plans to construct a sugar refinery at (Charleston), Boston, Mass.

The contract has been awarded for the construction of a 2-story, 45x45-ft. addition to the factory of the Carpenter Manufacturing Co., manufacturer of braided and twisted cords, at Norwich, Conn.

MIDDLE ATLANTIC STATES

The contract has been awarded for the construction of an addition to the plant of the Schoellkopf Aniline and Chemical Works, Inc., Buffalo, N. Y. Estimated cost, $16,000. Noted Mar. 30.

Plans are being prepared for an addition to the plant of the American Sugar Refining Co., South 3rd St., New York, N. Y. (Borough of Brooklyn). Estimated cost, $1,000,000. Noted Mar. 30.

Plans have been prepared for 2 agitator buildings at New York, N. Y. (Borough of Manhattan). Estimated cost, $8,000.

The General Chemical Co., 25 Broad St., New York, N. Y. (Borough of Manhattan), has awarded the contract for the construction of a factory at Laurel Hill (Flushing post office), New York, N Y. (Borough of Queens).

The Isco Chemical Co., Niagara Falls, N. Y., has awarded the contract for a plant at Royal and Union St. Estimated cost, $300,000. Noted Mar. 16 and Apr. 6.

Bids are being received by the Sodus Packing Co., Sodus, N. Y., for a 2-story addition to its plant.

The Figuerao Cut Glass Co., Hammonton, N. J., will construct a 7-story factory at Hammonton.

The American Lead Pencil Co., Hoboken, N. J., has purchased a site at Willow Ave. and 5th St., Hoboken, and will construct a 10-story building.

The Vacuum Oil Co., 61 Broadway, New York, N. Y., is having plans prepared for an oil refinery at Lincoln Park, N. J. Estimated cost, $2,000,000.

Berkowitz, Goldsmith & Spiegel Co., Newark, N. J., will build an addition to its leather factory on Garden St.

The Central Dyestuff and Chemical Co., Newark, N. J., has awarded the contract for the construction of an addition to its plant on Plum Point Lane. Noted Apr. 6.

Fire, Mar. 25 destroyed the plants of the Lister Agricultural Chemical Co., Lister Ave., Newark, N. J. Loss, $100,000. The plant will be rebuilt.

The contract has been awarded for the construction of 2 additions to the plant of the Seton Leather Co., Verona Ave., Newark, N. J. Estimated cost, $25,000. Noted Mar. 30.

The Yatman Rubber Co., Newark, N. J., will improve and enlarge its plant on Mt. Pleasant Ave.

The Cedartown Cotton and Export Co., Cedartown, Penn., will build 3 additions to its plant. Estimated cost, $225,000.

The Lee Tire and Rubber Co., Conshohocken, Penn., has awarded the contract for the construction of a 2-story fireproof mill construction building. Noted Mar. 30.

Plans are being prepared by E. Cornelius, Arch., House Bldg., Pittsburgh, Penn., for a 2-story addition to the plant of the Consolidated Lamp and Glass Co., Coraopolis, Penn. Estimated cost, $15,000. Noted Mar. 23.

We have been informed that the Northampton Silk Co., Easton, Penn., will not construct factory buildings at Ann and St. Joseph St., Easton, as stated in our issue of Mar. 2. H. J. Haytoel is Treas.

The Jenkins Kirby Co., Kingston, Penn., has awarded the contract for the construction of a 1- and 3-story packing plant. Estimated cost, $25,000.

The Benzol Products Co., Marcus Hook, Penn., has awarded the contract for the construction of a 2-story factory. Estimated cost, $55,000.

The Caledonian Dye Works, Philadelphia, Penn., has awarded the contract for the construction of a 2-story factory at Emerald and Westmoreland St., Philadelphia. Estimated cost, $11,000.

The L. H. Gilmer Co., manufacturer of webbing, belting and tape, has awarded the contract for the construction of an addition to its plant at Tacony, Philadelphia, Penn. Estimated cost, $12,000. Noted Feb. 3.

The Hardwick & Magee Co., 7th St. and Lehigh Ave., Philadelphia, Penn., manufacturer of rugs and carpets, plans to build an addition to its plant.

The contract has been awarded for the construction of a rug factory at Philadelphia, Penn., for Archibald Holmes & Sons, Allegheny Ave and A St. Estimated cost, $15,000.

Plans are being prepared by Frank E. Hahn, Arch., 1112 Chestnut St., Philadelphia, Penn., for the construction of 5 factory buildings for the Mifflin Chemical Co., Philadelphia. Noted Mar. 30.

Bids are being received by the Philipsburg Beef Co., Pine St., Philipsburg, Penn., for 2-story packing plant. Estimated cost, $10,000.

The St. Louis Independent Packing Co., 6349 Station St., Pittsburgh, Penn., plans to construct a packing plant. Estimated cost, $55,000.

The Quincy Engine Co., Quincy, Penn., has purchased the plant of the T. B. Woods Sons Co., Chambersburg, Penn., and will equip it for its own use.

Seldon & Leach, Wilkes-Barre, Penn., has awarded the contract for a silk mill at New Grove and Gilligan St., Wilkes-Barre. Andrew K. Leach, Pres. Noted Apr. 6.

The Baltimore Paper Box Co., 1201 South Howard St., Baltimore, Md., plans to enlarge its plant.

The F. X. Ganter Co. will rebuild its showcase manufacturing plant at Baltimore, Md., which was recently destroyed by fire.

William E. Hooper & Sons Co., Baltimore, Md., manufacturer of cotton duck has awarded the contract for the construction of a plant.

Plans are being prepared for an addition to the plant of the International Wood and Paper Products Corporation, 112 North Calverton Rd., Baltimore, Md. Estimated cost, $50,000. Noted Mar. 9.

The Mutual Chemical Co., 1348 Block St., Baltimore, Md., has awarded the contract for a 2-story addition to its plant. Estimated cost, $6,000. Noted Mar. 16.

An addition will be built to the plant of the Lansconing Glass Co., Lansconing, Md. A. Anderson, Mgr.

The Central Market Co., Washington, D. C., has awarded the contract for the construction of an 8-story cold-storage building at 12th and E st. Estimated cost, $70,000.

The Washington Market Co., Washington, D. C., has awarded the contract for an addition to its cold-storage plant. Estimated cost, $75,000.

SOUTHERN STATES

The United States Leather Co. plans to build a plant at Narrows, Va. Estimated cost, $250,000.

Swift & Co., Chicago, Ill., has awarded the contract for the construction of a plant at St. Paul, Va., for the manufacture of wood extracts. Estimated cost, $40,000. Noted Feb. 10.

The Hazel-Atlas Glass Co., Grafton, W. Va., is enlarging its plant.

The Toledo Glass Co., Toledo, Ohio, plans to construct a factory at Kanawha City, W. Va.

The Grasselli Chemical Co., Cleveland, Ohio, contemplates building a plant at Meadow Brook, W. Va.

The Cerro Gordo Warehouse Co., Cerro Gordo, N. C., plans to establish a knitting mill.

The Durham Knitting Mills, Durham, N. C., will build an addition to its factory and install new machinery.

The Durham Hosiery Mills, Goldsboro, N. C., has awarded the contract for the construction of a 3-story factory. Noted Mar. 16.

W. Y. Frazier and D. B. Mull, Connelly Springs, N. C., will build a knitting mill at Icard, N. C.

The Linn Mills Co., Landis, N. C., manufacturer of cotton yarn, has awarded the contract for several additions to its plant. Noted Feb. 3.

The Carolina Hosiery Mills Co., Marion, N. C., plans to build additions to its plant and install new machinery.

The Crescent Hosiery Co., Scotland, N. C., plans to build a 2-story mill to replace present one.

Fire recently destroyed the plant of the Union Compress Co. at Augusta, Ga. Loss, $100,000.

The Penfield Hosiery Mill, Greensboro, Ga., recently destroyed by fire with a loss of $20,000, will be rebuilt.

John Greer, Moultrie, Ga., is interested in the construction of a packing plant at Lake City, Fla. Estimated cost, $150,000.

The Fulton Cotton Mill Co., Athens, Ala., plans to increase the capacity of its plant.

Montgomery Cotton Mills, will build 2 brick buildings at Montgomery, Ala., for the manufacture of cotton goods.

Fire recently destroyed the plant of the Swift Packing Co., Alexandria, La. Loss, $90,000.

The Busch Box Co., New Orleans, La., plans to rebuild its plant recently destroyed by fire with a loss of $30,000.

W. B. Davis & Co., Chattanooga, Tenn., will build a knitting mill at Attalia, Ala.

Fire recently destroyed the plant of the Carcolite Chemical Co. at Copper Hill, Tenn.

The Federal Dyestuff and Chemical Co. plans to build a 1-story, 200x300-ft. addition to its plant at Kingsport, Tenn.

Cock & Howard plans to construct additions to its plant at Cocksville, Ky., and install new machinery.

MIDDLE WEST

Preliminary plans are being prepared for the reconstruction of a 2-story, 75x110-ft. packing plant at Akron, Ohio, for Zimmerly Bros. Estimated cost, $25,000. Jacob Zimmerly, 215 South Main St., Akron, is Pres. Noted Mar. 9.

The contract has been awarded for the construction of the Frederick Silk mill at Canton, Ohio.

Plans have been prepared for the construction of a 4-story, 26x150-ft. factory at Cincinnati, Ohio, for the Starr Piano Co., 139 West 4th St., Cincinnati.

The Aetna Rubber Co., Perkins Ave., Cleveland, Ohio, plans to build a factory on East 79th St., Cleveland.

The Grasselli Chemical Co., The Arcade, Cleveland, Ohio, has purchased a site at Terre Haute, Ind., and plans to construct a plant. Estimated cost, $1,000,000. W. T. Cashman is Asst. Secy.

The contract has been awarded for rebuilding the plant of the Capac Paper Co. at Capac, Mich. Estimated cost, $90,000.

Plans are being prepared for the construction of a factory at Pere Marquette Crossing and Madison Ave., S. E., Grand Rapids, Mich., for the Grand Rapids Leather Novelty Co.

The contract has been awarded for the construction of a plant at Kalamazoo, Mich., for the Riverview Coated Paper Co. Estimated cost, $150,000. Noted Feb. 17.

The Western Knitting Mills is constructing an addition to its factory at Rochester, Mich.

Plans are being prepared for the construction of a 49x155-tannery at Rockford, Mich., for the Hirth-Krause Co.

The Converse Shoe Co., Malden, Mass., plans to construct a factory at 618 West Jackson Blvd., Chicago, Ill. Estimated cost, $110,000.

Plans are being prepared for the construction of a 1- and 2-story factory for the Fulton Saw Works, 52nd Ave. and 22nd St., Chicago, Ill.

The Western Thread Co. has awarded the contract for the construction of an addition to its plant at Elgin, Ill. Estimated cost, $11,000. W. R. Swartwout is Mgr. Noted Mar. 23.

WEST OF THE MISSISSIPPI

The contract will soon be awarded for a 2-story addition to the plant of the Coleman Lamp Co., North St. and Francis Ave., Wichita, Kan. Estimated cost, $20,000. Noted Mar. 2.

A. D. Kennedy and associates, Greenville, Tex., plan to construct a cotton seed oil mill at Dallas, Tex. Estimated cost, $750,000.

R. B. White and associates, Ennis, Tex, plan to construct a cotton mill at Ennis. Estimated cost, $200,000.

WESTERN STATES

Irving Canning Co. plans to rebuild its plant at LaConner, Wash., recently destroyed by fire with a loss of $15,000. G. W. Irving is Pres.

The Inland Empire Paper Co. plans an expenditure of $250,-000 for additions to its plant at Millwood, Wash.

R. S. Clark, Seattle, Wash., plans to construct a fruit canning plant at North Yakima, Wash. Estimated cost, $65,-000.

G. C. Huber, Spokane, Wash., is promoting the construction of a packing plant at Palouse, Wash.

Thomas Carsten and Charles Frye, Seattle, Wash., contemplates constructing a packing plant at Pasco, Wash.

Carl Feller plans to construct a cold-storage plant at Marshfield, Ore.

R. H. Schwartz, E. J. Martin and H. T. Snufler, Bakersfield, Calif., plan to construct a canning plant at Armona, Calif.

A. M. Allen, Point Lobos, Calif., plans to build cannery at Cayucas, Calif.

CANADA

The Belding-Paul-Corticelli, Ltd., manufacturer of sewing silk, plans to construct an addition to its factory at Coaticook, Que., and will install machinery.

Fire, Mar. 27 destroyed the factory of the Canadian Rubber Co., Montreal, Que. Estimated cost, $50,000.

The D. H. Langlois & Co. will rebuild its furniture factory at St. John's, Que., recently destroyed by fire with a loss of $16,000.

The Chatham Shoe Co. plans to construct a factory at Chatham, Ont.

The Peerless Weaving and Belting Co., recently incorporated, will construct a factory at Hamilton, Ont.

The Bonner Worth Co., manufacturer of spinners worsted yarns, will construct an addition to its plant at Petersborough, Ont. Estimated cost, $8,000.

Talks With Our Readers

By the Publisher

DON'T get the idea that the Buyers Cyclopedia is a cure-all for any trouble you may have found in the search for advertised products.

But it *is a specific* cure for one great defect that up to now has existed in all technical papers.

You have learned the value of reading the advertising pages in the American Machinist. By so doing you keep yourself well acquainted with the points of superiority of, and the differences between various makes of machines intended to do the same work. But when you came to buy a machine for a particular job, you found that all was not so easy. Only a machine of a certain size, weight, capacity, price, etc., could qualify. When you looked under the heading of the article you wanted, all you got was a list of manufacturers, without addresses—provided you found even the right heading. There was no detailed information about the articles made by the various manufacturers; you didn't know whether the machine Jones & Co. made was small or large; or whether you would have to write to Philadelphia, Salt Lake, or what not. In other words, when it came to the actual point of buying something that you had seen advertised in the American Machinist, the exact information that you wanted to enable you to make the right purchase was NOT THERE.

The Buyers Cyclopedia, page 188 will provide that.

It should give you all that information about everything that you use at the instant you want it.

No looking through dusty directories.

No searching through out-of-date card files.

Fresh, up-to-the-week — it enables you at any instant with full knowledge and no delay, to buy advertised products— which are the most reliable.

The Buyers Cyclopedia is designed and maintained for your use and convenience.

The advertising pages keep you informed.

The Cyclopedia gives you the detailed data about the products you need and tells you where to get them.

Get acquainted with it. Use it.

Making Flexible-Back Metal-Cutting Saws

By Ethan Viall

SYNOPSIS—This article not only gives data on the kind of saws, the number of teeth and the thickness to use on various metals, but it also tells how the saws are made.

A mere description of how a certain thing is made does not insure, by any means, that a man can take that description and produce articles equal to those described. Experience, trained men and a certain "know-how" obtained only from actual mechanical production will give the desired results. Long experience and good mechanical methods in the production of both wood- and metal-cutting saws of every description enable the James Ohlen & Sons Saw Manufacturing Co., Columbus, Ohio, which has been in business since 1852, to make saws that give satisfaction.

This article, however, will deal only with saws intended for metal cutting. Aside from the various sizes and number of teeth, two classes of metal-cutting saws are made here. One is known as a bright, high-tempered metal bandsaw, which is hard from tooth to back and is used for cutting the softer metals, such as manganese bronze, aluminum and others of that class. It closely resembles a wood-cutting bandsaw, except that it has a harder temper and finer teeth. The metal bands from which these saws are made come already properly tempered previous to the cutting of the teeth. The teeth, while hard, are not too hard to be filed.

The other class consists of saws made for the harder metals. These saws are flexible—that is, the teeth are hard, but the backs are not—and they are made in both the bandsaw and the hacksaw shapes and of all the widths, thicknesses and with all the numbers of teeth required for different uses. It is with this class of flexible-back saws that this article will deal especially, though incidentally some data will be given on the all-hard class.

For convenience in assisting customers in selecting the proper saws for their particular needs, the Ohlen company has divided its output into the following classes, which are typical of those in general use in shops throughout the country:

Class A—14 teeth to inch; for cutting soft steel, castings and rails.

Class B—16, 18 or 20 teeth to inch; for cutting tool steel, iron pipe, angle iron or other hard metals.

Class C—20 or 22 teeth to inch; for cutting brass, copper, drill rod, sheet metals or medium thin tubing.

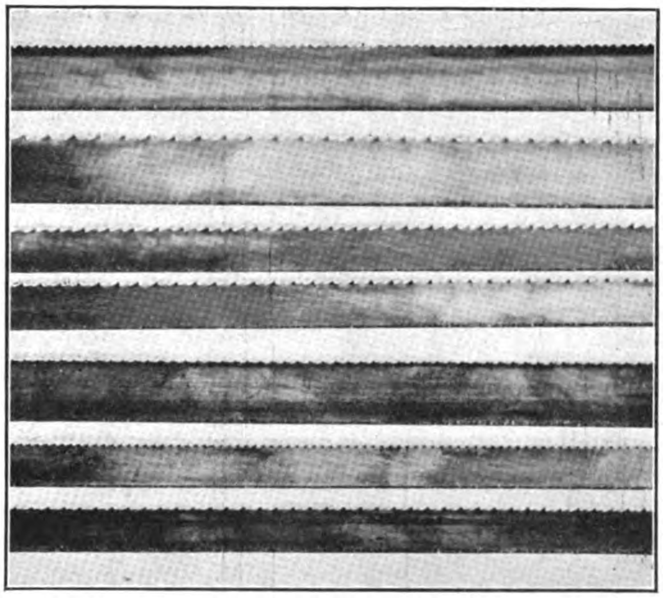

FIG. 1. SAMPLE SECTIONS OF METAL-CUTTING SAWS

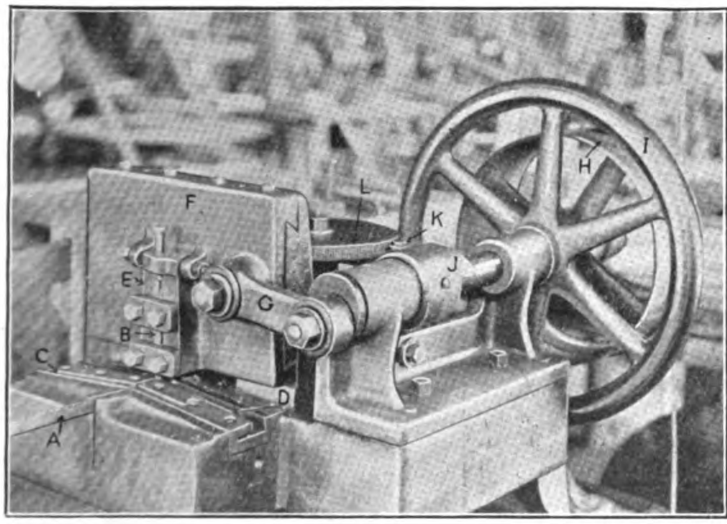

FIG. 2. A TOOTH-CUTTING AND SETTING MACHINE

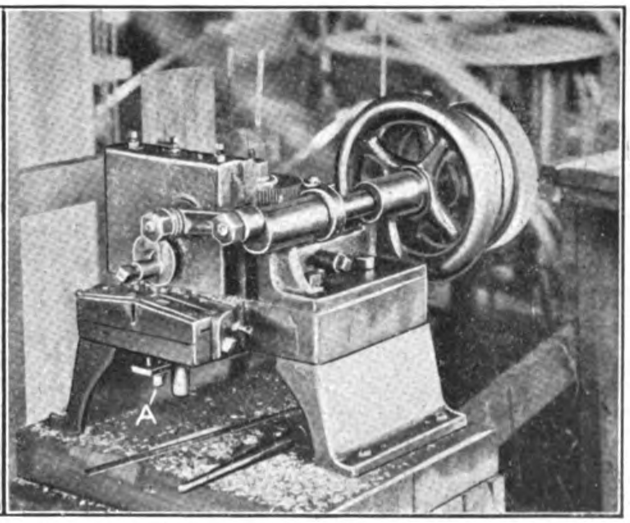

FIG. 3. ADJUSTMENT FOR STOCK WIDTHS

Class D—20 or 22 teeth to inch; for cutting manganese bronze.

Class E—28, 30 or 32 teeth to inch; for cutting tubing or thin sheet metal.

These saws are regularly ½ in. wide, 23 gage (0.026) thick and from 6 to 20 in. long. They are of the flexible-back type and ordinarily intended for use in hand frames.

For power, light gravity-feed machines the blades are 5/8 in. wide, run from 9 to 18 in. in length, are of 22 gage and cut with 14 teeth. For heavy gravity or power-feed machines the blades are from 12 to 24 in. long, 3/4 to 1 in. wide, 18, 19 or 21 gage and cut with from 10 to 18 teeth. For special purposes saws with teeth from 8 to 32 and of any required length, width or thickness are made. The foregoing classes, however, represent general practice.

Flexible-back metal-cutting bandsaws are made regularly from 3/8 to 1 in. wide, of different gages, and with any number of teeth up to 32 per inch. The all-hard bandsaws average 1/2, 5/8 or 3/4 in. in width and from 8 to 14 teeth. More of the 5/8-wide 23-gage 14-toothed saws are probably used than of any other size. As previously stated, they are suitable for the softer metals. All metal-cutting saws, whether of the hack or band type, flexible back or all hard, are made with a straight-faced tooth: that is, the cutting face of the teeth is at exact right angles to the back of the saw. This straight face is obtained by filing after the tooth has been cut and set.

Some of the blades, of various widths and different numbers of teeth, are shown in Fig. 1, though it is hard to give a clear idea by an illustration of this kind. Fortunately, every reader of this paper knows what hack-saw teeth look like and how they are set. The steel for these saws comes from the steel mills in big rolls that are placed on special holding tables, from which they are fed into the tooth-cutting and settling machines. Passing through the machines, the steel bands are again rolled up ready for the next operation.

One of the tooth-cutting and setting machines is seen in Fig. 2. The steel strip to be toothed feeds in from the back and out between the dies, as at *A*. The teeth, or "points," are cut by a reciprocating cutter, or punch, *B* working alternately against the cutting edges of two dies placed in slots at *C* and *D*. The cutter is carried in an adjustable tool block *E* bolted to the slide *F*, which is connected to the crankshaft by the rod *G*. The crankshaft is run by a belt on the pulley *H*, or for adjusting purposes it may be operated by the handwheel *I*. From this explanation it will be seen that two teeth are cut at each revolution of the crankshaft.

The steel strip is fed forward between each cut, which is accomplished by placing a double cam *J* on the crankshaft. These cams operate a pawl *K* every time they pass, or twice per revolution of the shaft. Thus two impulses are given to the notched disk *L*, which operates feed rolls so timed as to move the stock forward the right amount between the strokes of the cutting tool. By changing the notched disk or by varying the stroke of the pawl various leads per inch are obtained, so as to form the required number of points per inch.

Another machine, differing only in minor details, is illustrated in Fig. 3. This view shows better, however, how the machine is adjusted for different widths of stock. Adjusting screws at *A* move a guide up or down, as desired. The top of this guide rests between the dies, and the stock feeds over it; so that if the guide is raised, the stock is also raised up between the dies and vice versa.

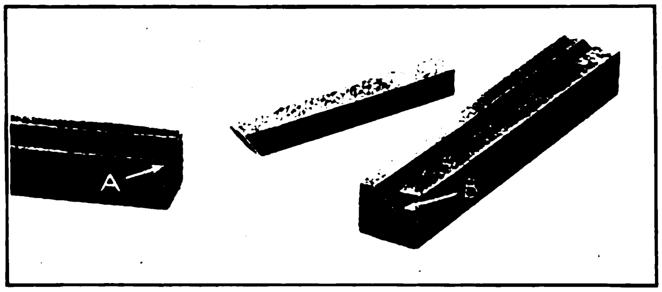

FIG. 4. TOOTH CUTTER AND DIES

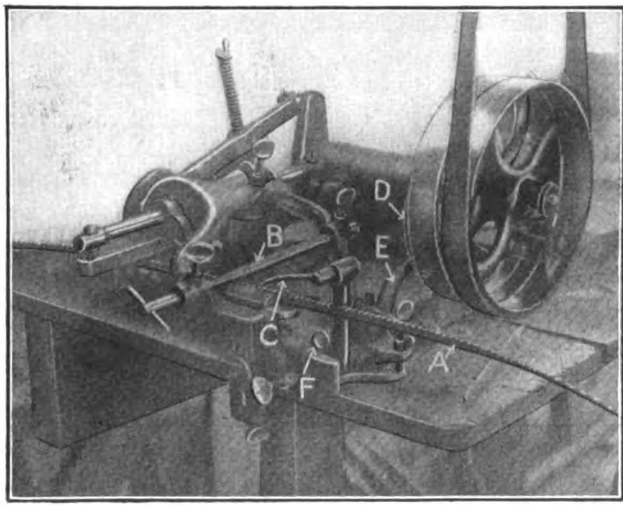

FIG. 5. AUTOMATIC TOOTH-FILING MACHINE

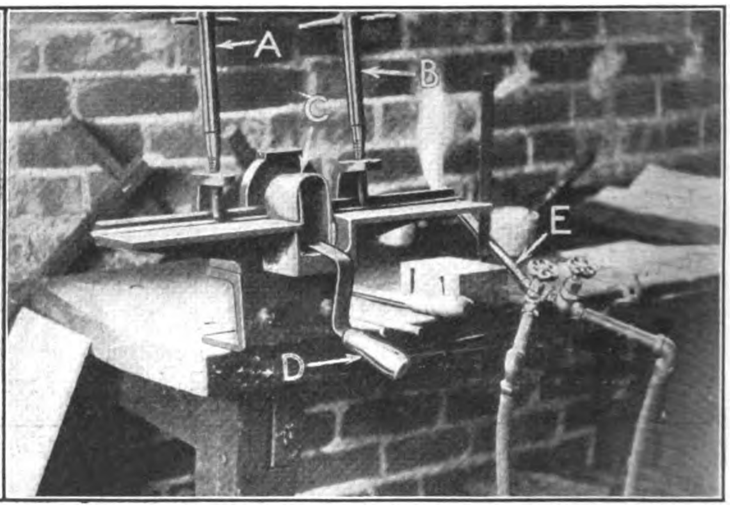

FIG. 6. A BRAZING FIXTURE

The method of setting the teeth as they are cut will be understood by referring to Fig. 4. Here two of the dies and a cutter may be seen. It will be observed that the ends of the dies are first ground off almost square and then have an angle ground at *A* and *B*. This angle and corresponding angles ground on the front edges of the cutter are what do the setting work. The additional clearance beyond the angled cutting edge of the die affords room for the set teeth to feed along. These dies and the way they are ground will show that the saws feed out "backward." The method of setting the dies in the machines makes it easy to remove and grind them, as they are practically made like straight forming tools.

By carefully observing the way the dies are ground and keeping in mind the way the strip feeds, it will be seen that the shearing action of the cutter tends to cut the back or slope of the tooth in line with the strip itself, but shoves the front or cutting edge outward to the angle at which the die is ground. This method gives an ideal

set to the teeth, as it does not distort or weaken the metal in the wrong place.

As previously stated, all metal-cutting saws are filed with a straight face to the teeth, so there is no hook whatever. This filing is done in automatic machines like the one in Fig. 5. The toothed bands are fed into the machine from the right, as at *A*. As they pass through guides, the file *B* strokes straight across. The feeding of the saw is done by the dog *C*, which engages the teeth one at a time in succession. This dog is operated from the cam *D*, which strikes the lever *E* at each revolution of the pulley. The cam action pushes the dog ahead, but it is returned by the spring *F*. As the spring forces the dog back against an adjustable stop; the regulation of the stop determines the length of the stroke of the dog. In this way the feed may be easily regulated for various numbers of teeth per inch. The file carriage is so made as to accurately guide the file and automatically lift free of the work on the return stroke. A number of these machines are kept constantly at work on both metal- and wood-cutting saws.

For bandsaws the ends, of the required length, are carefully beveled and fitted and are then placed in the fixture seen in Fig. 6, for brazing. In using this fixture the dressed ends of the saw are placed together and held by means of the clamp screws *A* and *B*. The removable "hood" *C* is placed over the saw ends, to confine the heat close to the place to be brazed. This hood is fitted with a handle *D* for convenient setting. The heating is done with a blow torch *E*. After brazing, the place is dressed up in the usual way, so that the joints are scarcely discernible.

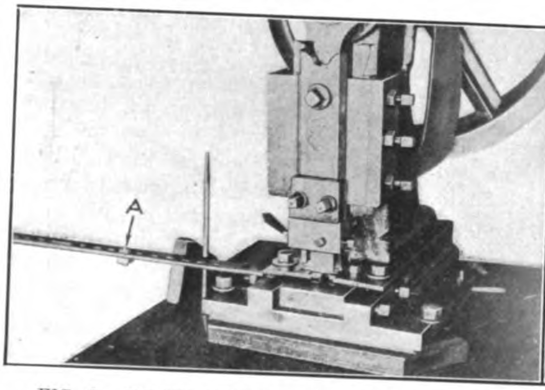

FIG. 7. PUNCH PRESS FOR HACKSAW ENDS

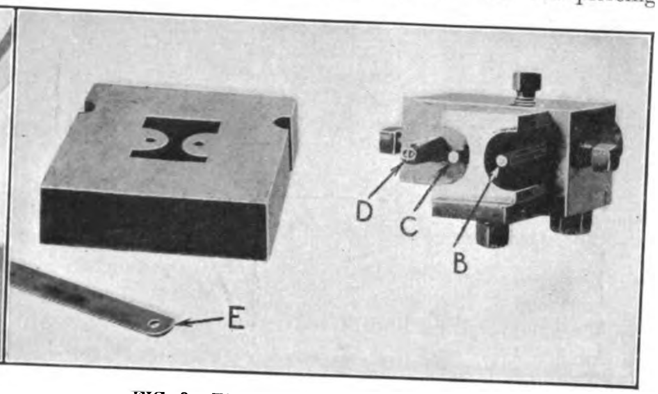

FIG. 8. THE PUNCHES AND DIE USED

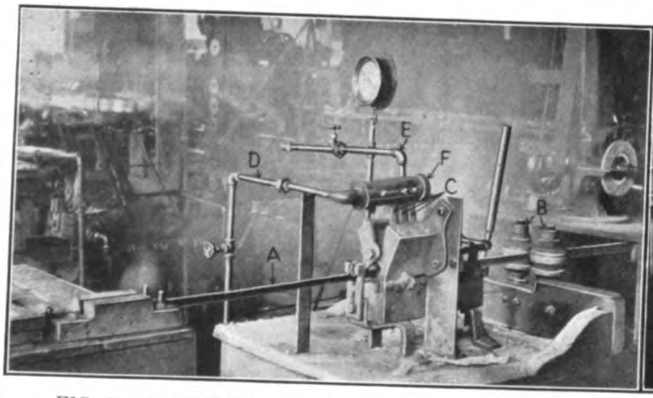

FIG. 9. AUTOMATIC TOOTH-HARDENING FURNACE

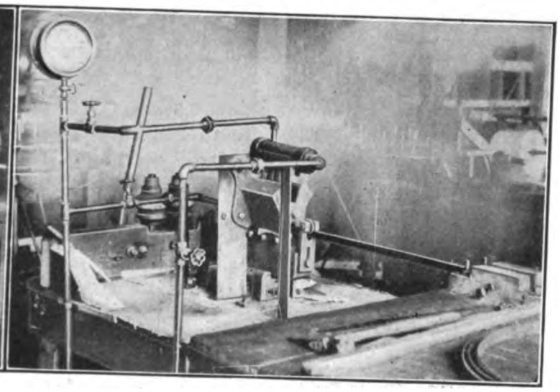

FIG. 10. ANOTHER VIEW OF HARDENING FURNACE

For cutting long bands into hacksaw lengths a punch press fitted as in Fig. 7 is employed. The band to be cut is fed in from the right against the stop *A*. The press is then tripped, cutting the piece to length and both forming and piercing the ends. As can be seen, the stop is adjustable for various lengths. The punches and dies for this work are shown in Fig. 8, from which it will be seen that two ends and two holes are pierced at each stroke, so that, once started, a saw blade is completed at each stroke of the press. The two piercing punches are illustrated at *B* and *C*. The punch *D* is a lettering punch for impressing the firm trade-mark on the blade. A sample of a finished saw end is given at *E*.

The method of hardening flexible-back saws leaves the extreme cutting points the hardest and does not harden the body of the blade or band at all. This treatment gives an almost unbreakable saw with fully as good cutting qualities as can be produced by an all-hard saw, but without the latter's brittleness. For hardening the teeth, special furnaces have been made that are practically automatic in action after being regulated for a certain class of work. One of these furnaces is shown in Fig. 9. The band to be hardened feeds into the furnace from a holding table, as at *A*, and is drawn through the furnace, teeth upward, by the power-driven rolls *B* at the back. As the band is slowly drawn along between asbestos-packed guides, gas jets *C* heat the points to the proper temperature. As they leave the heating flames, the points are cooled by a compressed-air blast, and the band then feeds on through the rolls to a holding reel. The pipe *D* is a gas pipe, *E* is an air pipe, and *F* is a mixing chamber from which the heating jets lead.

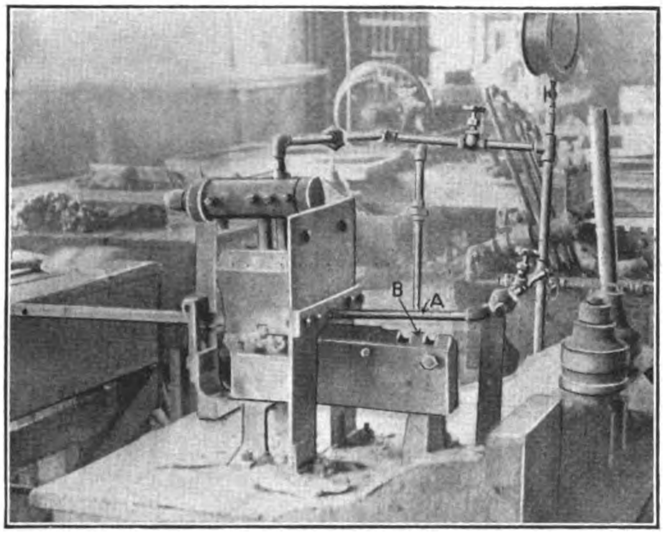

FIG. 11. REAR VIEW, SHOWING COOLING PIPE

Of course, the operator has first to blow all the moisture possible out of the compressed-air pipes and then carefully regulate both the heating and cooling jets to the work in hand. After that it is merely a case of watching to see that the product comes uniformly tempered. About 900 ft. of saw band may be hardened in one of these furnaces in 9 hr., taking a 5/8-wide 18-point band as an example. Other sizes and points will vary the amount one way or the other. About 140 lb. of air pressure is carried in the system.

Another view of this same furnace is given in Fig. 10 and shows the piping to better advantage. Fig. 11 is a rear view, and the cooling-air pipe is seen at *A*. This is simply a small pipe with holes drilled in the under side so as to throw the air directly on the teeth as they pass under. The guiding jaws through which the saw feeds are shown at *B*. Teeth properly hardened in this way cut freely, do not shell off and last unusually long on account of their soft backing.

Design and Construction of Textile-Machinery Cams

By Sumner B. Sargent

In this article I will take up and design a set of loom cams, commonly called harness cams. Their work is to raise and depress the warp threads. Then the shuttle containing the filling yarn is shot across. Such cams are made in sets of two, three, four, five, six, seven or eight and are commonly locked together on the same camshaft. The outer end of the cam lever is attached by straps to the bottom of the harness frames. The tops of these harness frames are attached by straps to rolls overhead. These rolls are each proportioned in size to the stroke of a corresponding cam lever, and they wind up or unwind the straps (thus raising or lowering the harnesses) as the cam lever moves up or down.

In Fig. 1, *M* represents the "fell" of the cloth, where each successive thread of filling is beaten in and tied in place by the warp threads *MAP* and *MAR* as they pass each other in rising or falling. The raised front harness is represented by *BC*, and *DE* represents the back harness depressed. At *P* and *R* is represented the eye of the harness wire, or needle, through which each warp thread passes. The line *MAP* represents the warp threads raised and *MAR* the warp threads depressed. Between these threads the shuttle lays the filling. At *H* is represented the boss of the roll, around which the front-harness strap winds as the harness rises. At *L* is represented another boss of the same roll, around which the back-harness strap winds.

The opening between the warp threads caused by cams is called the "shed." All the cams must have such a stroke as will make a uniform shed for the shuttle to shoot through. This means that the back-harness cams must have a longer stroke than the front ones.

In the case of a two-harness set such as I am now designing the back-harness roll should be of such proportion as to wind up the longer length of strap due to the longer stroke of the back harness; the conditions are the same in reference to the front-harness roll. In other words, one cam lever and top roll take up the slack delivered by the other. So the cams, levers and rolls must be proportioned; otherwise the shed opening will not be uniform and some of the threads will not show in their proper place in the woven cloth. The strain on the warp threads is generally greatest when the shed is open and lessens as

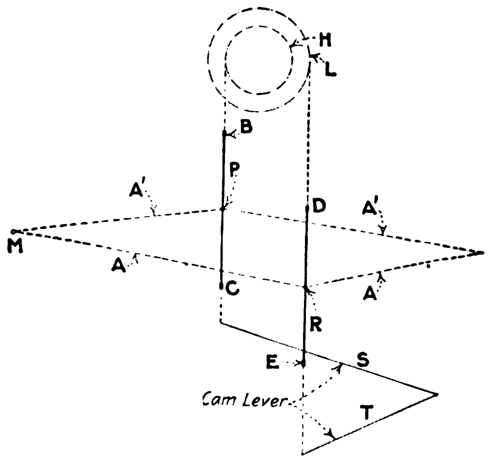

FIG. 1. ARRANGEMENT OF LOOM HAMMERS

the threads depart from this open position. Too severe or sudden straining of the threads causes frequent and undesirable breaking, with consequent imperfections in the finished cloth and loss of production while repairing break.

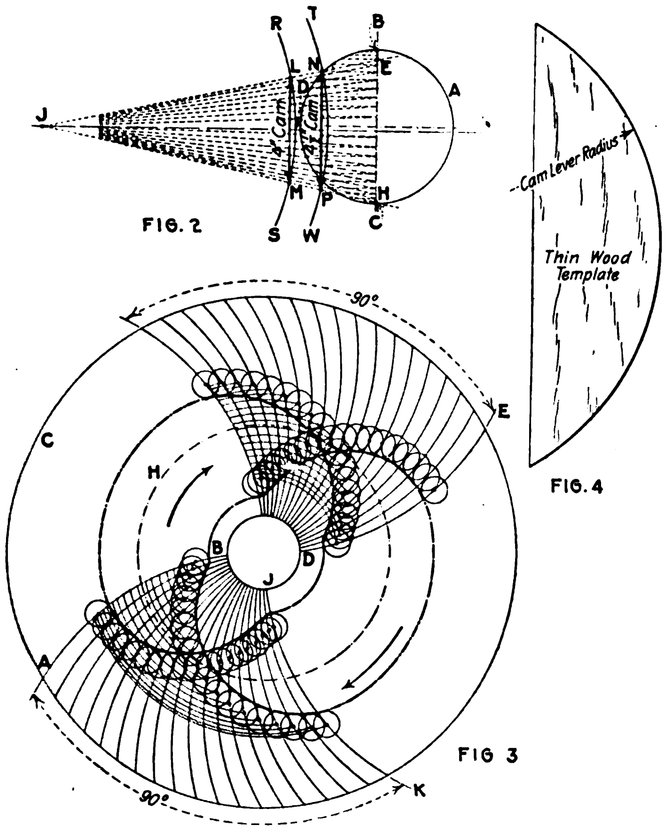
As the warp threads get tighter and the shed approaches the open position, more power is used in operating the cams. For these reasons I generally decide that the cam movement shall be uniformly retarded as the shed approaches the open position and correspondingly accelerated as it departs from that position. This result is accomplished by reversing the order in which the cam-stroke graduations are plotted on the cam.

If the graduations are numbered from 1 to 16, they are applied in that order to the stroke side and in reverse order—16 to 1—on the follow side of the cam. Therefore, to operate with the minimum breakage of warp threads and to consume the least power in operation I generally use a modification of the crank-motion principle in designing this class of cams (see Fig. 2).

To lay out such a cam, first strike the circle *A*, having a diameter somewhat longer than the largest cam stroke, in this case 6 in. Divide the semicircle *BDC* into 24 equal parts and square the division points across to the line *BC*. Of these 24 divisions representing a crank-motion stroke I arbitrarily select the 18 divisions from *E*

to H. The spaces at H are shorter than the spaces at E; therefore use the H-end of the divisions for the cam stroke as it approaches the open-shed position.

Now, in order to locate the center of the stroke for both cams, bisect the line EH with the line JK. Using the proportional method to determine the graduation for the 4-in. and 4½-in. cams, extend the lines EJ and HJ and erect the two lines LM and NP, representing the strokes. Now extend radiating lines from J to each of the division points on the line EH. Then with a radius equal to the distance from the center of the cam ball to the lever fulcrum strike the arcs RS and TW, representing the arcs described by the cam balls. When the radial



FIGS. 2 TO 4. LAYOUT OF TWO-HAMMER LOOM CAMS

lines cut the arcs RS and TW, the division points are indicated for the cam-stroke graduations.

I now decide that the cams shall complete their stroke in 90 deg., as in Fig. 3. The circle C is struck with a radius representing the distance between the cam-ball center and the lever fulcrum. Ninety degrees of the circle is divided into 18 equal parts, and radial arcs swing from each division point to the center of the circle.

In actual practice I rarely use the large circle and swing the radial lines as described. I find it too inconvenient; and after many radial arcs are swung through the center, I lose its location. But I obtain the same result in the following manner:

I make a thin templet of wood representing the radial arc, Fig. 4. Then I draw the circle C as large or as small as I find most convenient and divide it into spaces as desired. Then I drive a thin needle through the center of the circle into the drawing board, and with one end of the arc side of the wooden templet against the needle and the other end resting at the division points on the circumference of the circle, I use the templet to scribe the radial arcs.

Turning back to Fig. 2, transfer graduations of the stroke from the arc RS to the arc AB, Fig. 3. Next swing these graduation points onto the proper radial arcs and with the cam-ball radius strike the points of contact for the working side, or stroke side, of the cam. For the follow side, transfer the same graduation in reversed order to the radial arc DE, then swing these graduation points on to the proper radial arc and with the cam-ball radius describe the points of contact for the follow side of the cam.

The circle H represents the center of the stroke of cam ball and corresponds with the line JK, in Fig. 2. Now using the circle H to locate the center of the stroke for the 4½-in. cam, transfer to the arc JK the graduation for this cam.

The arrow in Fig. 3 indicates the direction of movement of the cams and therefore plainly shows the stroke side. For reasons already given, the finer graduations on the stroke side should be toward the outer periphery, and the coarser graduations nearest the center or hub.

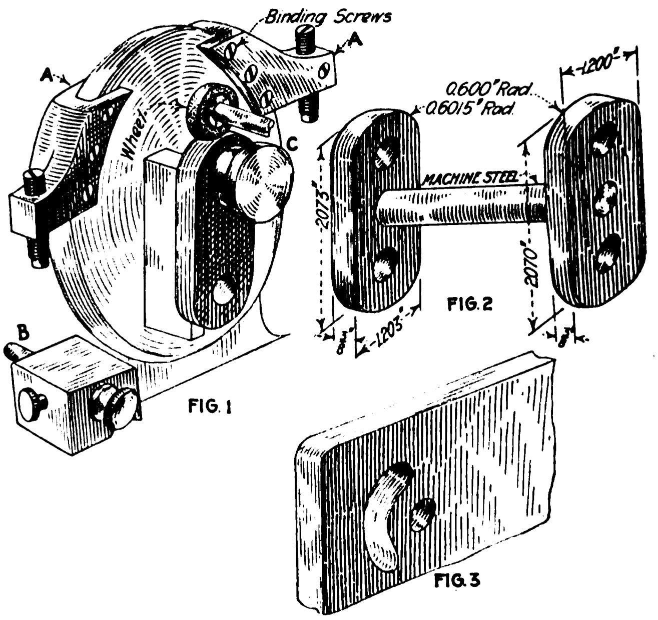
In cams thus designed an arrow should be cut into the periphery of the pattern to indicate the *direction in which the cam should operate.*

Precision-Gage Manufacture

By Gustave A. Remacle

When constructing gages that contain radii such as those shown at Fig. 2, the bench lathe is used for grinding the radii. Fig. 3 shows another form of gage that is ground in a similar manner.

The adjustable stops A, Fig. 1, enable the operator to grind any desired radius without grinding into other parts of the gage. The stop pin B, Fig. 1, may be withdrawn, thus permitting the gage to swing on the faceplate with-



PRECISION-GAGE MANUFACTURING METHODS

out interruption. This is a valuable feature of this method of grinding a radius, as the operator, after withdrawing the stop pin B, may grind the disk C following each adjustment of the wheel while grinding the radius. By grinding the disk and measuring with the micrometer the radius is accurately determined. The manner in which the stops are fastened to the faceplate is shown at D, Fig. 1.

The gaging parts of Fig. 2 were machined to shape, allowance being left for grinding after hardening. The two holes were bored so that the centers were 0.870 in. apart. After hardening, the faces of the parts were ground. The holes were ground, care being exercised to have them both of exactly the same diameter and 0.870 in. from center to center. The two remaining sides were ground in relation to the holes, the same methods being pursued as described in preceding articles on similar operations. The parts were swung on the faceplate of the bench lathe and ground as shown.

The plug, which is firmly located in the faceplate, is a good fit for the holes in the gage parts and disk. The object of the disk may be readily seen. After each advance of the wheel toward the work, the disk is ground and then measured.

Motor-Truck Repair Shop with the Army in Mexico

By Hi Sibley

So much dependence is placed in the motor-truck service between the base of supplies in the Mexican camp and the army of the punitive expedition, over 150 miles (at this writing) across the Mexican border, that new squads of trucks in lots of from 25 to 50 are being added every few days to take care of the extended line of communication. It is said that without motor trucks to transport supplies the expedition would have been impossible.

A repair shop, completely equipped with tools and machinery to take care of aëroplanes as well as motor cars, has been set up in camp and it is an extremely serious breakdown that cannot be handled efficiently here. An interesting feature of this department is the field repair truck. A Jeffery four-wheel-drive "quad" truck is equipped with a Seneca Falls 9-in. lathe and Hisey-Wolf friction drill press (about 16-in.), both motor driven with current supplied by a generator belt driven from the truck motor. The lathe is stationary, just behind the driver's seat, and the canopy top is high to give the operator sufficient headroom while at work.

The drill press is demountable for traveling, but when in use is set upon a drop platform, which is folded up against the side of the car during a trip. The rear half of the truck is fitted up as a combined stock and tool room, and here, systematically arranged in neat drawers and lockers, is a large assortment of tools and parts.

Thanks to the high quality of the American trucks in daily service between camp and the front, to date there has been no call for the repair truck to do any work on the road, but such contingency might arise.

The pictures show, in Fig. 1, the field repair car, with folding platform for drill press, this being covered with canvas to protect it from rain and dust storms frequent in this section. Fig. 2 shows the lathe and lockers with rheostat at side of driver's seat. Fig. 3 gives a right-side view of the field repair car, while Fig. 4 shows how the drilling machine is mounted on the platform.

Making Patterns and Castings for the Small Shop

By John H. Van Deventer

SYNOPSIS—What to avoid is even more important to know than what to do. This article throws cold water on the ambition of the small-shop owner who is thinking of operating his own foundry. Patterns also come in for their share of rapping.

A foundry is a handy thing to have in connection with a big shop—you can blame most mistakes upon it. This abode of the sand rammer has always been a convenient "goat," and many a shop foreman would lose his job if deprived of its unconscious support when it comes to excuses for spoiled work.

When the time clerk trots down the line with a job that took an hour and a half longer than it should, what is more easy and soothing than to tell him that the cast-

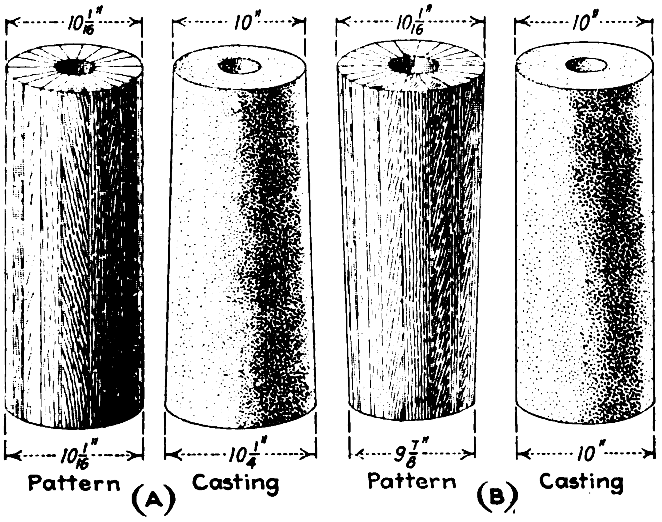

FIG. 1. TOM COOPER'S EXPERIENCE WITH ROLLS

ing was hard and sandy and that you think some cuss over in the foundry must have slipped a couple of files into the cupola? When the old man sits on your neck because a machine is three days overdue, what will change a disorderly rout into a glorious retreat more quickly than to tell him that the frame pattern was rapped so large that it required three cuts to get it down to finishing size? When a pulley or gear arm has cracks in it, how is it possible for these to have occurred in the casting anywhere but in the foundry where it was made? In one large shop with which I am familiar there is a saying as follows: "A slight error in the designing department, a mistake in the machine shop, a d—— big blunder in the foundry."

While a foundry is so convenient in this respect, aside from its capacity to deliver castings, it is usually an expensive luxury when attached to a small shop. When castings can be bought on contract as cheaply as is possible nowadays, it is foolish to assume a new burden of responsibility with the prospect of such a slight saving as that between the cost to make and the cost to buy, especially where the castings that are bought need not be paid for unless good, while those that are made must be paid for whether good or bad.

One of the supposed advantages of having your own foundry is in being able to get castings on time, but those who have foundries have come to believe that this advantage is not inseparably affixed to them. If the small-shop man is really looking for trouble, let him add the duty of a foundry superintendent and metal mixer to his already numerous and diversified duties and learn the 39 reasons why a casting can come out bad, starting with too high a barometric pressure and ending with too hard sand ramming, and he will feel as if he had his hands full.

There are of course exceptions to this even in the small shop. Some isolated cases exist where a foundry that can take no more than one heat a week will make a profit. But this is due to unusual conditions, such as the absence of competition; and since the majority of our small shops are in fairly close touch with competition, it does not apply in general.

There are some small-shop owners who think to add to their volume of business by adding to the number of

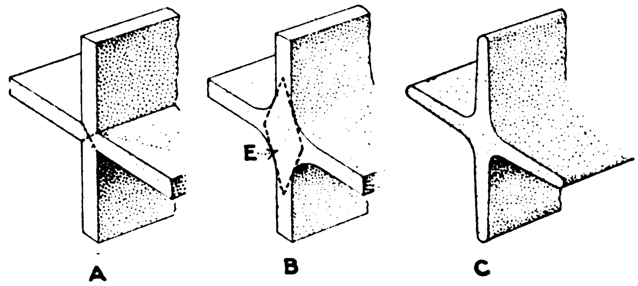

FIG. 2. TROUBLE WITH NOT ENOUGH AND TOO MUCH FILLER

departments in their plant. Not satisfied with an ordinary machine shop, they must have a foundry, blacksmith shop, pattern shop, nickel-plating department and what not. One shop owner of my acquaintance was doing a total volume of business of less than $12,000 a year and yet kept adding one department after another. Most people find it hard to support simply a machine shop on this amount of annual business, let alone extending it over a blacksmith shop, foundry and pattern shop. In addition to spreading the money very thin, the capacity of an ordinary human being must be stretched to the breaking point when he has to look after such a great variety of things. You will find the most successful shops are those that find out what they can do to best advantage and then cut out everything else as much as possible.

The same reasoning applies to making patterns. It is hard to get some men to realize that this is a special trade in itself. Unless a man is in daily touch with foundry conditions, knows foundry problems and has had years of experience with them as well as with his own trade, he is not fitted to make a real pattern. What I mean by a real pattern is one for a piece of work that counts for something, not the ordinary odds and ends of junk required about the shop from time to time, which may be made from whatever is at hand.

Old Bill Higgins, of Vermont, knew these facts as well as anyone and yet insisted on making his own patterns. But then he was a man who ran in unusually good luck. He said that to get a good casting you must have a good pattern; to get a good pattern you must have a good design; to get a good design you must have a good designer; and to get such a man you must have a lot of luck, so the whole casting business resolves itself into a matter of luck anyway, whichever way you look at it. Whereupon he would proceed to make a pattern that violated all the laws of nature. He would put the draft upside down and the cores inside out, mold it in too small a flask in the wrong kind of sand, ram it too hard and pour it too cold—and get a good casting!

Sometimes the carpenter finds that it falls to his part to make the small-shop patterns. They tell of one such wood butcher, newly hired by a small-shop owner, who, when told to put a little more draft on the pattern he was making, opened the window in front of the bench a bit wider!

Tom Cooper thought he knew enough to make a pattern for a plain cylindrical roll. He botched together a pattern such as shown at *A*, Fig. 1, allowing $\frac{1}{16}$-in. diameter for shrinkage. He sent this over to the nearest foundry with instruction to cast it on end, so as to get the surface clean all around. He was quite surprised on receiving the casting to find that one end of it was larger than the pattern. He jumped on the foundryman for rapping the pattern on this job with a sledge hammer, but got a quick come-back combined with the information that he should have made allowance for the pressure due to the head of liquid iron, which had expanded the mold at the bottom. After some experimenting he found the way to get a straight casting by making the pattern tapered, as shown at *B*. But he used up several hundred feet of good pattern lumber and a lot of time finding this out.

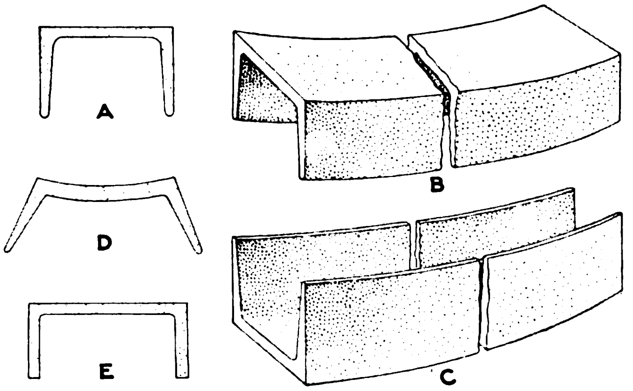

FIG. 3. CAM CUT DIFFERENT EVERY TIME IT WAS MADE

A JOB THAT BOTHERED TOM COOPER

Another little job that bothered him some was a pattern of which there were several + sections. Tom first made these as illustrated at *A* in Fig. 2 and got his pattern back in short order with a request to put fillets in the corners. He did so in the way seen at *B* and was shocked to find that too much fillet is as bad as too little, for the central portion was so heavy in comparison with the ribs that the unequal cooling set up heavy strains that resulted in cracks. Finally, the foundry owner took pity on him and told him to make it as shown at *C*, so that there would be a gradual change in the width of sections from one part to another. But while fussing around with these things, he overlooked a bad error in a machine for his best customer, and it was shipped without remedying the defect.

Not yet having his fingers badly enough burned, Tom tackled a pattern which had a channel cross-section, like that at *A* in Fig. 3. This pattern was straight, to be sure, but the casting came to him as hollow as an empty stomach, looking quite like the illustration at *B*. He called up the foundry on the phone, but dropped the receiver in a hurry when the foundry boss told him that he did not pay his men to furnish brains for amateur pattern makers. He sent the pattern to another foundry and got back a casting bent in the opposite direction, like the one shown at *C*. Then he changed the pattern a bit, thinning the metal at the center and thickening it at the ends. The casting which resulted, shown at *D*, reminded him of a dog stretching after a nap. In desperation he gave the job to a pattern maker, who solved the problem by thickening the ribs as at *E*.

A mistaken belief is a hard thing to kill, and Tom's belief in his pattern-making ability was not yet dead.

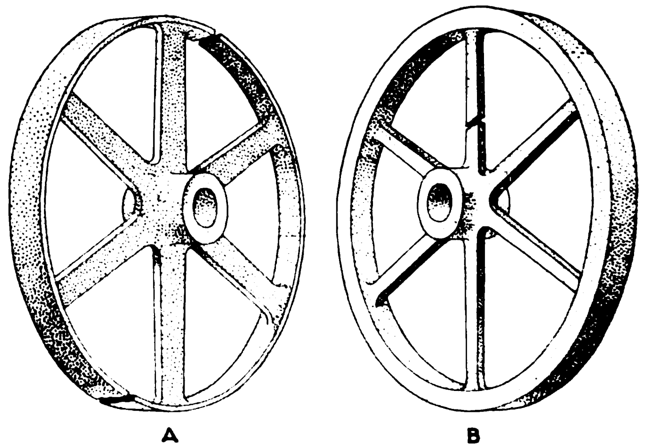

FIG. 4. CURING ONE DISEASE BROUGHT ON ANOTHER JUST AS BAD

even after such a severe shaking up, so he tackled a pulley.

A cast-iron pulley is one of the most innocent appearing objects, but beneath its honest sandy skin it contains a heart more full of stresses and strains to the square inch than anything else one can imagine. First, Tom made the rim light, as in Fig. 4 at *A*, so that it would not require a heavy cut for finishing. As a matter of fact it did not require any, meeting its finish while cooling in the sand. Then he made the rim heavy, so that this would not happen again, but unfortunately, with the results shown at *B*, the arms breaking this time instead of the rim. He lightened the rim a bit and made the arms a little heavier, but found that, although the casting looked good, the arms would snap under the slightest provocation, the hub thickness being much too great for equal cooling. Finally, it dawned upon Tom that he did not know much about pattern making and that it would be cheaper for him to have the few patterns he required made by someone who knew how.

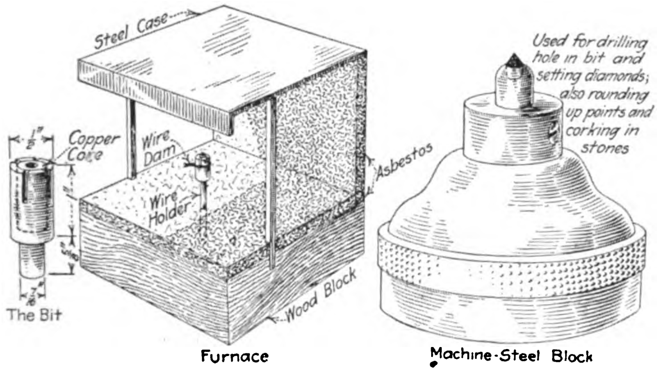
Not only with reference to making patterns and castings, but with almost everything else the following should be remembered: A man can know nearly all there is to know about one thing, he can know a great deal about a few things or he can know a little about a great many things. Take your choice, but remember that success will come only with the proper choosing.

Setting Diamonds

By O. F. Philler

For settings, or "bits," for small stones I use a piece of $\frac{5}{16}$-in. annealed copper wire about 1 in. long, driven into a hole in the end of a piece of $\frac{7}{16}$-in. cold rolled. For larger stones I use $\frac{1}{2}$-in. cold rolled with $\frac{3}{8}$-in. annealed copper wire about 1 in. long inserted in the end.

A hole is drilled in the copper to receive the diamond. Two saw slots, at right angles to each other, are put in to the bottom of the hole. The diamond is dropped in,



METHODS OF SETTING DIAMONDS

and by reaching in through the slots with a pick, the stone is turned over until the proper face is exposed. The stone is held in this position by pressing down on it with a small tube. With an automatic center punch the four copper walls are calked in around the diamond.

After the stone is anchored, the outside steel walls are pinched in with a pair of gas pliers. The stone and setting are placed in a coiled-wire holder and brazed, an ordinary 1-pt. gasoline blow-torch furnishing the heat. The slots act as vents and permit the solder to surround the stone completely. A coil of soft wire is wound around the setting just below the slots, to prevent the solder from running over the entire bit. Silver solder is used, with borax as a flux.

After the setting has cooled, the coil of wire is turned off in the lathe, and the end is faced off and rounded down so that the point of the stone is exposed a trifle. The setting is placed in the holder shown and the copper again calked with a set and light hammer. It is polished with a fine file. The reason for using the copper core in the setting is that it is easier to close for anchoring.

After the work is brazed, it is one solid mass. I generally use the same bit for resetting, by sawing it off just below the stone. I can center up and reset a stone ready for use in from 45 min. to 1 hr.

Boring and Planing Small-Car Bearing Brackets

The Standard Dry Kiln Co., Indianapolis, Ind., makes a great many brick and lumber trucks. The bearings for some of these are carried in cast-iron brackets as at *A* and *B*, Fig. 1. The bracket is placed in the fixture over the pin *C*. The fork *D* is run up, and the fork ends are thrust through the two side flange holes. The fork completely contacts with the rounded part of the bracket and holds it securely against the locating block while the hole is bored out with the piloted tool *E*.

The fork has a quick in-and-out action, making it unnecessary to turn the crank *F* more than a few times. The quick movement is accomplished by lifting up the hooked latch *G*, as shown, and moving the crank and fork

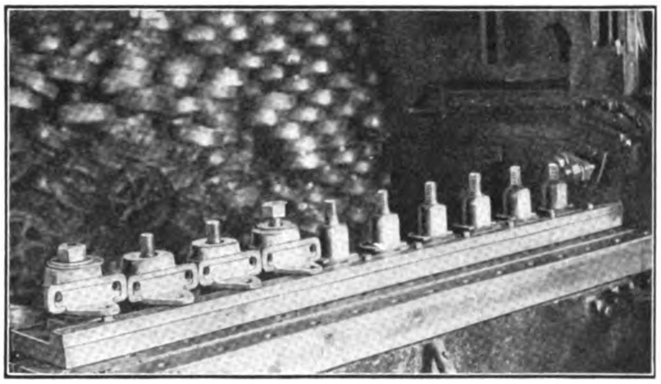


FIG. 3. GANG PLANING FIXTURE

in or out. The various parts are illustrated in working position in Fig. 2, but without the casting in place, in order to make clear the positions. The boring tool is set into its guide bushing at *H*; and the latch holding the fork and crank is shown down, as it is used while working.

The bolting flanges of these brackets are planed, as shown in Fig. 3. The fixture will hold ten brackets at a time. The bored bearing hole of the bracket fits over a holding plug, and it is located by means of a pin that fits into the hole in the triangular flange as shown.

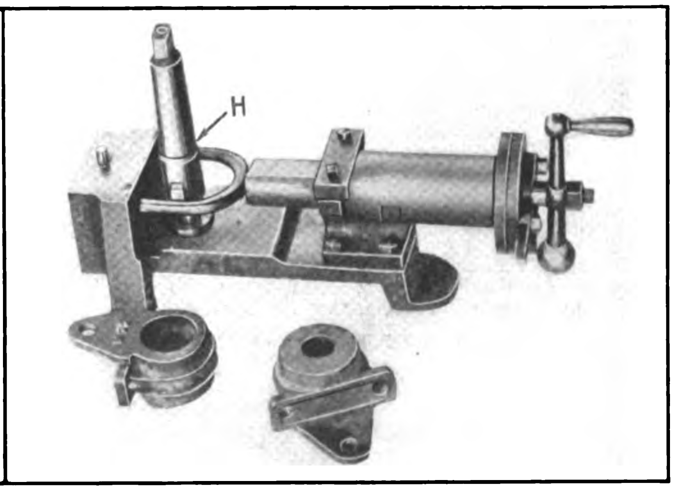

FIG 2. FIXTURE WITH PARTS IN WORKING POSITION

Punch, Die and Jigs Used in Machining Press Details

By Robert Mawson

SYNOPSIS—When making this printing press, not many punchings are required. In this article, however, one interesting element used and the tools employed are described. This punch and die pierces and blanks in one operation with a minimum amount of waste material. Three simple jigs are also shown which have, however, been found to be economical in operation, producing interchangeable parts. The castings are mostly rough when drilled, so that adjustable means must be employed in locating them.

The two-sheet rotary printing press illustrated on page 58 is manufactured by the United Printing Machinery Co., Woonsocket, R. I. Some of the jigs and fixtures used in making this press were shown and described on pages 138, 232, 458 and 492. In this article are illustrated and described a punch and die and jigs used in making and machining four other details used on the same press. These, like the ones previously shown, are examples of modern economical and small-tool design and construction.

The punch and die illustrated in Fig. 2 is a well-designed tool, as it locates one part while another is being blanked. The end of the punch rounds the end of the second part while simultaneously punching the first.

The jig used for the tumbler pin lever bracket employs a sliding bar to hold it after the casting has been located against a V-block. A screw that is tightened through the bar against the casting keeps it in position.

The jig seen in Fig. 6 is of the cover type. After the pieces have been placed in the jig, they are located by an adjustable setscrew. The cover is dropped down and fastened with a thumbscrew. A knurled-head screw through the cover holds the piece firmly.

The jig for the detector finger holder is of a simple type. The rough casting is placed on a plug, and a setscrew at the end holds the part securely in position.

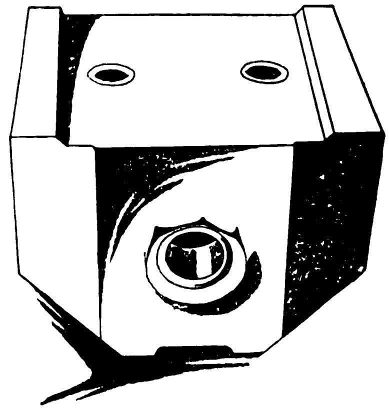

FIG. 4. DRILLING AND REAMING JIG

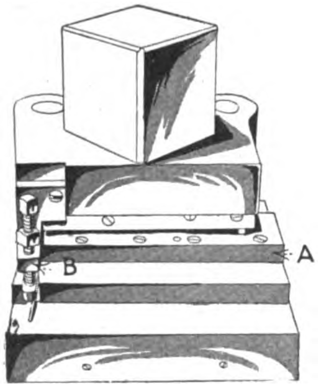

FIG. 2

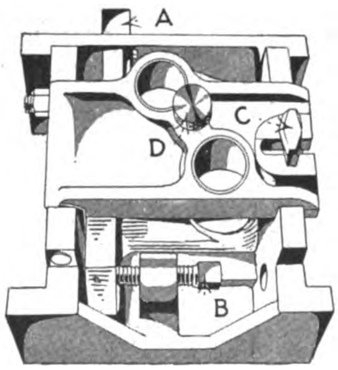

FIG. 6

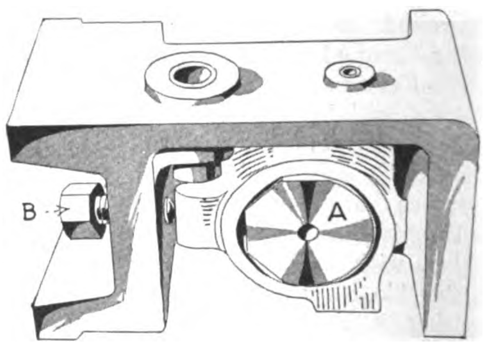

FIG. 8

PUNCH, DIE AND JIGS USED IN MACHINING PRINTING-PRESS DETAILS, WITH WORK IN POSITION

FIGS. 2 AND 2-A

Operations—Piercing and blanking feed gage rest blade, Fig. 1. The stock, which comes in a strip, is fed into the punch at A against the stop B. The punch is then made to descend, and the piece is pierced and blanked in one operation. It will be observed that the end of the punch when blanking also punches the rounded edges required on the slot. The punch is then raised and the part pushed along out of the die; and as the punch is made to descend, the strip is again located by the stop actuated by the spring shown.

FIGS. 4 AND 4-A

Operations—Drilling and reaming tumbler pin lever bracket, Fig. 3. The milled casting is placed in the jig, and the bar, shown in Fig. 4-A, is slid into position. The casting is located by a V-block inside of which the circular boss of the casting fits. A screw through the bar, when tightened, holds the piece securely.

Holes Machined—Two $\frac{25}{64}$-in. drilled, one $\frac{43}{64}$-in. drilled and reamed $\frac{11}{16}$ in.

FIGS. 6 AND 6-A

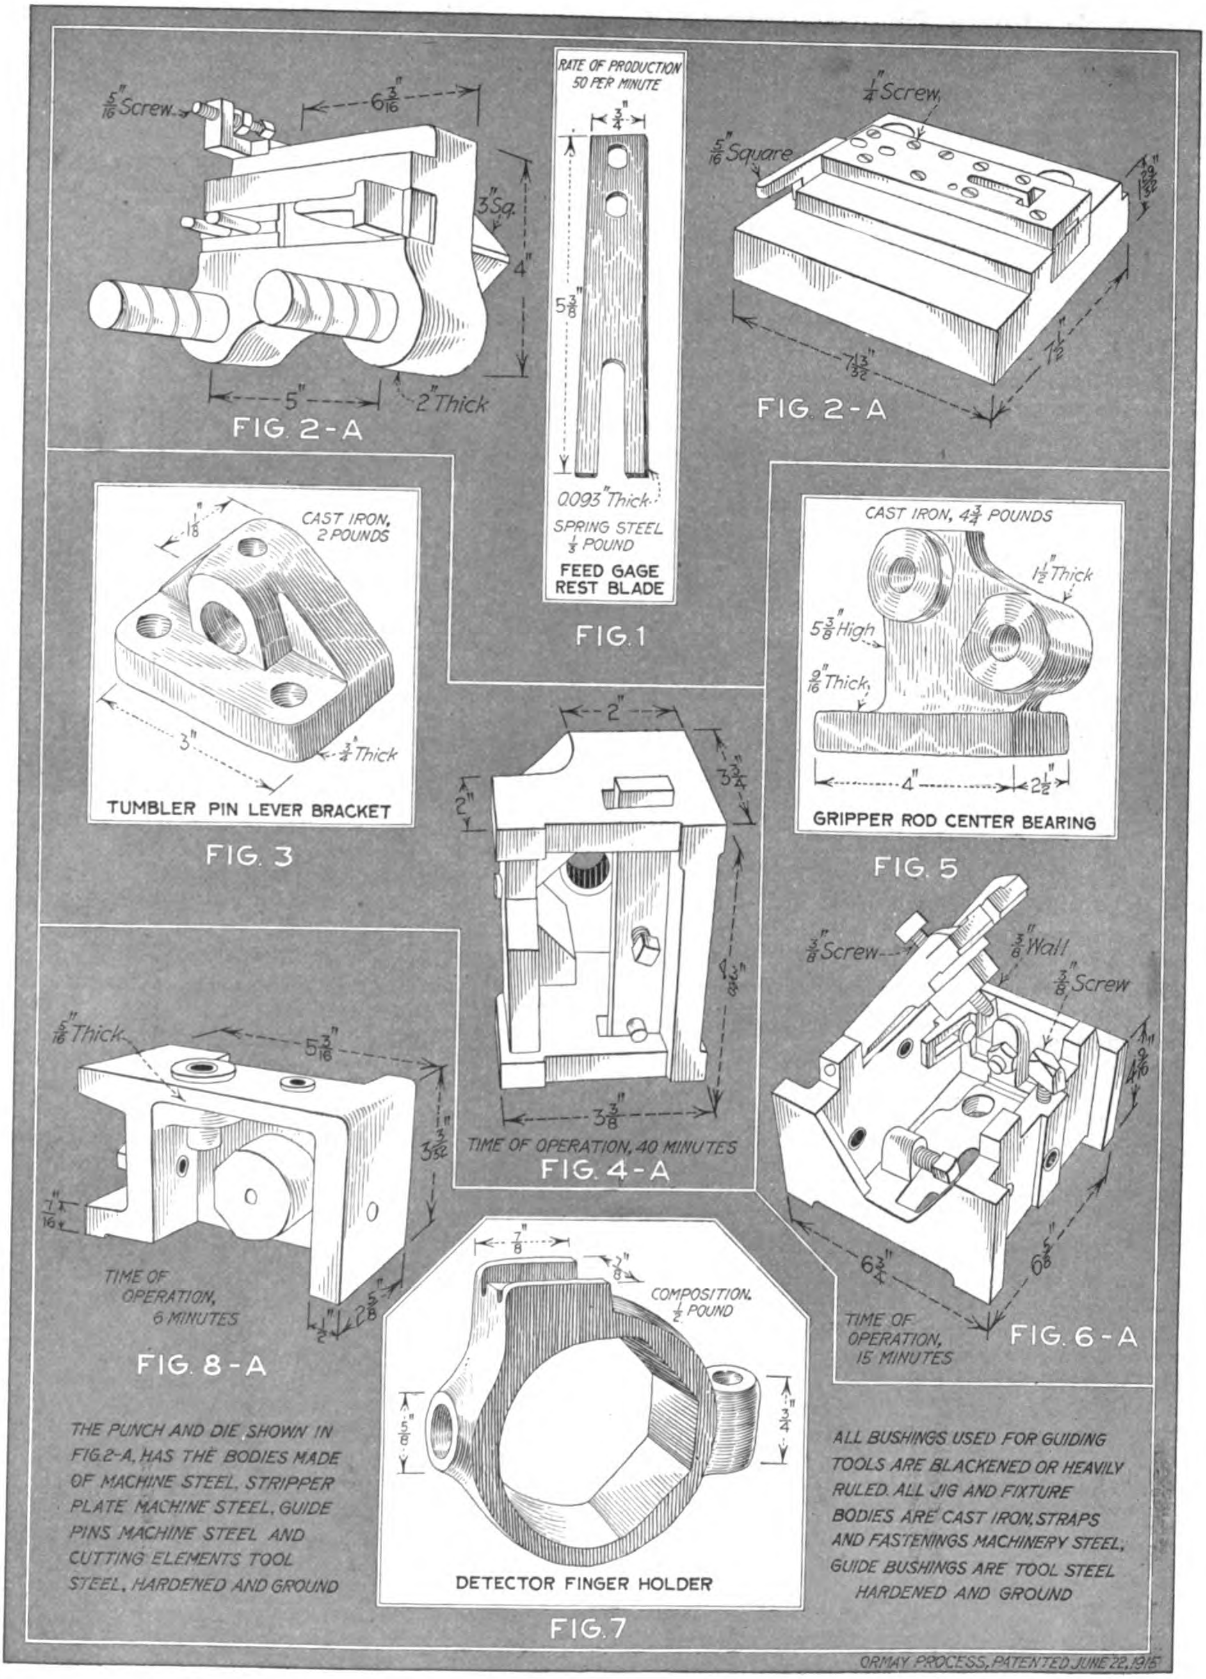
Operations—Drilling and reaming gripper-rod center bearing. The milled casting is placed in the jig and is located against an adjustable setscrew and forced against the side of the jig with the wedge A and setscrew B. The cover is then dropped down and fastened with the thumb-screw C. The knurled-head screw D when tightened holds the casting down in the jig.

Holes Machined—Two $\frac{33}{64}$-in. drilled, one $\frac{5}{8}$-in. spot drilled and reamed and two 1-in. holes are spot drilled and reamed.

FIGS. 8 AND 8-A

Operation—Drilling detector finger holder, Fig. 7. The rough casting is placed on the plug A, and the screw B bearing against the lug of the finger holder fastens it in position for the drilling operations.

Holes Machined—One hole drilled to suit No. 8-32 tap and one $\frac{5}{16}$-in. drilled for $\frac{3}{8}$-in. U.S.S. tap.



DETAILS OF PUNCH, DIE AND JIGS USED IN MANUFACTURING PRINTING-PRESS PARTS

Organizing for Industrial Preparedness*

By Spencer Miller†

The President of the United States, Woodrow Wilson, speaking from his intimate contact with foreign affairs, recently said, "There may come a time when I cannot preserve both the honor and the peace of the United States." He also urged that we should be "very adequately prepared, not for war, but for defense."

Both ex-Presidents Taft and Roosevelt have declared for the immediate and adequate preparedness of our army and navy. Our highly trained army and navy experts, whose life work entitles them to speak with authority, have been most earnest for far more effective military defenses. The public press, reflecting largely public opinion, is overwhelmingly in favor of adequate preparedness.

With so formidable an array of authoritatve opinion engineers patriotically, quietly and earnestly ask the question, "What may we do to serve our country?" Engineers are for peace with honor and will make personal sacrifices to insure it.

The United States Naval Consulting Board

It was a proud day for the engineers and scientists when Secretary Daniels of the United States Navy Department invited Thomas A. Edison, our own society and 10 other engineering and scientific societies to form a civilian advisory board of 23 members to aid in mobilizing the engineering and industrial world for preparedness. This invitation was eagerly accepted, and the United States Naval Consulting Board is now fully organized with Mr. Edison as chairman. Ten members of our society are members of this board, two representing it officially.[1] This board serves without monetary compensation, even paying its own expenses.

The Naval Consulting Board has resolved itself into committees, one of which, headed by Howard E. Coffin, member of this society, is the Committee on Production, Organization, Manufacture and Standardization. This committee formulated a plan for aiding in organizing the industries for preparedness. This plan, laid before the President of the United States, prompted him to invite the five leading engineering societies, whose combined membership is about 35,000, to effect such an organization. This he did by writing identical letters to each of the following societies: The American Society of Mechanical Engineers, the American Society of Civil Engineers, the American Institute of Electrical Engineers, the American Institute of Mining Engineers and the American Chemical Society.

The President's letter to our society, dated White House, Jan. 13, 1916, reads as follows:

> The work which the American Society of Mechanical Engineers has done, through its members on the Naval Consulting Board, is a public service which is deeply appreciated. It has been so valuable that I am tempted to ask that you will request the society to enlarge its usefulness to the Government still further by nominating, for the approval of the Secretary of the Navy, a representative from its membership for each state in the Union to act in conjunction with representatives from the American Institute of Mining Engineers, the American Society of Civil Engineers, the American Institute of Electrical Engineers and the American Chemical Society, for the purpose of assisting the Naval Consulting Board in the work of collecting data for use in organizing the manufacturing resources of the country for the public service in case of emergency. I am sure that I may count upon your cordial coöperation.
>
> (Signed) WOODROW WILSON.

This letter appeared everywhere in the public press and was received with a glow of patriotism in the hearts of engineers generally.

The President's Invitation Accepted

Each society named has accepted the President's invitation. Each has selected one director from every state of the Union, for the approval of the Secretary of the Navy. The five directors in each state will constitute a Committee of State Directors for Industrial Preparedness. These State Directors will report to the Naval Consulting Board through the committee of which Mr. Coffin is chairman.

The immediate work of these State Directors will be to obtain an accurate inventory of all the facts necessary to be known to the army and navy of the resources of our nation to supply munitions of war in case of need.

To obtain this census the State Directors will be assisted by the members of each of the five representative societies residing within the state. In many states there are more members than industries in which the army and navy may be interested. This indicates that this census will be rapidly completed.

The importance of such a census can scarcely be overstated. It has been estimated that for every million of soldiers and sailors at the front at least three million of workers will be needed to maintain them efficiently with the necessary implements and supplies of warfare.

Major General Leonard Wood, U. S. A., estimates that a serious war would require at least 2,000,000 men. Under such circumstances 6,000,000 men would be required for producing munitions of war. Some statistics about wars in the United States follow:

War of the Revolution (1775-83)—Number of troops	309.791
War of 1812 (1812-15)—Number of troops (including navy)	576,622
Civil War (1861-65)—Number of troops (including navy)	2,778,302
Cost of Civil War to date, including pensions (about)	$16,000,000,000
Present estimated wealth of the United States	$200,000,000,000
Present estimated population of the United States	100,000,000
Present estimated wealth per capita	$2,000
Public debt (less cash in treasury)	$1,027,000,000
Public debt per capita	$10
Appropriation in 1915, navy (about)	$145,000,000
Appropriation in 1915, army and forts (about)	$108,000,000
Cost of navy per capita	$1.45
Cost of army per capita	$1.08

David Starr Jordan, the eminent pacifist, recently said, "In all ages war costs all that it can." Benjamin Franklin observed, "War is not paid for in war time; the bill comes later." The Civil War cost about 16 billion dollars, or about as much as the whole estimated wealth of the nation at that time.

Have we any right to assume that a war with one or more first-class powers finding us unprepared would cost less than one-quarter of our national wealth—namely, 50 billions of dollars? Such a cost represents one-quarter of the wealth of each of our hundred million population on an average, to say nothing of lives lost and personal property destroyed.

To insure this country against successful invasion, a much greater navy is generally demanded. In fact, a

†Member of United States Naval Consulting Board.

[1] W. L. R. Emmet and the author.

navy superior to that of any nation save only England. Some declare even that our navy should exceed that of England, on the ground that we may have to fight two great nations at once. Today our navy costs about $1.50 per capita per annum, average. Even though our navy be doubled, we would only pay $3 per capita, average. Our per capita wealth is about $2,000. Is $3 per year a heavy tax on $2,000 worth of property, if such a tax would provide a navy adequate to defend us against successful invasion?

Schedule for Industrial Inventory

The term munitions of war covers the whole field of army and navy requirements—guns and ammunition, rifles and uniforms, food and blankets, tents and cooking equipment, automobiles and aëroplanes, battleships and submarines, coal and oil, medical supplies and hospital equipment, even mules and horses. Thus it will be apparent that this volunteer army of engineer census takers must needs visit woolen mills as well as machine shops, boot and shoe factories as well as foundries, coal mines as well as shipyards.

An elaborate printed form has been prepared for taking the industrial inventory. It will be "a strictly confidential, nonpartisan, nonpolitical and wholly patriotic inventory of our country's manufacturing and producing resources. The information given upon this form will be used by the United States Naval Consulting Board in aiding in effecting an industrial organization necessary to the plans for national defense. The information contained in these blanks is not to be used in any way to affect the business of the concern reporting or for comparison with any other report of any kind previously filed by it. The value of this patriotic work can best be insured by making this report complete in every detail. We must deal with the problems of an adequate national defense as we deal with the problems of our everyday business life. We must face facts—not theories. We must do now, in time of peace, quietly, efficiently and thoroughly, those things which all know must be done to achieve true industrial preparedness, and which, if postponed until an outbreak of hostilities, must result in tremendous losses in lives and money. The form properly filled out will give:

1. The names, post-office address, age and nationality of the officers and directors.
2. Capitalization, commercial rating and banking connection.
3. Description and location of plant, its possibilities for expansion, its fire protection.
4. The telephone and telegraph facilities of the plant.
5. Sources of raw material and its character.
6. Character of products, volume or tonnage and its value per annum—proportion shipped abroad.
7. If munitions of war have ever been manufactured, the quantity produced and ultimate possible capacity.
8. Character of labor—union, nonunion or open shop—number and nationality of employees.
9. If women are employed, and the possibility for further employment of women.
10. Transportation facilities—rail and water.
11. Under the heading "Agreements" appears the following, which is quoted in full:

AGREEMENTS

Will bid upon United States Army and Navy contracts in time of peace........

Will accept United States Army and Navy contracts in time of war........

Will accept minimum annual order (see Clause A)........

Clause A. Minimum order for annual production will be accepted with the understanding that such order will be restricted to that product for which the manufacturer's equipment is best fitted. Also, that such order shall be for only such small quantity of product as will insure familiarity with the work upon the part of the manufacturer's organization. The manufacturer agrees that this minimum annual order shall be put through the factory in regular course and in such manner that foremen and those holding positions of responsibility shall become familiar with the peculiarities incident to the manufacture of these goods. In time of war the manufacturer will be expected to concentrate upon this same product, and it is essential, therefore, that his entire organization, including purchasing, manufacturing, inspection, shipping, engineering, cost-keeping and administrative departments, be made familiar with the work. Minimum orders will not be of sufficient quantities to interfere with manufacturer's regular production.

Will accept payment in accordance Clause B........ (Wording of Clause B not fully determined at time of going to press.)

Will construct jigs and tools in accordance Clause C.......

Clause C. The manufacturer will agree to make and preserve one set of special jigs, tools, gages or fittings necessary for the production of these goods, and corrected drawings shall be kept on file in the engineering department of the plant covering such special jigs, tools, gages or fittings. In short, the engineering or designing department shall maintain at all times corrected drawings from which the shop may, upon short notice, construct the necessary equipment for quantity production.

Will enroll skilled labor in "Industrial Reserve" (see Clause D).

Clause D. In war as now waged the industrial force has become quite as important as the fighting army. Skilled mechanics in all lines of production work must be kept from enlistment in the regular army and must be retained in the factories, mills and mines for the production of munitions. It is essential, therefore, that the names of these skilled workmen be listed and that the men themselves be enrolled in the industrial reserve. Explanations and instructions as to the detail of such organization will be submitted at a later date. A button or other distinguishing mark will be supplied by the Government in the event of war to skilled workmen enrolled in the industrial reserve, and such enrollment will be considered to carry with it honors equal to enrollment in the fighting army. A Government card will be issued to each man enlisted.

Will agree to limit profits in time of war in accordance with governmental regulations (basis cost plus........).

Will insert clause in all civil contracts making them contingent upon governmental needs in time of war........

Will agree to restore existing labor agreements at close of war........

List any and all agreements now in force........

12. An inventory in detail of tools, furnaces, etc., and their capacity.

With the facts in this census properly collated we shall learn where the nation is weak and where strong. Not only will the Government be instantly enabled to determine where munitions can be obtained, but how rapidly. We shall also know from this inventory:

1. Whether America is independent of foreign countries for raw or manufactured war material and if not, wherein we are lacking and to what degree.
2. In what kind of munitions we have ample manufacturing facilities and wherein we must provide means for making up the deficiency.
3. Whether it is prudent for the Government to build new arsenals and other works in the central part of the United States.

Tools, Gages, Jigs and Templets

This inventory will probably show that many shops well equipped to manufacture ammunition will not employ the skilled machinist to make the required tools, jigs, gages and templets. Possibly then it will transpire that the most efficient plan would be for a government

factory to make standard gages, jigs and templets and lend or sell them to certain shops for use in the manufacture of shells, rifles, etc.

This work of industrial preparedness should serve to inspire our machine-tool builders to perfect and improve their product and perhaps to standardize their machine tools to the end that those who must needs purchase them would find an adequate and immediate supply available in case of emergency.

The various engineering societies contain in their membership men who could prepare most valuable papers on the subject of ammunition manufacture. For the present there may be many secret processes which for the time being may not be forthcoming in the way of books and papers, which, however, might be prepared in advance and held until the hour of need, when, through patriotic motives, they could naturally be published for the benefit of the nation at large. The old saying that "Necessity is the mother of invention" is now applicable to the nations at war, and it is reasonable to assume that they have discovered superior methods, processes and tools for the rapid and economical manufacture of shells, etc. The best method of overtaking such a lead would be by a combination of talent and experience such as might be brought about by a congress of ammunition manufacturers, assembled for the purpose of exchanging experiences, etc. The best way for the manufacture of each element should then be arrived at, and the widest publicity should be given to descriptions of such methods.

Fuels for Internal-Combustion Engines

Wholly aside from the needs of war, there is a growing demand for liquid fuels for automobile and aëroplane motors. An interesting and profitable inquiry might be directed toward securing other fuels than gasoline, such as grain alcohol from sawdust and other wood wastes, sugar-house waste and cornstalks. Here the chemist will find ample fields for investigation.

These State Directors will be an influence in every state by urging the military value of good roads, especially along and near tidewater, and they should not forget that the bridges be made strong enough for heavy automobile trucks and extra-heavy cannon.

Such an army of engineers census takers actively at work cannot fail to breed a better spirit of citizenship. Working without compensation, they will set an example of patriotism which is bound to be felt. This spirit of patriotism will be transmitted to the workingman producing war supplies. These workers are surely a part of the defensive force of the country and should receive adequate recognition as such.

Ex-Senator Elihu Root recently said: "Eternal vigilance is the price of liberty. The principles of American liberty today stand in need of a renewed devotion on the part of the American people. . . . I want to see in my country the spirit that beat in the breasts of the men at Concord Bridge—who were just and God-fearing people, but who were ready to fight for their liberty; and if the hundred million people of America have the spirit and it is made manifest, they won't have to fight."

Time Necessary for Cutting Off Shell Forgings

By A. H. Anger

Since the manufacture of shrapnel and other shells has lately become such an important industry in this country, a table conveniently arranged for determining the cutting-off time of shell forgings will no doubt find extensive use in the plants at present engaged in this class of work.

The accompanying table covers a wide range of speeds and feeds for cutting off shell forgings, and the constants given in the table are such that the product of the thickness of shell and the constant in the table will give the cutting-off time in minutes. The constants in the table are tabulated with respect to the revolutions per minute and the feed of tool per revolution. These constants give the time in minutes required for cutting off a shell forging 1 in. thick. So, if it is desired to find the time required for cutting off a shell forging of a given thickness at a certain speed and feed, it is only necessary to multiply the constant found in the table under the given speed and feed by the given thickness.

Thus, if we wish to find the cutting-off time for a shell forging 1½ in. thick at a speed of 40 r.p.m. and a feed of 0.03 in. per revolution, we multiply the value 0.833, given in the table, by 1½, which gives us 1.25 min. for the cutting-off time. It is an easy matter then to form an accurate estimate of the output of a cutting-off machine after allowance is made for handling the work into and out of the machine.

TABLE OF CUTTING-OFF TIME IN MINUTES FOR SHELL FORGINGS

Feed per Revolution	Revolutions per Minute 10	15	20	25	30	35	40	45	50	55	60	65	70	75	80	85	90	95	100

Manufacturing 12-In. Shrapnel--IV*

By Robert Mawson

SYNOPSIS—The shells now receive the finishing operations. The balls, resin, powder and pellets are put in, and the manner in which this is done is here described. The adapter bottom, adapter and plug are also inserted and the shell finally weighed and passed. The shells are packed in individual packing cases after being covered with grease to prevent rust. A target is shown similar to that employed in testing some of the shells to determine the covering capacity of the balls when the shells were fired and exploded.

After the shell has been finally inspected and passed, the powder tube, adapter, adapter bottom and plug are inserted. The shell is then transferred to the loading department. The plug, adapter bottom and adapter are there removed. The spider, Fig. 121, is screwed into the thread at the open end of the shell. It will be observed that the spider is made with an $1\frac{1}{8}$-in. hole, which the powder tube fits, thus holding it central.

The shell receives ½-in. diameter balls, composed of lead and antimony, for about 4 in. of its height. Melted resin is then poured over the balls until they are entirely covered. On top of this is placed about 6 oz. of smoke compound. Another 4-in. layer of balls and resin is then added in a similar manner. This operation is repeated until the balls and resin come to approximately ½ in. from the top of the open end of the shell. The balls are fed into the shell through the funnel, as in Fig. 122. The resin is poured in as shown in Fig. 123.

*Previous installments appeared on pages 537, 581 and 625.

The reason for placing the balls and resin in the shell in layer form is to insure their cementing into a solid mass. As the shell is so large, if the balls were all inserted and then the resin poured in, the probability is that the resin would not reach between all the balls before solidifying. Under such conditions the mass would not be homogeneously held together; and when the shell was fired, it would act in a biased manner and its "flight" would not be true.

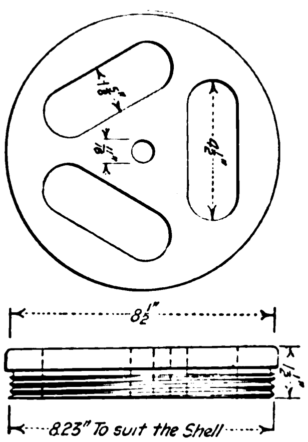

FIG. 121. SPIDER FOR HOLDING THE POWDER TUBE

Further, as all air is expelled from the shell by the resin filling the gaps between the balls, the explosive charge has less room to expand and the shell, besides being fired with a truer aim, also bursts with greater force. To insure the best results, it is found that the melted resin should be at a temperature of from 365 to 400 deg. F. Then the crevices between the balls are properly filled.

In Fig. 124 is shown the spider screwed into position in a shell ready for receiving the resin. Attention should be directed to the boss in the center of the spider, through which the powder tube fits, thus holding it in position while the resin is being poured. The spider is then removed, and the threads on the inside of the shell and adapter are covered with red-lead paint. The adapter

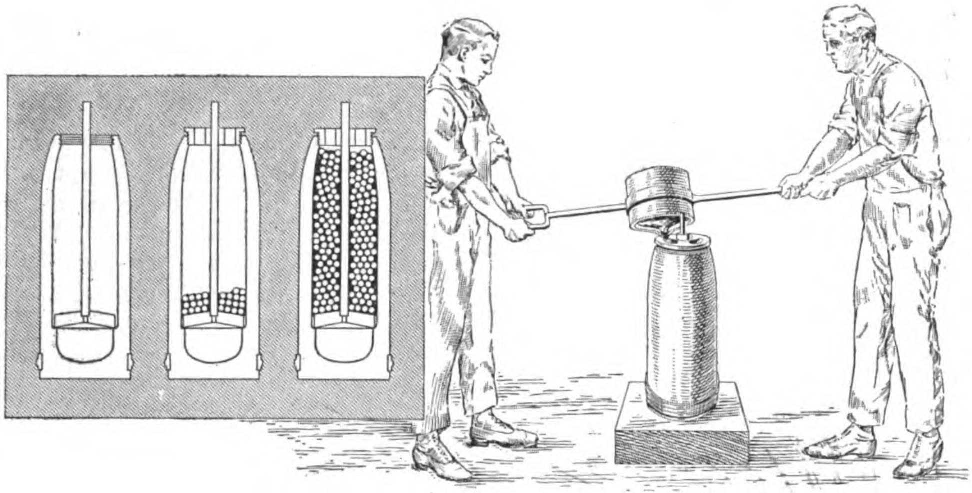

FIG. 123. OPERATION 19: FILL WITH BALLS AND RESIN
Equipment—Spider, funnel and resin-pouring pan. Production—Two men, 2 per hr. References—Figs. 121 and 122.

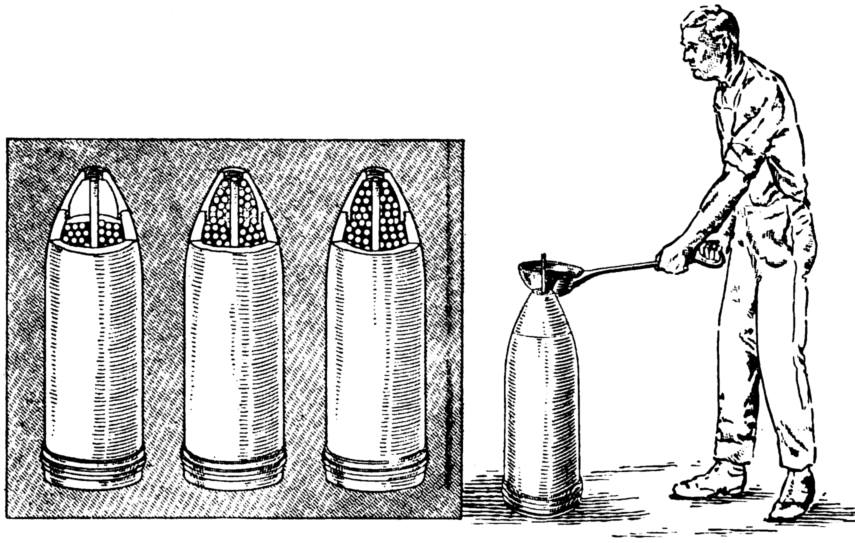

FIG. 126. OPERATION 20: FILLING ADAPTER WITH BALLS AND RESIN
Equipment—Plug to fit in top of powder tube and resin-pouring scoop. Production—Two men, 6 per hr. Reference—Fig. 125.

is screwed down, using the clamp, Fig. 34. More balls and melted resin are added until the shell weighs 729 lb.

In Fig. 125 is shown the shell set up ready for this loading. It will be observed that a plug A is placed in the top of the powder tube to prevent the melted resin from entering it. A view of the operation of pouring in the resin is given in Fig. 126.

The adapter bottom is placed in the adapter by the aid of the wrench, Fig. 127. It will be noticed that this tool is provided with a "tit" that enters the powder tube. The purpose of this is to hold the tube central while the bottom is being screwed down. The shell is left for about 4 hr., so that the resin will properly solidify and cool.

The funnel, Fig. 128, is then screwed into the end of the adapter. Powder fed into the funnel passes through the powder tube into the powder chamber. The funnel is afterward removed, and powder pellets are put into the tube. One purpose of the pellets is to prevent the powder grains from coming back against the fuse threads if the shell should be turned over. This precaution eliminates accidents that would result when the fuse is inserted, if powder grains were resting on the threads and the fuse was screwed down against them. The primary purpose of the pellet is, however, to convey the spark from the fuse to the powder chamber. Fig. 129 illustrates the funnel in position ready for pouring in the powder. This operation is shown in diagrammatical form by Fig. 130.

The plug is next screwed into the shell, which is then ready for the final weighing. In Fig. 131 one of the shells may be seen on the scales being weighed. This operation is also shown in diagrammatical form by Fig. 132. A number of shells being loaded with balls and resin are illustrated in Fig. 133.

The shells are covered with axle grease, to prevent rust, and are packed in individual cases, as in Fig. 134. The cover of the box is securely fastened down; and after the case has been properly marked, it is ready for its journey across the water. This operation is shown in diagrammatical form by Fig. 135. A detail of the packing case is given in Fig. 136.

It will be understood that the shell industry is new to most shops, and on a shell of such large size as described

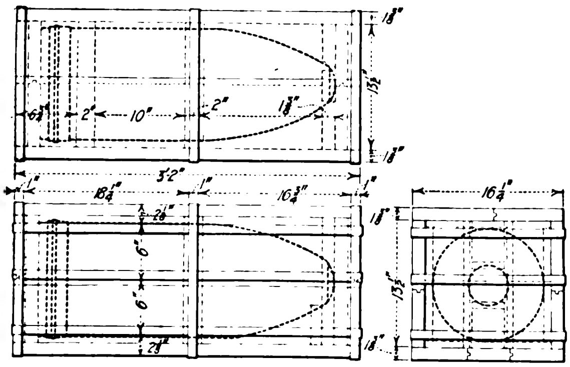

FIG. 136. DETAILS OF PACKING CASE SPECIFIED FOR THE 12-IN. SHRAPNEL

in this series some slight modifications in the machining operations will occur. However, the methods outlined enable the manufacturer to turn out shells in increasing quantity week by week and also meet the highly accurate requirements.

In the series of articles of which this installment is the concluding one it has been the aim to show the methods used in sufficient detail to act as a guide for any shop not already accustomed to shell-work requirements. It will be seen how the methods employed in making the 12-in. shrapnel differ in many respects from those previously described covering the smaller sizes. It is thought quite likely that the practice illustrated in the present instance will undergo changes as the large-shell work reaches a more abundant stage, notably in case hollow forgings become generally available in the 12-in.

Making Copper Rifling Rings

By Fred H. Colvin

Although the copper rifling ring used on the base of a shell to make it follow the rifling grooves in the gun barrel and secure the necessary rotation seems like a comparatively trifling part, it must be remembered that one of these rings is forced on every shell of every size. This fact makes their total number mount up to large proportions. The American Steam Gauge and Valve Manufacturing Co., Boston, Mass., was fortunate enough to secure a large quantity of copper tubes early in the war and is supplying bands to many who are making shells. Making rings is a comparatively simple operation, as it consists merely of cutting off the tubing into rings of the proper width; but when the product must be turned out by thousands, it becomes something of a problem to cut off the rings quickly and economically.

Two ways of cutting off are shown in Figs. 1 and 2. The first method uses a semispecial machine having a hollow spindle and a quick-closing chuck, together with a substantial cross-slide and a tailstock for stopping the tube in the proper position.

There is a power feed for the tube, which is fed against the stop at the right and then clamped by the forward lever. The tools in the cross-slide are then fed in to the work, the one at the right cutting a little in advance of the others. Each in turn is set somewhat behind its right-hand neighbor, as is usual in this kind of cutting-off work.

Each cutting-off tool is substantially held in a separate block, as shown, these tools being made of Dreadnaught high-speed steel, forged and ground on the face, as shown in Fig. 4. The groove has been found to prevent an excessive burr at the cut-off; the cutting edge is $\frac{5}{32}$ in. wide.

The cutting speed is set at 225 ft. per min., the lubricant being mineral lard oil charged with fire sulphur. On the small sizes the production is 250 rings per hour, while on some of the larger rings 110 per hour have been secured. The largest rings, as shown in Fig. 2, are cut on an engine lathe especially equipped for this work. To begin with, the tube is held in special chuck jaws, which are set out so as to first grip the tube on the inside, and then the setscrew in each jaw is screwed down against the outside of the tube. The end of the tube is supported in a substantial follow rest, which is bolted to the lathe carriage. The stop C is bolted to the other side of the

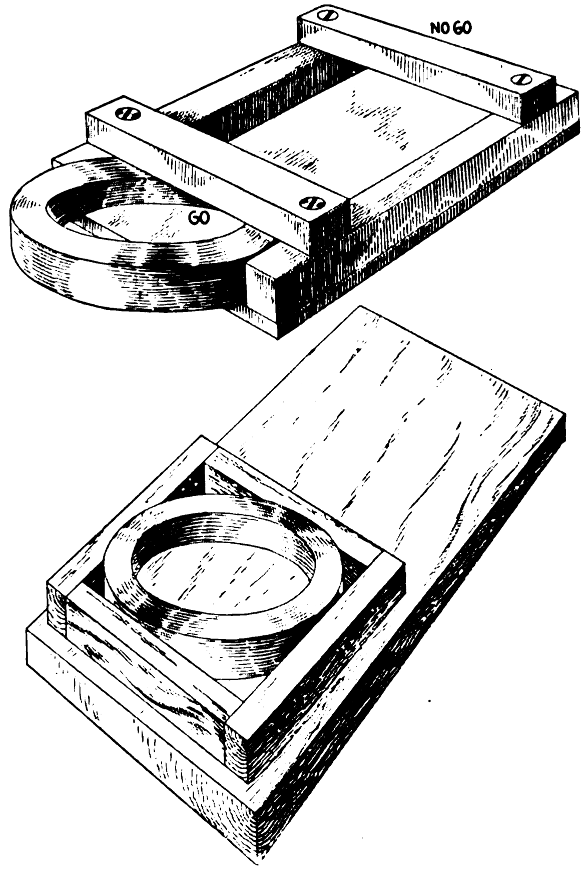

FIG. 3. GAGING COPPER RIFLING RINGS

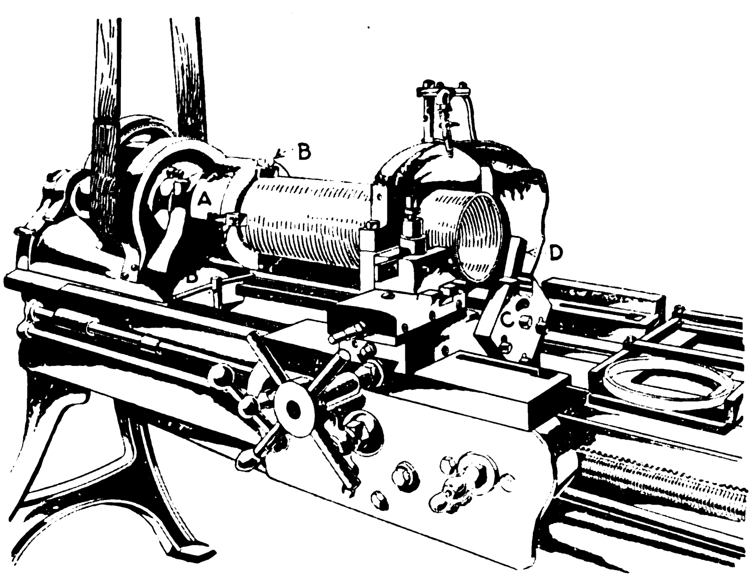
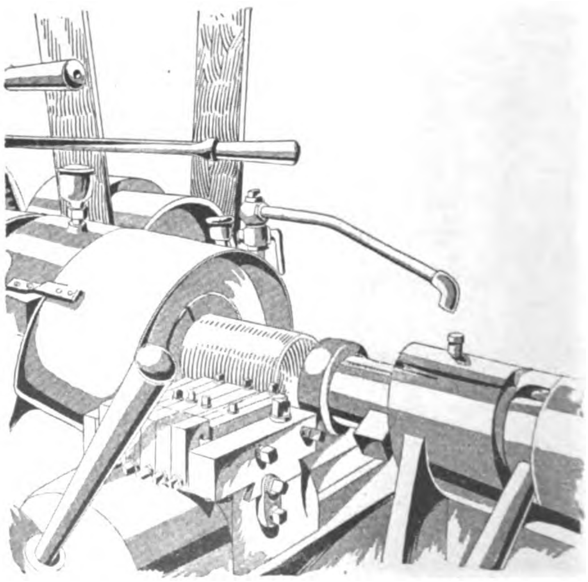
carriage and carries the distant finger D, which forms the actual stop.

The lathe carriage is moved until D comes against the end of the pipe, the cutting-off tool then being in position to make the ring of the proper width. The stop is swung down out of the way, and the cutting-off tool is fed in





FIGS. 1 AND 2. TWO METHODS OF CUTTING OFF COPPER RIFLING RINGS IN THE LATHE

by means of the large cross-handle, shown. The same lubricant and cutting speed are used on this lathe as on the simispecial machine, and the results are extremely satisfactory. Those who have had experience in cutting copper and know its peculiarly disagreeable cutting

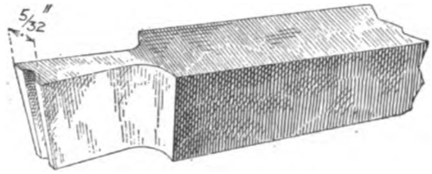


FIG. 4. THE CUTTING-OFF TOOL

qualities will appreciate the results obtained by the tools, feed and lubricants employed.

The rings are gaged by the simple device shown in Fig. 3, consisting of a steel plate with built-up sides and two crossbars of hardened steel, one forming the "go" and the other the "no-go" end of the thickness gage. In case a ring is a trifle too thick, it is placed in the shallow box built on the end of the board, shown below and the sides are taken down with a smooth file. It takes only a few judicious strokes of the file to bring almost any oversized ring to its proper thickness. While this method may seem somewhat crude, it obtains the desired results in remarkably quick time and prevents the necessity of moving the rings to a grinder or other machine.

Future of American Machine Tools in Belgian Market

By One Who Knows Belgium

Although it is early to forecast what the machine-tool business in Belgium will be after the war, it is generally admitted that immediately peace has been declared there will be considerable activity in all industries appertaining to railway material, building material, etc., in Belgium. The fact that a large number of machine tools have been taken out of the leading factories to Germany will undoubtedly create immediately a tremendous demand, and consequently there will be a very great opening for American and English manufacturers.

It is interesting, however, at first to consider what were the industrial conditions before the war. The majority of the metal-working factories in the country devoted their activities to the semifinished product; this was the dominating industry of Belgium. The fact has been confirmed in a speech made by Minister Francotte at the opening of the new factory of the Minerva Motor Co. in Antwerp a few years ago, in which he congratulated the promoters of the business on trying to extend the manufacturing capacities of Belgium in the finished article. He stated that, while Belgium was holding a considerable position in the world market for semifinished products, she was hardly recognized as an exporter of the finished article, and he urged Belgian manufacturers to devote more of their time and energy to the production of finished goods.

This situation was quite natural in view of the small area of Belgium. The home consumption was comparatively small, and in the world market Belgian manufacturers had to compete with big competitors such as America, England and Germany, all with considerable home consumption and able to reduce the cost of producing the various articles needed for their own countries by enlarging their capacities and exporting the surplus.

This situation may change after the war. As Belgium possesses a considerable number of skilled metal workers and a vast number of enterprising men, it is quite certain that many industries which have so far not flourished very greatly in Belgium will make great extensions, because in the allied countries preference will be given to the Belgian articles, provided they are produced at the same cost as in Germany and Austria.

Before the war the price of living in Belgium was rather moderate. Hence, wages were lower than in any other industrial country. It is to be assumed that after peace is concluded these conditions will still prevail proportionately and will be better than in England, France or Germany. Consequently, the lack of a home market will be compensated by the advantages arising from better labor conditions.

Steel Making an Important Industry

The manufacture of steel is one of the principal industries in Belgium, and machine tools in steel works are mostly of the heavy type. A great number of these machines formerly came from Germany, and among them are the punching and shearing machines with plate-steel frames. These were in great demand, and it might be advantageous for some of the American manufacturers to take up this line. I understand that one manufacturer has already started; it remains to be seen whether the freight conditions will allow these heavy machines to be imported from America.

Locomotive and car manufacturers also used machines imported from Germany. Lately, however, the heavier radial drills have been imported from England. The boiler and engine manufacturers, while having many machines made in America, used a considerable number of a heavier type made in Germany. The larger rifle factories, electric-motor manufacturers, automobile manufacturers, etc., had in their equipment a large proportion of American machines.

However, the vast community of manufacturers doing a medium or small amount of business formed the largest buyers of the cheaper grade of German and English machines. They did not give enough attention to the improvements of modern American and English machines and were mostly influenced by the first cost of the tools. Such manufacturers require the special attention of the American machine-tool manufacturer. They must be educated to the advantages of the labor-saving devices in American machines. After the war, while labor may be abundant in Belgium, it will be dearer than before. Consequently, much more attention will be paid to equipment that will enable the saving of this labor. This is one of the essential points of the campaign which American manufacturers will have to open as soon as conditions permit, and their arrangements should be such as to have one of their practical men on the spot, to demonstrate all the advantages of modern American tools.

As the greater part of the manufacturing plants in Belgium are owned by Belgians, it is certain that preference will be given to any machines or goods not of German make; and undoubtedly a great outburst of patriotism will take place after peace has been declared.

Before the war the Belgian manufacturers in general were not particular as to the origin of the goods they

were buying; but this situation no longer exists, and the users of machine tools will avoid as much as possible all buying from Germany or from German firms. Also, there were established in Belgium besides the German firms a certain number of other foreign dealers in machine tools. These firms were holding the agencies of renowned American and English manufacturers. It is a fact hereafter preference will be given by Belgian manufacturers to the Belgian dealers. As it is the duty of the builders of machines to please the buyer as much as possible, it stands to reason that the best policy for the American or English machine-tool manufacturers to adopt is to intrust their Belgian agency to Belgian firms of good standing.

Previous to the war the Belgian firms were not able to develop their capacity to the fullest extent, being hampered by foreign firms established in Belgium and holding agencies for several countries at the same time. Among original Belgian firms several were hard working and deserving of every assistance. They sometimes had strenuous struggles against the foreign competitors in Belgium, and it was not always the house that deserved the business that obtained it.

It is quite natural that the Belgian merchants know their market better than anyone else. They know how to deal with the consumer; they know his ways, his character and his peculiarities; they deal with him in his own language. Moreover, in the future all genuine Belgian houses will certainly not, if they can possibly help it, sell any machines made by the enemies of the country. In the case, however, of firms from neutral countries there will be no reason why they should not try to sell machines made in enemy countries, and they will consequently bring upon themselves the mistrust of the Belgian manufacturers.

Belgian Representatives Preferable

It is generally admitted that Belgium will be overrun by firms from neutral countries after the war is over, and they will try to swamp the market with any kinds of machines they can get hold of, whatever the origin. It would therefore be against the interests of American and English manufacturers to intrust their Belgian agencies to any such foreign firms.

Several large organizations seem to be formed in America for obtaining the agency of the leading American manufacturers for the European countries. Is it in the interest of American manufacturers to patronize such organizations? Some of them seem to have immense capital at their disposal, and manufacturers are of course the best judges whether it is to their advantage to place their agencies in the hands of such very powerful concerns. Aside from this, the selling organization of such firms is rather complicated, and the overhead expenses run up to a considerable percentage of the value of the machines. I believe that one large firm with a branch in Belgium had something like 17½ per cent. selling expense.

Now, is it right for the prospective buyers to pay such an extremely high margin for expense that could certainly be reduced if the concerns representing manufacturers did not handle so many different lines? It is quite natural that foreign firms having only a branch office in Belgium should have these heavy overhead charges, as they have to pay double office expenses.

If the American manufacturers arrange for the Belgian market with a firm whose head office is in New York, Paris or London, they will hardly be in direct touch with the Belgian market and consequently will not know so well the conditions there as if they were directly represented.

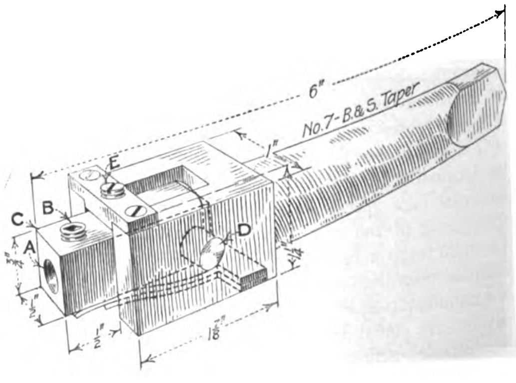
The direct representation by Americans is not to be advised, as the Belgian consumer has quite a different character and tendency from the average American salesman; as already stated, however, the latter may be of very great assistance as technical adviser to the Belgian firm, which is better able to smooth out differences arising from opposed views. Some American tool makers of repute have in late years kept a good technical man in Europe. This practice should be general, as the Belgian manufacturers doing a small business need a good deal of sound technical advice and are certainly not familiar with all the merits of American tools. In past years they have given preference to the cheaper German machines, simply on account of the price, and this attitude should and can be overcome more easily now than ever before. The opportunity should not be lost.

In conclusion it would be well for American and English manufacturers not to settle their agencies for Belgium without first completely investigating the aspirations and tendencies of the firms that solicit them. They should intrust their representation exclusively to good Belgian firms that will agree to sell nothing but American and English machines, as any other policy adopted by their agents would certainly ruin the business for the tool manufacturers.

Boring Head for Miller

By H. M. Darling

The accompanying illustration shows a boring head for use in the miller. Boring tools for this head are made of ⅜-in. drill rod and are inserted in the ⅜-in. hole *A*, being securely clamped by the screw *B*. The



BORING HEAD FOR THE MILLER

block *C* swings on a ¼-in. pin *D* and is adjusted by the ¼-in. 40 screw *E*. The swinging block is held against its adjusting screw by a strong double-leaf spring made from two pieces of $\frac{1}{16}$-in. spring steel. The two screws *B* and *E* are hollow and are adjusted by the wrench shown.

This head has a large range. I have bored holes with it all the way from $\frac{3}{16}$ to 2 in. in diameter.

Special Truck Wheel and Axle Lathe

SYNOPSIS—This lathe was built expressly for handling large numbers of small truck wheels and axles. Details of the operating mechanism show considerable ingenuity and will interest mechanics generally.

A company building large numbers of lumber-, coal-, brick- and stone-handling trucks or small cars and in consequence using very many cast-iron truck wheels decided to build a big machine capable of adequately handling both the wheels and the axles. The machine shown and described in this article was the result. This double-end lathe is in use in the shop of the Standard Dry Kiln Co., Indianapolis, Ind.

Some of the cast-iron truck wheels are illustrated in Fig. 1 and, together with the axle, will give a good idea of the work to be handled. The axles will average about 1¼ in. in diameter, and the holes bored in the wheels will run from 1¼ in. to 2 in. or more, according to the size and type of truck on which they are to be placed. The holes in the wheels are cored out, so that the operation is boring only. A two-cutter bar of the usual pattern is employed. The ends of the axles are machined with box tools that feed on both ends at once.

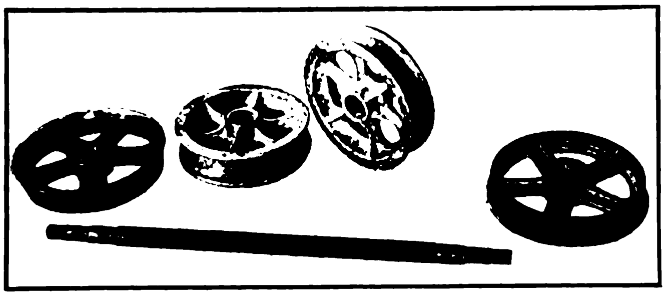


FIG. 1. SMALL TRUCK WHEELS AND AXLE

A front view of the lathe is given in Fig. 2. Here, two wheels are shown at *A* and *B*. It will be seen that the work is held in chucks of the steadyrest type, with two stationary jaws and one adjustable jaw each. Of course, the two lower jaws are adjustable for setting in the first place; but after the work has been centered, they are supposed to be let alone. The upper jaw of each chuck is carried in a swinging yoke in exactly the same way as on a regular lathe steadyrest. A handwheel on top, as at *C* and *D*, enables the operator to lock the wheels tightly in place after the yokes have been swung down and clamped by handwheels *E* and *F*. Boring bars feed into the cored holes of the wheels from each end of the lathe in opposite directions, so that both wheels are finished simultaneously. In machining axles the chuck jaws shown are replaced by longer ones, and an axle is held in them with the ends projecting far enough to allow box tools to be fed on and both ends finished at once.

In Fig. 3 is a rear view of the machine. It measures 14 ft. in length, 3 ft. in width and is about 5 ft. 6 in. to the top of the upper handwheels. It will weigh approximately 5 tons. About 700 wheels per day are bored out, or about 70 per hr. This makes 35 per hr. for each spindle. The axle output averages about the same.

The main drive of the machine is by a five-step cone *A* driven by the belt *B* from a countershaft above. This five-step cone is placed directly on the end of the shaft *C*, which runs the entire length of the machine and is geared to the large gears *D* that drive the boring spindles at each end. A pulley *E* is placed on the shaft *C*, and from it a crossed belt runs to a jackshaft above. Pulleys on each end of the jackshaft are belted to pulleys like *F*, which drive the feeding mechanism at each end. The handwheels *G* on the front of the machine enable the operator to run the boring spindle in or out when the feed clutch is not engaged. The entire feed mechanism is thrown in or out on the end shown, by the lever *H*. However, this action will not start the feed unless another intermediate clutch is also thrown in. As the clutch is thrown in by the lever *H*, the worm *I* turns and causes the worm gear *J* to rotate, revolving the shaft *K*. Now if the feeding of the boring spindle is desired, the clutch operated by the lever *L* must be engaged. The clutch jaws are shown at *M*; and as these engage, the feed bar is fed along through a rack and chain of gears *N*.

A similar mechanism, which operates on the opposite end of the lathe, may be seen with the same lettering in Fig. 4; but some other parts are shown more plainly. The feeding of the boring spindle *S* is controlled by a sliding rack *O* yoked to the spindle by the bracket *P*.

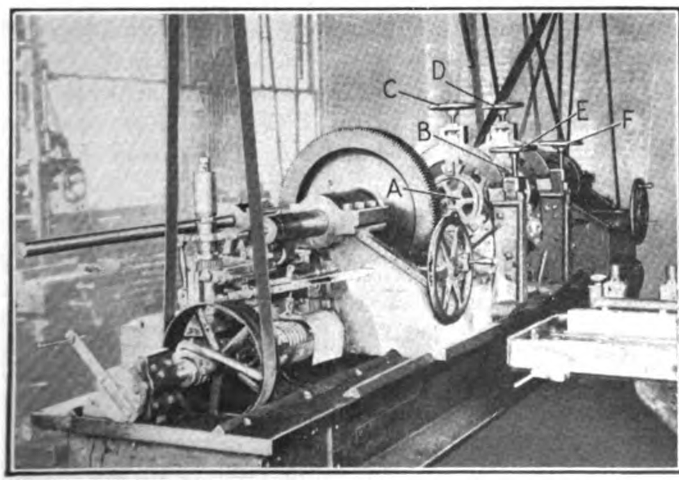

FIG. 2. FRONT VIEW OF WHEEL AND AXLE LATHE

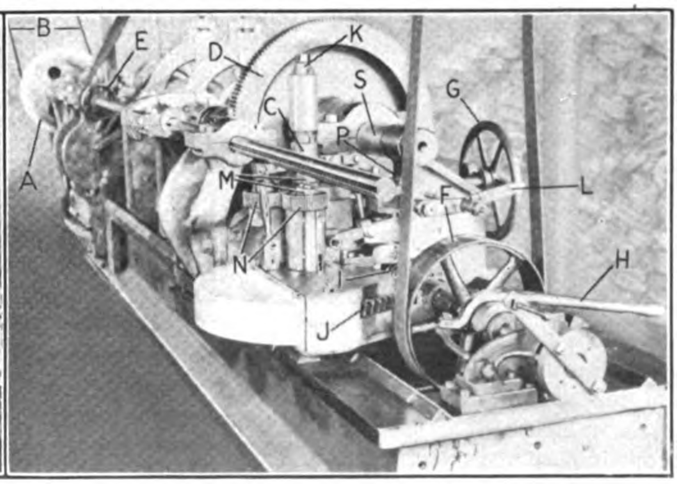

FIG. 3. REAR VIEW OF LATHE WITH WORK IN PLACE

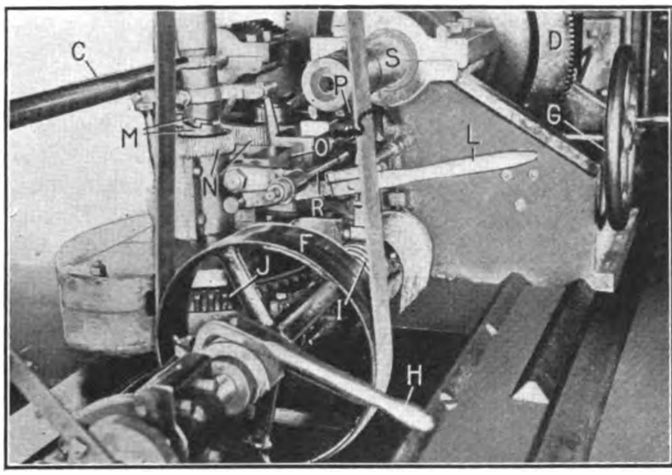

FIG. 4. CLOSE VIEW OF FEED MECHANISM

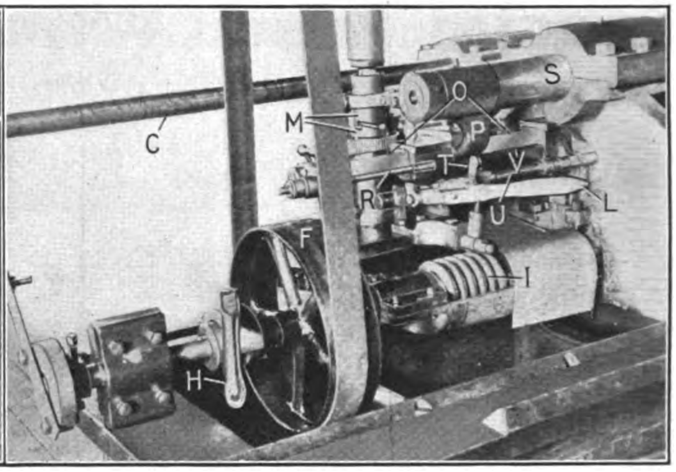

FIG. 5. ANOTHER VIEW OF FEED MECHANISM

The rod *R* is an adjustable stop for knocking off the feed clutch *M*. As the chain of gears operates, the feed-bar rack *O* moves along and carries the boring spindle *S* with it. This is more clearly shown in Fig. 5, which is also lettered in the same way as the two previous views. This illustration shows the clutch not engaged; but when it is engaged, the lever *L* is held down by a hooked piece *T* that is held secure by the spring *U*. The bar *O*, the spindle *S* and the stop *R* move along together until the

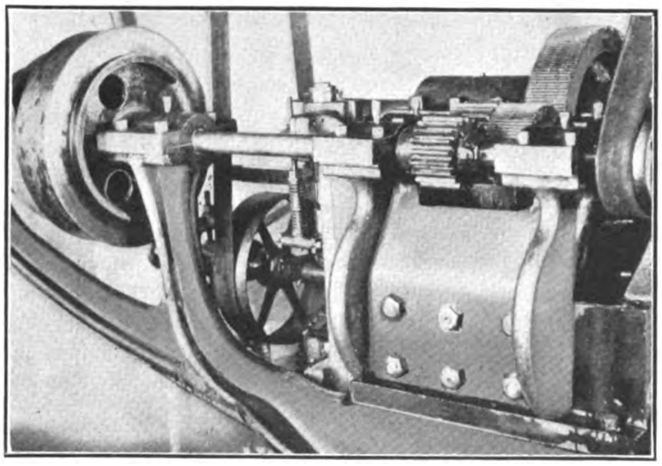

FIG. 6. CLOSE VIEW OF DRIVING END

end of the stop *R* hits the end of the hooked latch *T*, when the clutch level is released and flies up, throwing out the clutch and stopping the feed movement. Rack teeth are the ones with which a pinion operated by the handwheel *G* meshes. This relation will explain how the boring spindle is moved out or in when the feed clutch is out of engagement.

Fig. 6 is a close view of the opposite end of the machine. The driving and feeding mechanism is practically the same, except that it is placed more under the head and carries the cone-pulley bracket in addition.

The 60-Deg. Screw Thread

It was anticipated that there would be some difficulty in duplicating European sizes and fits on munitions, but that this trouble should lead to the adoption of United States standard proportions was not expected. However, in one important particular the unexpected has happened.

In the Mark-VII British fuse, as recently modified in design from the former Mark-V fuse, all of the screw threads, with a single exception, are 60 deg., three being A.S.M.E. standard, eight U.S.S. and the one exception Whitworth standard. The latter is used for the thread where the fuse screws into the nose of the shell and could not be changed because of the necessity of having any fuse assemble with any shell. The list of threads of the new Mark-VII is as follows:

Part	Pitch	Diameters in Inches Maximum	Minimum
A.S.M.E. Standard			
Setscrew for cap	32	0.164	0.1593
Needle plug	24	0.216	0.2108
Screw plug in base plug	24	0.190	0.1848
U.S. Standard			
Time-pellet plug	24	0.299	0.296
Time pellet	24	0.303	0.300
Percussion pellet	24	0.303	0.300
Percussion-pellet plug	24	0.299	0.296
Thread on stem of body	14	0.866	0.858
Thread in cap	14	0.872	0.867
Thread on base plug	24	1.378	1.374
Thread in body for base plug	24	1.383	1.379
Whitworth Standard			
Base of body	14	1.996	1.990

This change of standards proves the difficulty of overturning settled shop practice, for the modification was made to facilitate production in the United States and Canada and for no other reason. The question is also raised whether or not the American 60-deg. thread is a form that possesses inherent advantages that make it easier to cut with small tolerances than the Whitworth shape. A definite answer to this query would be instructive.

Properties of Steel

A review of the work done in correlating the magnetic and mechanical properties of steel has been published by the Bureau of Standards, Department of Commerce, in its Scientific Paper No. 272. Special attention is paid to the commercial application of the magnetic data as criteria of the mechanical fitness of a given steel and of magnetic changes of steel under stress as indications of the state of strain. The evidence presented shows that the interrelation of the magnetic characteristics and the mechanical behavior of steel is so close that the magnetic examination in conjunction with the mechanical tests may be expected to add considerably to our knowledge of the material.

The magnetic method tests the whole amount of material and not merely some surface phenomenon. It does not destroy the test piece, but leaves it unaltered. Thus it is possible to apply a magnetic test to the identical material that is to enter into a given structure.

Specifications for Purchase of Leather Belting

SPECIAL CORRESPONDENCE

SYNOPSIS—In general, present-day leather belting specifications are largely confined to describing minutely how belting should be made, without prescribing satisfactory tests to determine whether or not it has been so made. As a result, most buying has been done on price alone. The author points out the absurdity of this course and makes a plea for new specifications safeguarded by proper tests and prepared from the viewpoint, "What service will the belt give?"

Leather belting, one of the oldest means of power transmission, is still the best for general use on all but the heaviest machinery. Substitutes in great number have been developed, but more leather belting is used today than ever before. Repeated predictions of the failure of the raw-material supply have not materialized, nor will they as long as the human race continues to require an increased food supply. Confirmation of this statement may be found in the splendid response of the leather industry to the unprecedented demands created by the European War. Leather belting will continue to be widely used for many years to come.

Satisfactory belt service is an important factor in the production of nearly all manufactured goods, and in cases where competition is especially keen the success of the enterprise depends upon continuous maximum output. Yet little is known, even by large users, of the actual physical properties of leather belting, and most of it is purchased without any attempt to forecast its performance in service. Most buyers make no real attempt to determine which of the numerous brands offered at the same price are superior or, where prices differ, which offers the best value. Lowest cost per belt per year is seldom the governing consideration. Some large users invite competitive bids on uniform specifications, but only a small part of the total output is purchased on anything but a price basis.

Defects of Present Specifications

A careful survey of current specifications in use by Federal and municipal governments, railroads and large manufacturing corporations reveals many indefinite, useless and even misleading clauses, of which the following will serve as examples:

All butts used in the construction of this belting shall be of No. 1 selection, free from all defects and blemishes and of the native packer-steer hides class, tanned by the slow oak-bark process.

No solutions or bark or wood extracts shall be used, nor any chemical or electrical process used to force or hasten the process.

The leather shall be stretched in straight-edged clamps . . . Centers and sides must be stretched separately.

The scarfing, joining and cementing shall be done by expert and experienced workmen. . . .

. . . all sizes below 8 in. shall not be cut from any other section but the quality area, which extends not more than 15 in. each side of the backbone. . . .

. . . absolutely no shoulder or belly stock shall be used.

The finished leather shall be smooth to the touch on both sides. . . .

. . . the leather shall show no excessive amount of matter soluble in water nor of ash. . . .

Each piece shall be of fine close fiber, and all pieces shall be of uniform thickness.

Each piece shall be stretched by hand.

Dressing must be mixed hot in a double tank and applied with a brush.

Most of these requirements are such that the purchaser, or even an expert belt maker, cannot be sure that they have been carried out. Others do not represent best modern practice, and nearly all ignore the purpose for which the belt is to be used—the transmission of power. Such specifications discourage progress in the art, place the reliable belting manufacturer at the mercy of his unscrupulous competitors and make it impossible for the user to ascertain the merits of competing brands. Some of the most important characteristics of good belting, such as pliability and durability, are not even mentioned.

In general, present-day specifications are largely confined to describing minutely how belting should be made, without prescribing satisfactory tests to determine whether it has been so made. As a result, most buying is done on price alone, with no standards by which to judge relative values. Such is the situation at the beginning of 1916.

The Advent of More Intelligent Buying

Each year sees fewer advocates of price as the first consideration in the purchase of materials and a keener realization that the true basis is lowest ultimate cost. More and more frequently the purchasing officer is an engineer or makes excellent use of his company's engineering organization to determine true ultimate cost. The result is a gradual casting off of antiquated trade customs, the establishment of rational specifications based on the service expected and the development of fair and accurate tests. If the work is well done, both the buyer and the seller are greatly benefited. To the manufacturer is presented the opportunity to get away from unfair price competition by obtaining recognition for quality, while the user, provided with definite standards and means for testing, can be sure he is getting what he pays for.

The essential features of any specification are: (a) Explicit requirements based on the service expected; (b) definite tests to show whether the requirements are met or not. Present belting specifications do not even approach a fulfillment of these conditions, and much must be done to improve them before they will be fair to either maker or user. The task is difficult, because the raw material grows on the back of an animal and cannot be made to develop every desired characteristic. Furthermore, it is essential that means be provided to determine in advance, approximately at least, what kind of service the belting will give, so that if necessary it may be rejected. All tests laid down must be such that they may be performed quickly and cheaply, that they may be reproduced with concordant results at any time and, above all, that they do not discourage progress. All reference to the details of manufacture should be omitted and the way left clear for new and better methods. The

main issue is not, "How has this belt been made?" but, "What service will it give?"

Much careful study of these matters will be necessary on the part of both makers and users before real progress can be made toward better conditions. The following tentative suggestions are put forth to stimulate thought and research rather than as concrete proposals:

Strength—Ultimate tensile strength should be as high as possible without sacrificing other desirable qualities, in order to protect the belt from unusually severe strains to which most belts are occasionally subjected. This is now commonly specified in pounds per square inch—a thoroughly unsound practice. Two hides of the same thickness may be manipulated during tannage and the subsequent processes so as to produce finished leather of appreciably different thickness; yet they contain the same amount of fiber and show approximately the same strength for equal widths of belt. The power required to drive a given machine, its belt speeds and pulley widths are determined by the builder and can seldom be changed by the user. The latter is therefore not primarily interested in the strength per square inch of cross-section, but is vitally concerned in the strength per inch of width. To give the user what he really needs and still be fair to all makers of belting, tensile strength should be specified in pounds per inch of width.

Stretch—A belt that stretches unduly in service is a source of considerable trouble and expense, yet it must yield instead of breaking when subjected to severe strains. Even when operated far below its capacity, however, leather will permanently elongate in service for some time after installation. Manufacturers aim to remove as much of the natural stretch of the leather as may be done without damage to its other properties, but depend upon the judgment of the individual workman. If his judgment is faulty in either direction, the belt will be unsatisfactory. The best present method of testing this important property is by observing the elongation of a test specimen at rupture or some fixed strain, but we have no assurance that this bears any direct relation to elongation in service. Some way of predetermining this point would be of great value. Existing specifications allow 8 to 12½ per cent. elongation of the test specimen, but actual tests of the best brands show double this amount.

Pliability—The value of the power consumed in friction between the fibers during the life of a belt is probably many times the cost of the belt. Even a small gain in pliability would therefore be quite worth while. Greater pliability also means better pulley contact and less slip. Yet present specifications are wholly silent on this subject. An accurate method of testing for pliability should be worked out and belt makers given every inducement to develop this quality.

Thickness—As a general rule, the thinner the belt the less power required to bend it around the pulleys, the less wrinkling on the inside and the less stretching on the outside. This means better pulley contact and less internal friction, resulting in better service and longer life. Hence it would seem desirable, from the user's standpoint, to place a premium on the thin, strong belt. This should not be done, however, at the expense of more important properties. Whatever the thickness, it is of prime importance that it be uniform, especially on light, high-speed machines where vibration is serious. More attention to this point would result in decreased upkeep expense on the machine and better quality in its output. Most specifications ignore this feature entirely or require the thickness to be "uniform." It is obvious that some tolerance must be allowed, and $\frac{1}{32}$ in. is entirely feasible, although this degree of uniformity is seldom attained unless careful inspection is enforced.

Weight—This is now specified in ounces per square foot. This practice is a clumsy attempt to indicate, in connection with the prescribed tensile strength in pounds per square inch, the total strength of the belt. Prices are quoted per foot of length, but belting is really sold on the basis of weight—a custom that gives the dishonest manufacturer an opportunity to stuff his product with white lead or other heavy material, bringing light-weight stock up to standard weight. The users should have little or no interest in weight, if the other characteristics are right, and this premium on deception should be entirely removed. The self-interest of the maker would then lead to the lightest weight consistent with the required strength. Thus would be attained the nearest practicable approach to the zero weight of the ideal belt. With strength specified in pounds per inch of width, thickness and weight need not be mentioned.

Piping—When a belt passes over a pulley, the inner surface is compressed and forms corrugations. A certain amount of wrinkling is inevitable; but when it becomes very pronounced, the area in contact with the pulley is materially lessened. This condition is known in the trade as "piping." It is universally agreed that piping should be absent in first-quality belting, yet the borderland between permissible wrinkling and objectionable piping is still shrouded in mystery. At a meeting of belt manufacturers not long ago not one was able to put into words his idea of what constituted piping.

Cemented Joints—Poor workmanship or material at the joints will cause more trouble than any other defect. Great advances have been made in recent years along both these lines, and it is no longer necessary to resort to riveting or sewing. With reasonable care a cemented joint should be as strong as the remainder of the belt and should be so specified.

Injurious Blemishes—Current specifications as a rule do not discriminate against soft spots, knife cuts, grub holes and other injuries that weaken the belt and shorten its life. Healed barbed-wire scratches and similar surface defects are harmless. Such a thing as a perfect hide is unknown in the trade, but proper selection of the strips from which the belting is made should eliminate most of the injurious blemishes. Such selection should be insisted upon in first-quality belting.

All these matters and numerous others (such as the effect of varying humidity, dust, heat and fumes; the best methods of lacing; whether the points of laps should run toward or away from the pulley; and proper working tensions) offer fruitful fields for research. The ground to be covered is so great that no single commercial organization can afford to undertake it all. Lacking a Federal Department of Manufactures, much can be accomplished by hearty coöperation between manufacturers and consumers. An engineering bureau maintained jointly by all makers of belting and given every opportunity for study in the plants of their customers would be of great service to the manufacturing industries.

Making Small End Mills

EDITORIAL CORRESPONDENCE

SYNOPSIS—In making the tools and fixtures shown here great care was necessary in order to produce accurate work rapidly enough for commercial purposes. They are so designed that the output of one about balances that of another.

For making a large number of small end mills of various sizes special fixtures had to be designed and made in order to produce the pieces with sufficient precision and rapidity. These small end mills are being made by the Grayson Tool and Manufacturing Co., Indianapolis, Ind., which also made the fixtures. The mills are of the four-fluted type, and a number of them are shown in Fig. 5. Two sizes only are quoted in this article, but a number of other small sizes are also manufactured in this shop. The larger size is made from $\frac{1}{4}$-in. drill rod, cut into $1\frac{1}{4}$-in. lengths. The smaller size is from $\frac{3}{32}$-in. drill rod cut into $1\frac{1}{2}$-in. lengths. The cutter diameter of the former is 0.180 in. and of the latter 0.105 in., with 0.0015 limits in both cases.

The flutes are milled in a Brown & Sharpe miller, using four milling cutters on the arbor and a special indexing fixture to hold the work. Both the indexing fixture and the milling cutters are so made that by a slight shifting of the table and a movement of the work holder either the flutes or the ends of the small end mills may be machined. Fig. 1 shows the fixture set for milling the flutes. The blanks are held in the fixture by spring collets operated by crosshandles at the back. The holding spindles are indexed separately, each one being supplied with a disk notched quartering, into which a spring latch engages. Between each pair of holding spindles there is set a bevel-end locking-pin, which is pressed down by means of the strap and capscrew shown on top. In this way the tightening of the capscrew locks all four of the spindles. For milling the flutes the regular table feed is engaged in the manner shown in Fig. 1.

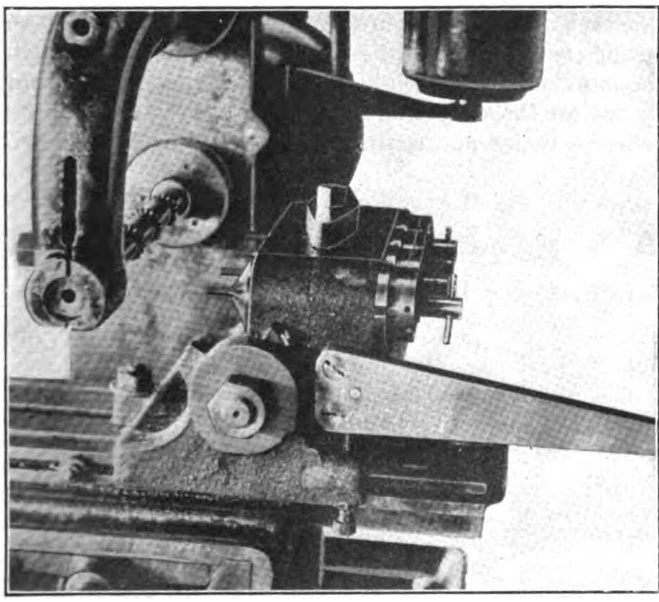

FIG. 1. MILLING THE FLUTES

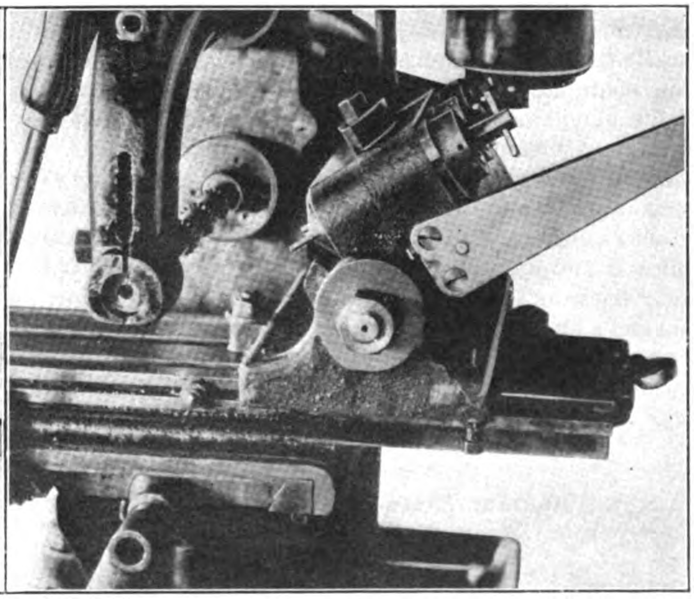

FIG. 2. MILLING THE ENDS

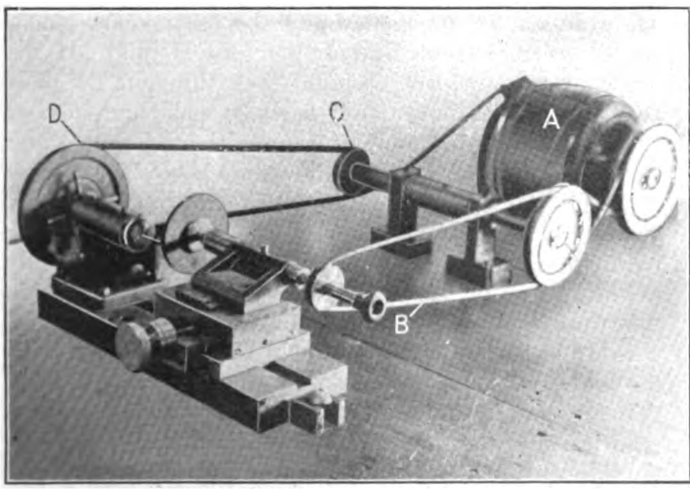

FIG. 3. SET FOR CIRCLE GRINDING

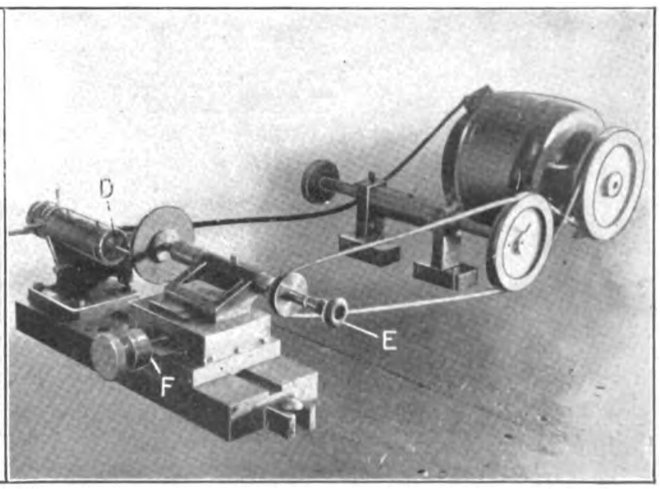

FIG. 4. SET FOR GRINDING THE RELIEF

The ends of the small cutters are milled by shifting the table over so that the opposite sides of the arbor mills will contact with the work. The table is also raised and the fixture tilted, as in Fig. 2. Adjustable stops are provided on the fixture, and the table is set by means of the graduated dials.

After being milled, the cutters are carefully hardened and drawn and are then ground. The grinder is made both to circle-grind and to relieve. The machine set for

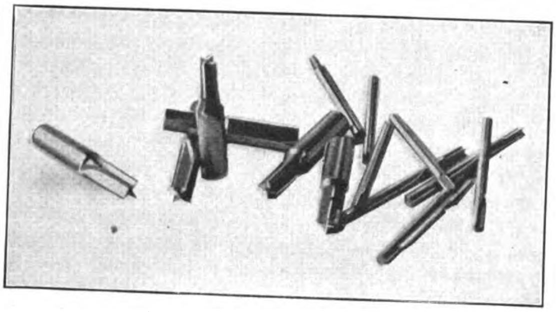

FIG. 5. SMALL END MILLS

circle-grinding is illustrated in Fig. 3. From this view it will be seen that the motor A runs the grinding spindle by means of the belt B, which is crossed so as to run a jackshaft carrying the small pulley C on the opposite end. This small pulley is belted to the pulley D on the outer end of the spindle holding the work, which is slowly revolved while the grinding wheel runs at a high rate of speed.

After the mills have been circle-ground, the pulley D is removed and the machine set for grinding the relief, as shown in Fig. 4. The indexing is done by a notched collar E and a spring stop. The grinding wheel is fed along the work by pushing on the knob E. A micrometer dial and a knurled knob F give an accurate means of cross-feed when needed. A 3-in. wheel is used, running at about 7,000 r.p.m., and the output is 500 end mills per 10-hr. day.

Adjustable Bushing and Center

By F. Fisher

The adjustable boring-bar bushing shown in Fig. 1 enables one to take up all the looseness and shake from the bar and at the same time allows perfect freedom for

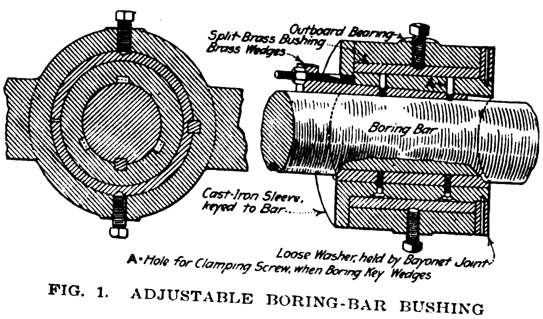

FIG. 1. ADJUSTABLE BORING-BAR BUSHING

its regular working movement. We have one of these bushings for each size of bar in use, the outside diameter of the cast-iron sleeve being made a standard size to fit the brass bushing in the outboard bearing or steadyrest. The latter bushing is keyed into the bearing, is split and is provided with adjustment screws to take care of wear and slight variation in size of the different bushings. The holes A are provided for clamping screws when boring key wedges.

The other detail, Fig. 2, is an adjustable bushing, or rather centering plug, for hollow shafting and similar jobs. We have a good many heavy drum shafts to make with a large hole through the center for a clutch-operating device. We find that, after the hole is bored, the shaft is apt to be out of true. We accordingly make

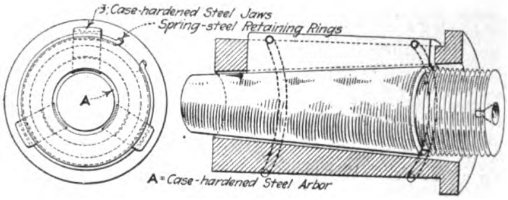

FIG. 2. ADJUSTABLE CENTER PLUG

the finishing cut and do the grinding after this hole has been made. The adjustable plugs are used to center up these shafts. They accommodate themselves nicely to any variation in the size of the rough-bored holes and are easily removed when the job is finished. The two spring-steel retaining rings, which are threaded through the movable jaws, not only tend to keep these jaws drawn in against the wedge, but also keep them from dropping into the center of the sleeve when the plug is removed.

A Suggestion on Preparedness

By Burton A. Prince

One of the problems that sometimes confronts the public-school machine shop is the matter of securing sufficient commercial work to keep everybody busy on it. Of course, there is generally enough of that variety to be obtained; but then, too, there is the danger of incurring the enmity of the local union, if too much commercial work is taken on.

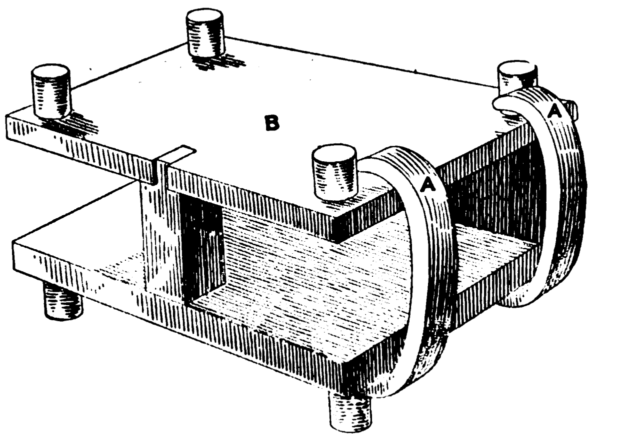
If the Federal Government is shortly to become a partner in the matter of educating boys for the trades, it seems only fair that it should get some return for its money; and I should like to offer the following scheme, which will be of benefit to both parties concerned, giving one a return on its money and the other some much-needed work. Briefly stated, the idea is this: If the proposed preparedness program goes through, the War Department will immediately begin to make and store at least another day's supply of ammunition—shrapnel and high-explosive shells. The different school shops are as well equipped for some parts of this work as were many of the commercial shops a year ago and would require no more changes to make shrapnel or parts thereof. It would be possible for the War Department so to divide this work that some of it could be done in the schools, possibly in such amounts as would be in proportion with the amount of money paid in aid to that particular school.

Before people land too heavily on this scheme, let them keep in mind the fact that a big percentage of the ammunition made today is being turned out by women and boys.

Letters from Practical Men

Rocker Arrangement on Jigs

In designing jigs it is often necessary to drill from the top and bottom of the jig. To drill from the bottom, feet must be put on the lid. After the holes are drilled from the top, the jig is turned over on the feet in the lid. If a jig is not equipped with the rockers shown at *A*



ROCKER ARRANGEMENT ON JIGS

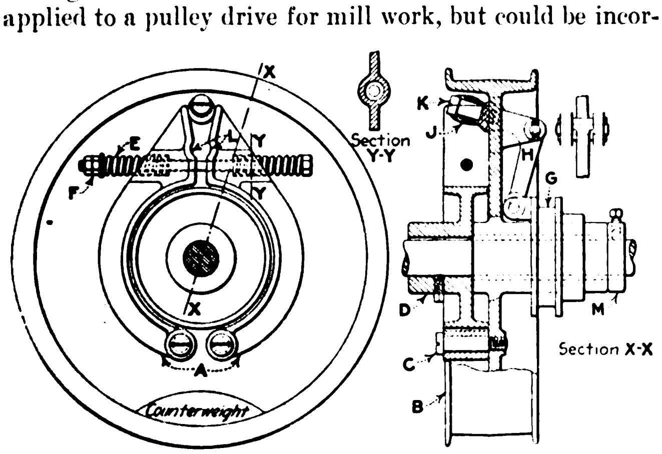
in the illustration, the edge of the lid *B* hits the drill-press table, and the lid may be injured or the jig thrown out of alignment.

The rockers do away with this trouble and also make easier the handling of the jig. These rockers are made of cold-rolled steel $\frac{5}{16}$ to ½ in. thick, to suit different sizes of jigs. B. Maxman.

Dayton, Ohio.

Design for a Friction Clutch

In the illustration is shown a design for a friction clutch having some unusual and desirable features. It is shown applied to a pulley drive for mill work, but could be incorporated in almost any design of clutch mechanism. Its favorable features are: (1) Few parts of rugged proportions; (2) it is free from end thrust, except a very small amount during engagement; (3) it is easily adjusted to any load; (4) the shifting sleeve revolves only when the clutch is engaged.



DESIGN FOR A FRICTION CLUTCH

Two clutch shoes *A* are hinged on the center web of the pulley *B* by a screw *C* and are drawn into contact on the drum *D* by the two helical compression springs *E*. These brake shoes are lined with a friction lining, preferably of the woven-wire asbestos-fabric type. The compression on the springs is regulated by the nuts *F*, and the loading of the spring determines the driving power of the clutch within the limits of the design. When the two clutch shoes are in the position illustrated, the clutch is engaged.

If the shifting sleeve is moved in the direction of the arrow, it will transmit a motion through the bell crank *H* such that the roller *J*, on the stud *K*, will be forced between the inclined or beveled jaws of the clutch shoes, thus separating the shoes and disengaging the clutch. The reverse of this operation will cause engagement. The clutch is held in the disengaged position by having the roller fit the depression *L* in the clutch shoes. The collar *M* is used to retain the whole assembly in place against the drum.

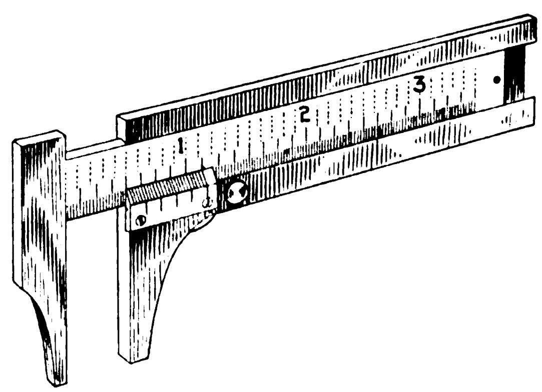
It is necessary in designing such a clutch to recognize the effect of centrifugal force and to proportion the compression springs accordingly. Also, a counterweight should be provided, as shown. W. Burr Bennett.

Bridgeport, Conn.

Button Gage with Vernier Reading to Thousandths

One of our surface-grinder operators had a lot of fairly accurate work that, because of its shape, could not be measured with a micrometer. He did not want to buy a vernier caliper, so to overcome the difficulty I fixed up a tool that was accurate enough.

He bought a Starrett button gage, graduated in fortieths of an inch, upon which I set a vernier plate.



BUTTON GAGE WITH VERNIER

I was surprised at the accuracy of the tool. In testing it out I made a large number of settings, checking them up with micrometers. None of these settings was out more than a scant half-thousandth, and most of them

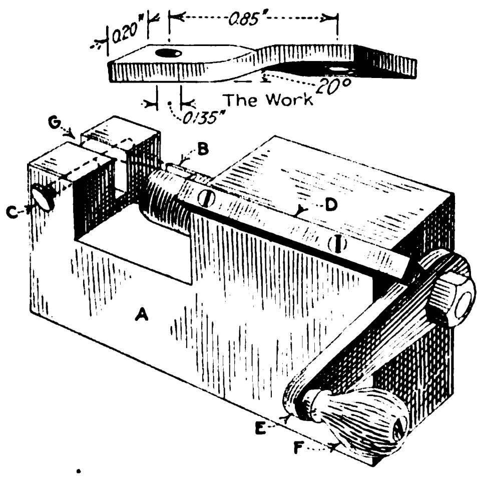
were much closer. I graduated the vernier scale by fastening it to an angle iron on a surface plate and marking the divisions with my Brown & Sharpe height gage. Every fifth graduation on the button gage was longer than the rest, to facilitate reading it. I extended every fourth graduation as shown by dotted lines in the illustration. H. M. DARLING.

Greenfield, Mass.

Hand Bending Fixture

The machine part illustrated is of $\frac{5}{16}$x0.083-in. oval-edge cold-rolled steel. The specifications require that it shall have a twist of 20 deg. at a certain part of its length. Just how to do this work in a power or hand press was a question, so a hand bending tool was designed.

The machinery-steel base *A* has a slot to receive the work. It is bored to take the locating pin *C* and a tool-steel stud *B* whose function is to bend or twist the part to be made. It will be seen that *B* is operated by the



HAND BENDING FIXTURE

crank *E*, which is fitted with a wooden handle *F*, the whole fastened to *B* by a hex nut. A steel piece *D* is fastened to *A* by screws and acts as a stop, allowing *B*, *E* and *F* to travel only a required distance.

The operation is as follows: The part is placed with one end in the slot *G* and with the locating pin *C* in the hole. The other end is in the slot in *B*. The operator grasps the handle *F* and rotates it until *E* comes in contact with the stop *D*, when the work is completed. GEORGE P. BREITSCHMID.

Arlington, R. I.

The Use of Stellite for Fine Brass-Turning Tools

I wish to contribute my mite to your columns in return for the many good things I have gained from the *American Machinist*. I have been trying out an alloy of chromium and cobalt (Stellite) for lathe tools in my laboratory and find it truly remarkable for holding its edge on unannealed steel at high speed. This quality, I believe, is of common knowledge.

Recently I have been using it for fine brasswork and find that it leaves the most beautiful finish—such as is found on the higher grades of optical and mathematical instruments. This surface is at present obtained only by skilled workmen and the use of carefully graded emery papers. Tools of this alloy leave the work finished perfectly, and the lacquer may be applied at once, thus saving much time and preserving the sharp edges and square shoulders so apt to be dulled by the use of emery paper. This feature may be new to some of your readers and may suggest applications of stellite for other brass work.

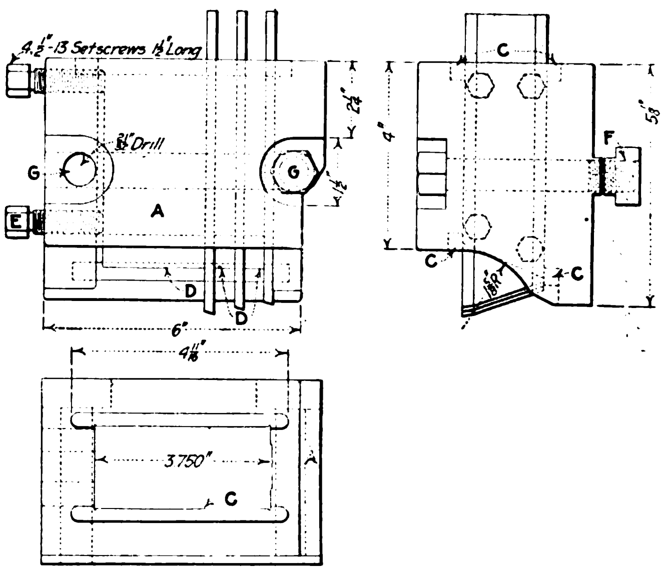
I am inclined to the opinion that this characteristic is not so much due to the property of the alloy to keep its edge as to the fact that its peculiar dense structure enables it to be given a more perfect edge than can be given to other alloys. FRANK D. SKEEL, M. D.

New York City.

Cutoff Block for Automatic Screw Machine

It is often profitable to form two or more pieces at once. For such jobs the block shown in the illustration was designed for holding a number of cutoff tools.

The body *A* is made from a solid machine-steel block, with the rectangular hole milled and planed in to take the cutoff tools. The dimension *B* is 0.005 to 0.012 in. larger than the cutoff tool. This clearance is provided so that the cutoff tool need not be a tight fit all the way across the block. In order to make the tools fit tight,



CUTOFF BLOCK FOR HOLDING MULTIPLE AUTOMATIC SCREW-MACHINE TOOLS

four strips are inserted at *C*. Slots are milled in so that the strips will press against the cutoff tools, thus insuring a tight fit at all times. The cutoff block is set on the front cross-slide. Shims *D* are made for each different width of piece to be cut off.

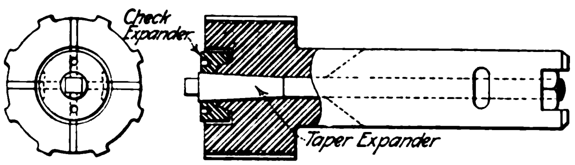
The tools are held by the four screws *E*, which squeeze the tools together. A clamp *F* is put in the tee slot of the cross-slide, and the block is tightened down with the two bolts *G*. The cutoff tools are set one ahead of the other, the pieces drop off very easily and are held to size.

This tool is used on all cold-rolled steel parts where there is no facing or counterboring operation.

Dayton, Ohio. RAYMOND W. BECKMAN.

Parallel Expanding Tap

The illustration shows an expanding tap that, I think, has improvements over others that I have seen. The expander regularly used will not expand a tap parallel; it makes the tap larger at the end. Also, the tap will



A PARALLEL EXPANDING TAP

not hug the expander as it should. In other words, the tap will make a smaller hole than it measures before using.

The check expander corrects these faults. It causes the tap to expand parallel and enables one to measure the tapping size correctly. This feature should prove valuable in shell work, where the limits are fairly close.

Kenosha, Wis. ERIC HAWKINSON.

Spring-Plunger Gages and Two Other Small Tools

Two gages that are used in a factory where accuracy is important are shown in Figs. 1 and 2.

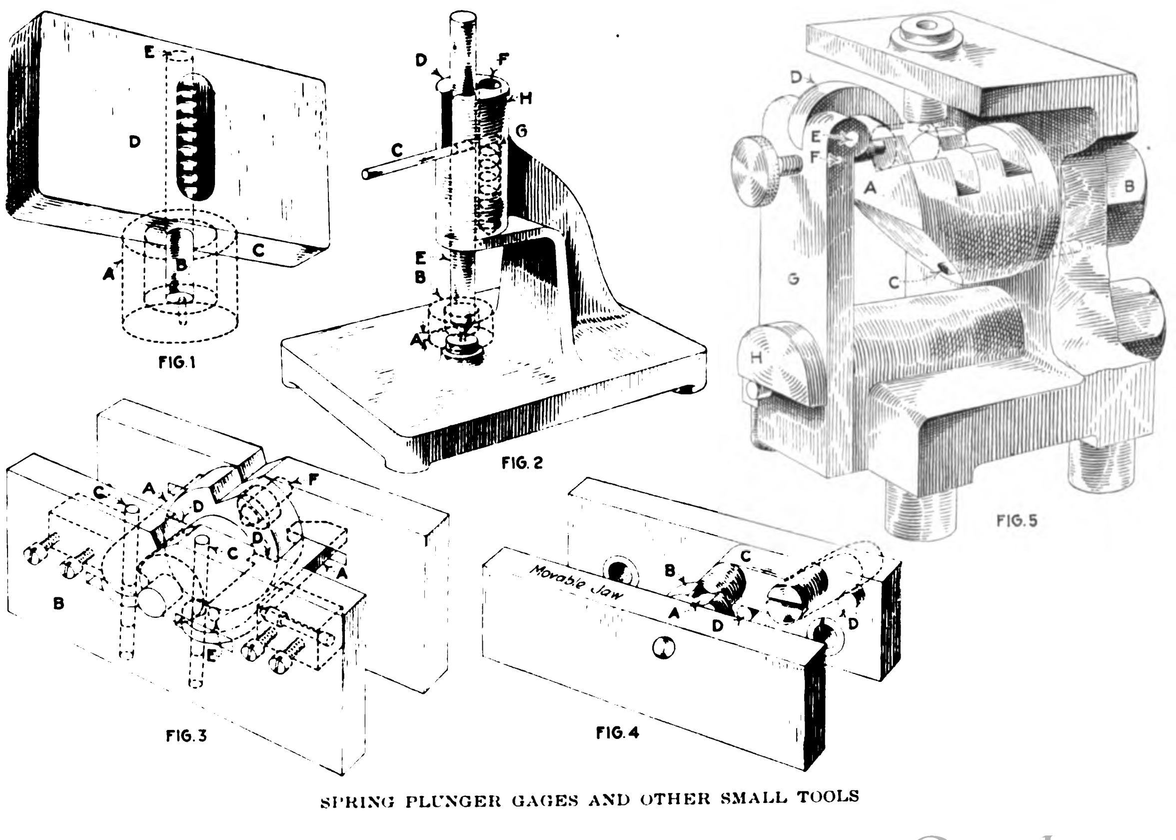
In Fig. 1 is shown a tool for gaging the depth of the piece *A*. Assuming the depth is to be 0.406 in., the plunger *B* must project 0.406 in. from the bottom edge *C* of the body *D*, while the top of the plunger must be flush with the top *E* of the body. Any difference between the top of the plunger and the edge *E* can be detected by feeling. The spring must be made strong enough to insure a good bearing on the bottom.

Fig. 2 shows a good gage for measuring the thickness *A* of the bottom of piece *B*. In this gage the plunger is pulled down upon the piece by the handle *C* instead of the spring, as in Fig. 1. The body *D* is made of cast iron. The handle *C* is driven into a hole drilled in the drill-rod plunger *E* and extends into the hole *F*, which contains the spring *G*, placed underneath the handle. The pin *H* keeps the plunger from coming out. The body *D* is slotted out for the handle.

A vise jaw which pulls the work off the locating pin when the jaws are opened is shown in Fig. 3. The ejectors *A* are fastened to the movable jaws *B* by the pins *C*. With the jaws open, the piece is placed between the ejectors in the openings *D* and upon the pin *E*. The ejectors slightly pinch the piece, hold it in an upright position and keep the hole in the piece opposite to the locating pin *F*. After the cut is made, the jaws are opened and the hooks on the ejectors catch hold of the piece and pull it out to a position where it can easily be taken off.

In Fig. 4 are shown vise jaws for making the clearance cut *A* in the piece *B*. The part that makes the jaw quick acting is the block *C*. To take off the piece *B*, loosen the vise a quarter turn and throw the block into the position shown by the dashed lines. The throw of the block is regulated by the pins *D*.

A handy little jig used mostly for studs is shown in Fig. 5. The locating V-block *A* is made of round tool steel. It is fastened to the body of the jig by a tenon, turned on the end and clamped tight by the nut *B*. The dowel pin *C* keeps it in place. The equalizing part of the jig is the part *D*, which pivots on the pin *E*. The pin *F* holds the clamp approximately in place. The hole



SPRING PLUNGER GAGES AND OTHER SMALL TOOLS

in the clamp D is slightly larger than the pin F, to take care of any variation which might be in the work. The swinging part of the jig is part G, which moves on the stud H.

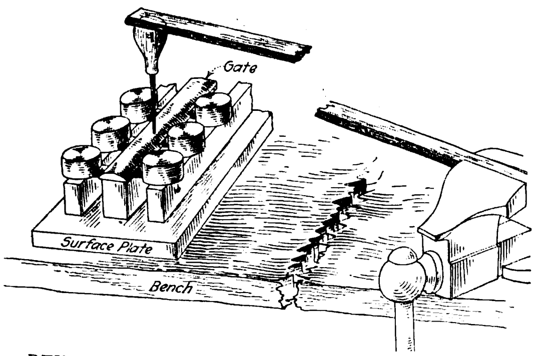
Dayton, Ohio.

Fastening Gates in Making Metal Patterns

The illustration shows a holding device for use in making metal patterns. We have used all kinds of devices for holding gates while soldering the patterns to them, but I think this simple kink is the best.



DEVICE FOR HOLDING PATTERN GATE WHILE SOLDERING PATTERNS

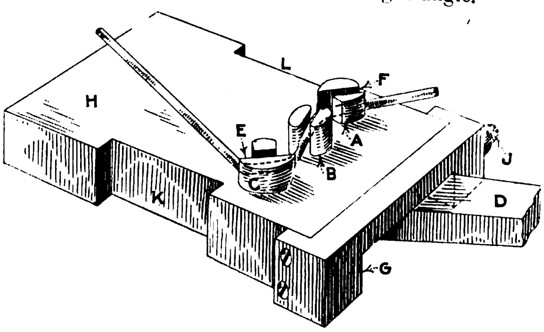
The patterns and the gate are placed on parallels, and the gate is held in place by a piece of wood acting as a spring. One end of the strip is held in a vise so that, when the other end is raised and an awl is placed between it and the work, the spring of the strip holds the work in place. While the gate is firmly held, there is room to work all around it.

A. E. HOLADAY.

Naugatuck, Conn.

Wire-Bending Fixture

The fixture shown in the illustration is of the multiple-operation type, as it performs in one operation a bend that at first seemed likely to require two or more handlings. The wire is received in the form of a right angle.



WIRE-BENDING FIXTURE

The view shows the fixture and the work as it is when completed. A, B and C are tool-steel wipers operated by the handle D, which is fixed to the center wiper B by a squared end and washer. The wire itself swings the wipers A and C to the position required to conform to the bend, and they are returned to their normal position by two pins in the handle operating against the surfaces E and F. The steel piece G is attached to the steel main part H carrying the adjustable stop J, which regulates the travel of the handle.

The fixture is milled at K and L for holding in a vise.

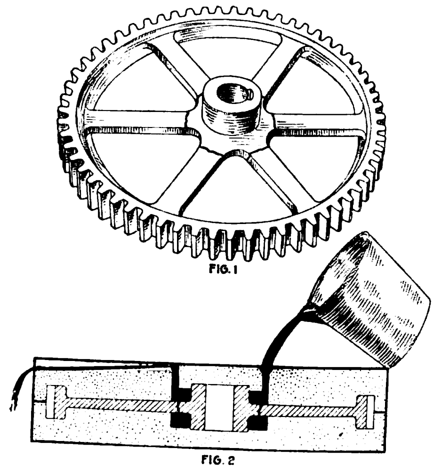
Arlington, R. I.

Repairing a Large Gear Wheel

A breakdown that looked like a hopeless job was recently solved in an interesting way. A large cast-iron gear wheel about 4 ft. in diameter had every one of its six spokes broken, as shown in Fig 1. The following solution of the problem proved successful:

The gear was put into a flask and the hub lined up true. Then it was rammed in place and the whole gear withdrawn, to permit the molder to cut out the mold for the "patch." The gear was replaced and a gully made on the cope from the riser to the ground, so that



METHOD USED FOR REPAIRING GEAR WHEEL

the metal could flow away. About 300 lb. of iron was poured through the mold, to heat the gear and make the new metal bite. Then the overflow was stopped and the remaining metal allowed to cool.

JACK HOMEWOOD.

Alberta, Canada.

Tracing-Cloth Curtains

Direct sunshine on work is usually avoided whenever possible, as shadows interfere with proper lighting. Also, in summer the direct sunlight becomes uncomfortably warm, and a curtain is usually drawn down to cut it off, at the same time preventing a desirable amount of light from being admitted.

All this trouble can be overcome by making the curtains of tracing cloth or by tacking a sufficiently wide strip of the cloth to the bottom stick of the regular curtain. This arrangement will allow almost as much light to enter as if no curtain were present, but the light will be diffused, no shadows will show, and the objectionable hot sunshine will be kept out.

Pullman, Wash.

Discussion of Previous Question

Best Way To Do Certain Things

I have no doubt that many of the readers of the *American Machinist* have become tired of my preaching improvements in mechanical construction. When some months ago I suggested, on page 936, Vol. 43, that your readers tell the best way to do the everyday things, there were not as many responses as I had hoped for; but the criticisms called out were better acknowledgment than if no responses had been made.

The point I wished to make was that, if one gave some way to do one thing applicable to various jobs, it was better than to describe the same thing in connection with some machine. For instance, when a lever or a pulley is to turn between two ears or cheek pieces, it is much better in nearly every case to have the pin or pivot tight in the lever or pulley than, as is almost universal practice, loose in the internal element.

A good way to do this in pieces of moderate size is to drill through all three parts and ream with a standard taper-pin reamer, relieve the holes in the two outside parts, drill the oil holes, assemble the elements and drive in the taper pin.

It does not seem necessary to argue why this is the better way. JOHN E. SWEET.

Syracuse, N. Y.

Grinding-Operation Kink for Hardened Rollers

On page 474 Mr. Breitschmid describes a method he employed in preparing for grinding some small hardened-steel rolls which were to be driven by the live center. That plan is all right, but it seems to me a good deal of time must be lost in guessing at the center, if the square center punch is used. Further, since it is certain that the punch mark must be tried again and again before even an approximate center can be found, the latter must be considerably battered by the time it reaches the grinder.

Why not locate the square center true and save all the time and patience expended? In the absence of a centering machine the place to center work is in the lathe. It is the quickest, most workmanlike and accurate in the end.

Were I doing the work described by Mr. Breitschmid, I should have both ends of the rolls centered in the lathe, using a small universal chuck. Afterward I should simply square one of the drilled centers with a square or three-cornered center punch, grind the grinder center to correspond, have the rolls hardened and proceed as Mr. Breitschmid says.

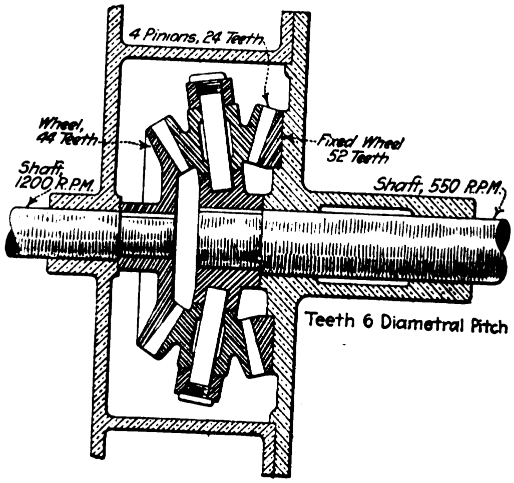
It must be borne in mind, however, that if good work is to be done, the center is of great importance; and a bad center is a very undesirable thing, whether the center be round, square or three cornered. Both the square center punch and the driving center of the grinder should be put in a dividing head and ground truly square—the punch to an angle of 59 deg. and the machine center 60 deg. This method will give a good, uniform bearing on all four sides of the square and will tend to prevent chatter or running out or round. J. B. MURPHY.

Plainfield, N. J.

New Design for Reducing Gears for Aero Propellers

The illustration shows a simple design of gear to reduce from 1,200 to 550 r.p.m., when the shafts have to be in line and run in the same direction.

The space occupied by this gear is no larger than that required for the design shown on page 79, yet it permits the use of much stronger gears.



REDUCING GEAR FOR AERO PROPELLERS

Ball bearings have not been shown, because the gearing itself was advanced as the difficult problem. A good design should be simple, strong, and cheap to manufacture. R. B. DOMONY.

Barrow-in-Furnace, England.

Grinding Die-Setting Pins

The article on page 518, suggesting a method of grinding die-setting pins, leads me to describe the plan which I have used with entire satisfaction for the past five years.

It is a constant surprise to me to see how many people use hardened and ground pins, working in hardened and ground bushings, when the expense is unnecessary. Drill rod 1 in. in diameter and guaranteed accurate to size within 0.0005 in. can be bought for all sizes of dies from small punching dies 1/4 in. in diameter, with two pins, to blanking dies 6x14 in., with four pins, for $\frac{3}{32}$-in. stock. I have two reamers—one, 1 in., for a running fit; the other, 0.001 in. under size.

The shoe and punch holder are clamped together with care not to spring them. A plate is set on the drill-press

table and leveled with a sweep and indicator. The holes are drilled and reamed by drilling through with a ½-in. drill first, to avoid springing, followed by a $^{63}/_{64}$-in., then by the undersize reamer all the way, and last by the full-sized reamer through the punch holder only.

To get the best results, do not clamp to the drill press. The pins are cut to length, the ends finished in the lathe and driven into the shoe. I allowed from 1¾- to 2½-in. bearing in both the shoe and the punch holder. This work can be done in a quarter the time necessary for hardened pins and bushings.

Sometimes the pins are fitted last; but more often—always with small punching dies—the pins are first put in and located, the punch plate and punches last. The punch plate is so much lighter than the whole punch holder that it is easier to get a nice fit that way. Furthermore, the screws can be put in place in oversize holes and will hold the plate more securely than clamps while fitting and placing the taper pins.

I believe that the natural surface of good drill rod makes a better bearing with cast iron than a ground surface.

W. B. GREENLEAF.

Plymouth, Mich.

Take Warning!

Apart from the relative merits of the metric and the English systems of measurements your reference to Dr. Stratton as "the most dangerous enemy of our industries which our country harbors" savors of abuse and slander, which neither the controversy nor the long record of meritorious public service that Dr. Stratton has rendered justifies.

Any manufacturer who may have taken the trouble to visit the Bureau of Standards in Washington and acquaint himself with the work that Dr. Stratton is conducting there in a most efficient and helpful manner in the interests of American industries leaves that institution with the feeling of admiration for its work and profound respect for its Director. You could render a far greater service, in my estimation, to American industry by urging manufacturers to get into closer touch with Dr. Stratton and the Bureau of Standards and to consult more freely with him on problems that confront them from time to time than to raise false alarms such as are conveyed in your editorial on page 563, Vol. 44.

Dr. Stratton, in preparing his report on "Metric System in Export Trade," acted upon instructions from his superior officer and had no intention of "foisting" the metric system on this country overnight.

My personal experience with both the English and the metric system of measurements in designing and manufacturing has demonstrated to me the superiority of the latter system. I believe there are few engineers who would today question the advisability of ultimately making a change from the English to the metric system, which is relatively as much superior to the English measurements as the system of dollars and cents is to the pounds, shillings and pence method, when used in calculation and manufacturing.

Even in Russia, where the English system was first introduced and adopted, the metric system has superseded it during the past ten or fifteen years in almost every industrial enterprise. It was done gradually, to be sure, but the fact is that now in all engineering works through Russia the metric system is standard. It is only a question of time when the metric system will be universally adopted in all South American countries with which we are endeavoring to extend business relations.

Would you favor handicapping the American manufacturer of the future in doing business with South American or European countries by urging him not to be far-sighted enough, nor to take the necessary steps, to adapt himself, his personnel and his equipment to execute contracts for export to the metric system with the same facility with which he executes contracts to the English system of measurements? It is this point that Dr. Stratton had in mind in making his report on "Metric System in Export Trade."

No one, and Dr. Stratton in the least, advocates that the change to the metric system be made overnight, but it is highly important that this question be agitated and that serious consideration be given to it by all manufacturers and particularly by a publication such as yours. The metric system should be gradually introduced by our manufacturers in the execution of orders for engineering products for export. It should also be obligatory that all trade and engineering colleges and universities teach their students the use of the metric system in their calculations, so that they can think in both units and form their judgments in the metric and in the English equivalents with equal facility.

Your attitude against the adoption of the metric system shows the same lack of foresight and adaptability that is evident in the English railways, which alone, against the railways of the entire world, including the British colonies, continue to base their statistics on car- and wagon-miles instead of the ton-mile basis universally adopted.

CHARLES M. MUCHNIC.

New York City.

The Suggestion System

On page 561 J. H. Davis discusses the suggestion system and gives one very good argument in favor of it—namely, that when it gets to the point where only 20 or 30 suggestions are received a year, it helps in finding the men who are above the average.

There is also another reason that is perhaps important enough to justify the slight expense of starting or maintaining a suggestion system. In every shop there are a few mechanics who think they are a little better than the rest. The suggestion box gives them an opportunity of proving it. Without such a system in the shop, the chances are that they would write a letter to the department head and tell him in what way this or that might be improved.

This action necessitates going over the foreman's head, and many hesitate to do it. Other men who may be more reserved and not quite so self-confident would not be likely to take this roundabout way of showing that they know something too. Consequently, both they and the firm would lose. With the suggestion system this injustice is avoided, and everyone gets a square deal.

The latter point is an important one in favor of the suggestion plan, for undoubtedly many mechanics hesitate in making suggestions under the impression, false or otherwise, that full credit will not be theirs unless submitted direct.

J. LIMBRUNNER.

Shelton, Conn.

Industrial Preparedness the Keynote at New Orleans

EDITORIAL CORRESPONDENCE

SYNOPSIS—One of the most successful spring meetings ever held by the American Society of Mechanical Engineers convened at New Orleans from Apr. 11 to 14. The keynote topic of discussion was organizing for industrial preparedness. The social features of the meeting were unusually enjoyable.

The usual practice of holding the spring meetings of the American Society of Mechanical Engineers in May or June was broken this year because of the selection of the Southern City of New Orleans as the place for the convention. The attendance was very satisfactory considering the distance of the convention city from the great industrial centers of the North. The total registration numbered 113 members and 363 guests.

The members and their friends from the North chose three general routes to reach New Orleans. One party assembled in New York and went through to the convention city in special cars, making a stopover for one day at Birmingham, Ala. The party from Chicago and Cincinnati also made this day's stopover in the "Pittsburgh of the South." A few members who wished to enjoy the recreation that the spring meetings usually offer preferred to go from New York to New Orleans by water.

THE DAY IN BIRMINGHAM

A representative of the Birmingham local section met the party at Chattanooga on Sunday evening, for the start from New York was made on Saturday afternoon. The day's program in Birmingham began at 9:30 o'clock in the morning and continued until 10 o'clock in the evening—or just in time to catch the train for the rest of the journey. The program included visits to the plants of the Republic Iron and Steel Co., the Tennessee Coal, Iron and Railroad Co. and the American Steel and Wire Co. The visits were made in the order given. At noon a Southern barbecue was served at Bayview—a picnic park on an artificial lake used for impounding the water-supply of the Tennessee company.

The visit to the Republic Iron and Steel Co. included the Thomas furnaces. These were reached from Birmingham in a special train that was at the disposal of the party for the entire day, taking them on from one point to the next and finally bringing them back to the city in time for a brief rest before dinner in the evening.

Several plants of the Tennessee company were visited, including the blast furnaces, openhearth department, rail mill, rail-mill power station, Edgewater coal mine and Fairfield byproduct coke plant. These visits and the journey from plant to plant on the company's railroad gave an excellent opportunity to observe the industrial betterment work that has been planned and carried out on an extensive scale. It is possible that this work and the byproduct coke plant aroused the keenest interest among the visitors.

The byproduct plant is now producing benzol, toluol, zylol, naphtha and ammonium sulphate. Another byproduct produced at another plant from blast-furnace slag is a commercial fertilizer high in phosphoric acid.

The Tennessee company employs a working force of some 18,000 men, who with their families represent a population of about 50,000. Some 66 per cent. of them live in the cities, villages and country sides contiguous to the mines and works. The other 34 per cent. of the employees live in houses owned by the company. About 53 per cent. of the employees are negroes, 37 per cent. white Americans and 10 per cent. white Europeans. Although the mines and plants of the company are distributed over a wide territory, by far the greater portion are comprehended within an area having a 15-mile radius from Birmingham.

The industrial betterment work as now organized was started some three years ago by Dr. Lloyd Noland, who had had several years' experience in similar work on the Panama Canal. At the outset it was believed that general sanitation and preventative medical care not only constitute a moral responsibility, but give results that pay. It is cheaper to prevent disease than to cure it. The workman who is sickly himself or has a sickly family is always an expensive investment. The soundness of this viewpoint has already been demonstrated. The average earnings of the employees have increased in a higher percentage than their rates of wages. The average number of working days per month has increased from 16 to 22.

For convenience the work of the health department is separated into three divisions—the sanitary, the medical and the welfare. The first is responsible for the purity of the water-supplies, disposal of all wastes, the cleaning and draining of all streets, the supervision of living premises, the elimination of mosquitoes, prevention of fly breeding, the supervision of dairies supplying milk and the inspection of the commissaries, including the safeguarding of the purity of all the food supplies. All this work is under the direct charge of a supervising physician, who has a sanitary corps that devotes its entire time to these matters.

The medical department consists of a staff of resident physicians and nurses. Their duties include the physical examination of all applicants for employment, the physical examination of all school children (with frequent inspections of the schools), the care of all sick and injured employees and their dependents (without regard to the nature of the illness or its cause) and close coöperation with the sanitary division in general health work.

The welfare division has charge of the clubhouses, the conducting of courses in cookery, sewing and practical housekeeping, the kindergarten instruction of children below school age, home visiting, supervised play and the oversight of the various social organizations.

FIRST SESSIONS AT NEW ORLEANS

Tuesday, the first day of the meeting in New Orleans, was devoted to registration, sight-seeing about the city, including points of historical interest for the ladies and some of the engineering features for the men. The first social event was an informal reception on Tuesday evening.

The keynote professional session was held Wednesday morning. It was opened by a paper by Spencer Miller, member of the United States Naval Consulting Board, on

"Organizing for Industrial Preparedness." An unusual amount of discussion followed, which showed conclusively that engineers as a profession are unanimously and wholeheartedly in favor of industrial preparedness—and in fact, preparedness in its broadest meaning. Because of the volume of this discussion only a small part can be incorporated in this report, and the remainder will be presented in full in next week's *American Machinist*. Mr. Miller's paper will be found on page 672 of this issue.

FUNDAMENTAL PRINCIPLES UNDERLYING PREPAREDNESS—DISCUSSION BY H. L. GANTT

In considering the subject of preparedness, either for peace or for war, it is imperative that we learn as quickly as possible the lessons that are being made clear to us by the developments in Europe.

In order to do this we must ask ourselves why it is that Germany has shown so much greater efficiency, both from a military and an industrial standpoint, than have the Allies.

It is becoming perfectly clear that the principles underlying industrial and military efficiency are the same and that, if a nation is to be efficient in a military sense, it must first be efficient industrially.

We have talked efficiency in this country for several years, and many books have been written on the subject; but many of us feel that the actual results so far have been lamentably small and that we should be much more nearly in the class with England than with Germany if we were suddenly confronted with England's problems. It would seem therefore that we should find the fundamental reasons why England presented such a strong contrast to Germany and see if we cannot learn something therefrom.

It is only a short time since England led the world in the arts, but recently Germany has demonstrated her superiority to both England and France.

We must ask ourselves how this happened. It would seem to be something in this wise: The financiers of England, feeling that wealth could purchase whatever was needed for themselves and their national life, have devoted their energies for a number of years to securing the wealth that was produced by others rather than making strenuous efforts to produce it themselves. In this attempt they have sent abroad millions of dollars to develop industries in foreign lands, which brought them great returns.

The leaders of Germany, on the other hand, not being able to exploit foreign people to the extent that was possible in England, turned their attention to developing their own resources and the ability of their own people.

When the supreme test came, Germany was found to be a nation of people who, in general, knew what to do and how to do it, while the industries of England were in too many cases controlled by people who understood only their commercial side.

We, following the footsteps of England, have regarded financial strength as the most important strength, forgetting the comment which the ancient philosopher made to the rich man who boasted of his possessions, when he said: "What availeth all thy wealth? He that hath better iron than thou will come and take away all thy gold." In those days iron meant weapons. Today iron may be taken as the symbol of both weapons and tools of industry, and the statement is just as true today as it was two thousand years ago that he that hath the better tools is more powerful than he that hath the wealth.

The move, therefore, to get the engineers of the country working together for preparation is a most hopeful sign, for in the strenuous times in which we are living our wealth may be of little more value to us than it would have been to Great Britain but for the 20 miles of water which separate her from the Continent of Europe.

On the other hand, the power to do things cannot be taken away from us. The greater that power the more important will its possessor become, as we realize the real meaning of the titanic contest which is now going on in the world.

The man who knows what to do and how to do it is preeminently the engineer. The new world, therefore, which is being ushered in by the great struggle now taking place is one in which the engineer is destined to be the supreme power, for it is becoming increasingly clear that in future the man who owns things will not be as important a factor in the world as the man who can do things.

IMPORTANCE OF MACHINE TOOLS IN INDUSTRIAL PREPAREDNESS—DISCUSSION BY L. P. ALFORD

Mr. Miller, in his excellent outline of the need of organizing for industrial preparedness, points out that consideration should be given to machine tools from several aspects of their design and supply. The importance of these machines in time of war is strikingly proved by comparing the machine-tool exports from the United States for the calendar year 1915 with the record of the best previous year in our history. In round figures $42,000,000 worth of machine tools was shipped during 1915, while the highest preceding yearly record was about $16,000,000 worth. The influence of the European War has multiplied our average machine-tool exports some three times. Tables 1 and 2 are compiled from the reports of the Department of Commerce of the United States Government.

TABLE 1. EXPORTS OF MACHINE TOOLS FOR LAST THREE YEARS OF CALENDAR

	1913	1914	1915
France	$2,088,515	$2,309,635	$11,700,299
Germany	2,838,268	1,086,404	....
United Kingdom	3,491,050	5,441,575	16,633,648
Other Europe	3,689,123	3,280,402	8,045,995
Canada	1,888,463	767,064	4,336,065
Australia	....	....	325,263
Other countries	1,562,793	1,956,300	996,509
Total	$15,558,212	$14,841,380	$42,037,779

TABLE 2. EXPORTS OF MACHINE TOOLS FOR PAST TEN FISCAL YEARS

1905	$4,332,665	1910	$5,975,503
1906	6,445,612	1911	9,626,965
1907	9,369,056	1912	12,151,819
1908	8,696,235	1913	16,097,315
1909	3,640,034	1914	14,011,359

These relate to the exports of machine tools, and from them the figures quoted have been taken.

Although there has been some scattered buying during the last 20 months, the greater number of the machine tools exported from the United States have been taken by Great Britain, France and Russia. Exports have been cut off from Germany and Austria, while the Scandinavian countries, Holland and Italy have increased their buying much beyond the normal amount. But little is known in this country of the methods that Germany has employed to build and maintain the machine tools necessary to produce her munitions of war. On the other hand, there is considerable information available in regard to the methods employed by Great Britain and France. Thus it is with the experiences of these latter-named countries that we are at the present moment concerned. From their methods we can formulate the principles of action to govern the design, purchase, production and distribution of machine tools in preparing for a national emergency of war.

The events of the past 20 months justified the statement that the machinery-building industry is the backbone of any defensive or offensive warfare at the present day. This statement emphasized anew the need of carefully considering machine tools in any plan for industrial preparedness.

The machine tools shipped abroad within the past 20 months analyze into three general classes: First, simple, plain machines that were either standard with certain manufacturers before the outbreak of war or have been designed and built under the stress of the tremendous foreign demand; second, regular machine tools of a more highly organized grade, particularly automatic machines that were standard product of some manufacturers prior to the outbreak of war; third, special machine tools developed for some operation or series of operations in the manufacture of some particular detail of munitions. These group into (a) lathes for the outside turning of shells; (b) lathes for boring shells; (c) lathes for waving, grooving and undercutting shells. The first class comprises by far the greater volume of the exports, and simple lathes are the predominating machines. In like manner lathes predominate in the third class.

The methods adopted by Great Britain, France and Russia in buying these machine tools need brief consideration. The early orders were placed by European machine-tool agents who had handled American machine tools for years. Their knowledge of the business gave them the first entrance into the field.

These dealers' contracts were followed by others given by special agents or government commissions who came over to this country during the first year of the war. These orders brought about a condition of scarcity of machine tools in the United States and at the same time filled all the regular machine-tool building plants with such a volume of business that deliveries in many cases have been seriously delayed. The third class of buying has been by government commissions in shops making high-grade machinery other than machine tools, as printing presses and wood-working machinery, and in general have been for machines of the third class previously mentioned. Their buying has been most ably managed, and the results of their work have been more uniformly successful and satisfactory than that of any of the private buyers.

The private buying—that is, the buying done by machine-tool dealers—can be roughly divided into three periods. Dur-

ing the first period simple lathes and turret machines were bought almost exclusively. The demand during the second period was for grinders, drilling machines and millers. The demand during the third period was for planers, shapers and toolroom machinery.

After learning from the hard school of experience it is now realized that toolroom machinery should have been bought during the first period. The reason is obvious, for such machines are needed to produce the jigs, fixtures and gages that are the necessary accompaniment of machine tools for duplicate production.

In case of war with a first-class power the United States would unquestionably need to add an enormous number of machine tools to the present equipment of her machine shops. Based on the record of the years immediately preceding the outbreak of the war, the normal surplus of machine-tool production of the United States, as represented by the amount shipped abroad, has a value of about $15,000,000. This supply would naturally be kept at home, but in addition thereto we would have to draw from the industrial nations of Europe, provided we were not involved in a European war. This buying would have to be done by some organization not now in existence, for the reason that there are only a few agencies in this country that market European machine tools here.

Thus the European buying for the United States would have to be placed in the hands of experienced men, perhaps civilians representing both builders and users. The present British Ministry of Munitions with its subcommittees might well form a model for the American organization charged with the duty of buying machinery abroad. There are facts that tend to prove that the work done by the British commission has been most efficiently handled and has brought excellent results. This is an experience well worth careful weighing.

One of the early acts of the British Ministry of Munitions was the prohibition of the importation of machine tools into Great Britain, except under license of the ministry. A number of reasons led up to this decision. Among them is the necessity of suppressing speculative buying and selling, controlling the kinds of machine tools bought abroad, the effective utilizing of ocean-borne freight, the distributing of machine tools in a manner to best further the manufacture of munitions, and the control of quality.

But little is known of the conditions that have surrounded the machine-tool industry in Germany during the war. However, at the outbreak of war edicts of the Ministry of War placed a prohibition upon the exportation of machine tools as one of the items in a list of articles that might be of value to the enemy. As the war progressed, the ministry formed two committees—one the War Raw-Materials Committee and the other the Industrial Committee. These committees have controlled the machine-tool building industry as well as other German industries. They have directed what machines should be built, where they should be built, have handled the supplies of raw materials for machinery building and have arranged for the distribution of the new machines as well as other machines that could be released from their regular employment.

It is reported that France mobilized the machine tools of the Republic as one of the early war measures. The purpose was to bring together the machine-tool equipment into units of such a size that manufacturing could be carried forward expeditiously and efficiently.

Thus from the experience of Great Britain, Germany and France the necessity of controlling the supply and distribution of machine tools is evident in case of war between first-class powers.

No exact estimate can be given of the number of machine tools that might be immediately available in Germany in case there should be an emergency demand from the United States. A careful estimate for Great Britain, however, is that under normal conditions there are some 1,200 to 1,500 lathes in the stocks of dealers and builders at any normal time. In any event it is fair to assume that the stock of machine tools in the possession of dealers and builders in Europe would not be very great and in fact would be a very small factor in the number that we should be likely to need. Accepting this situation as a starting point, a decision can be made as to whether the United States should buy standard machines regularly manufactured abroad or order special machines particularly adapted to our own needs. It is conceivable that it might be much better to have machines built to our own drawings and specifications than to attempt to use the regular products of European builders.

Mr. Miller has pointed out the necessity of standardizing machine tools. If they are to be standardized for our own makers and needs, it follows that the machines brought from Europe should be uniform with those produced here. Without question, machine tools should be standardized, and the motive of industrial preparedness should be sufficient to inaugurate the study and work of standardization at once.

Turning again to the European situation, it is estimated on reliable authority that plain lathes of, say, 16 to 24 in. in swing could begin to be shipped from British machine shops in 12 weeks from the receipt of detailed drawings of their parts and detailed specifications for their manufacture. Not only could they be procured in this time from machine-tool building shops, but also from other machine shops accustomed to doing high-grade work. Broadly speaking, any machine shops that are accustomed to do accurate planing and scraping can build machine tools under the conditions of demand such as exist at the present time.

Because of the small stocks of machine tools in Europe, it is evident that not many could be obtained during the brief period of waiting for American standardized construction to be produced. It is of course possible that the essential standardized details could be reduced to a minimum, with the insistence that these should be incorporated in the regular designs of European builders. In this way the essential needs of uniformity with American products would be met, and it is possible that a certain amount of time could be saved over the estimates just given.

From the experience of the allied nations in purchasing machine tools during the past 20 months it seems justifiable to lay down the following principles for the standardization and procurement of machine tools in organizing for American industrial preparedness:

1. Organize at once in skeleton form an industrial committee to control the standardization, design and preparation of machine tools for the production of American munitions.

2. Through joint action of this committee, the American Society of Mechanical Engineers and the National Machine-Tool Builders Association standardize the details of regular machine tools and design whatever additional special machine tools may be necessary for the rapid and economical production of American munitions.

3. Immediately on the outbreak of war prohibit the exportation of any machine tools from the United States.

4. Immediately on the outbreak of war prohibit the importation of any machine tools into the United States except under license and control of the committee mentioned under 1.

5. Order all machines abroad through this committee or its representatives in the capitals of Europe and intrust these men with the responsibility of securing the desired deliveries and quality.

6. Order no machine tools abroad except to standardized American designs, either for the complete machine or the essential details, as the committee may determine.

Turning now to the important matter of standardization of machine tools, this subject was thoroughly talked over at a convention of the National Machine-Tool Builders Association a few years ago. However, as that body is a business rather than a technical organization, no efforts have been made to bring about uniformity. The suggestion has been offered that this work of standardization should be done jointly by the American Society of Mechanical Engineers, the industrial committee outlined in this paper and the National Machine-Tool Builders Association. I believe this society should initiate and prosecute the work.

As a possible aid in bringing this matter forward for consideration, Mr. Alford offered an appendix which contained excerpts from an address he made before the 1911 annual convention of the National Machine-Tool Builders Association. It outlined a number of features of machine tools that might properly have consideration at the hands of a standardizing committee and was published in full in *American Machinist*, page 725, Vol. 35.

The preparedness session was both enthusiastic and emphatic and indicated a unanimous sentiment in favor of organizing. A resolution was passed providing for a committee to standardize details of machine tools.

Another paper of interest to machine builders was presented by N. W. Akimoff, on "Dynamic Balance." This paper and the discussion on it will be published in a later issue.

Wednesday afternoon was devoted to a boat trip, giving an opportunity to inspect the harbor, the recently constructed cotton warehouse and its mechanical equipment. A visit was also paid to the new reinforced-concrete grain

elevator that is being erected by the Board of Commissions of the Port of New Orleans.

Following the usual custom, Wednesday evening was devoted to an address of general engineering interest, at which the ladies and the public were made welcome. The speaker was W. B. Thompson, Commissioner of Public Work of the City of New Orleans.

Interesting Social Features

The City of New Orleans lived up to the reputation for Southern hospitality. An informal festival was held on Thursday evening at the New Orleans Country Club, and this was followed by a tea at the Newcomb College of Art Pottery. A reception dance was held on Thursday evening. Many technical excursions for the men were arranged to the various pumping plants, drainage and irrigation projects, and automobile rides to the local points of interest were pleasantly arranged for the ladies.

From all points of view, this spring meeting was one of the most successful in the history of the society.

Measurement of Viscosity and New Form of Viscosimeter*

By H. C. Hayes and G. W. Lewis

This article deals with the measurement of viscosity. It predicts the errors which are introduced by the various types of viscosimeters and verifies these predictions in case of the short capillary types, such as the Saybolt, Engler and Redwood, and the orifice types, such as the Carpenter, by comparing the temperature vs. viscosity curve for a light and a medium lubricating oil as given by these meters with the true curves as determined by a modified form of Poiseuille's capillary-tube method.

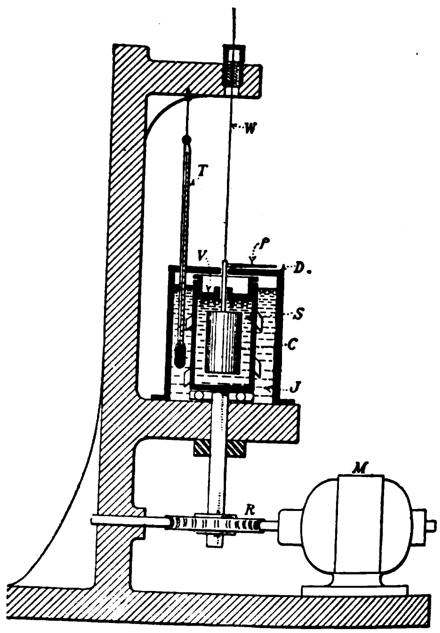
The work shows that the short capillary types give results about 50 per cent. too small, and the orifice types give results about 100 per cent. too small; and further, that none of these meters give accurate comparative results for two different oils or for the same oil at different temperatures.

The only type of viscosimeter on the market that can be expected to give accurate results on theoretical grounds is the Stormer. This instrument attempts to measure the viscosity in terms of the torque required to spin a disk within the liquid, but the mechanical difficulties met with are such as to debar this type.

The authors have designed and thoroughly tested out a viscosimeter which is believed to embody all the good points of the Stormer and none of its defects. This machine measures the viscosity in terms of the torque that a cylinder experiences when suspended within a rotating liquid. This method eliminates all error due to friction. The results given by this meter agree with the true curves for the light and medium oils to within 1 per cent. and can safely be used as a standard.

The advantages of such a viscosimeter are evident: The instrument can be calibrated to give direct readings of the viscosity; the oil is not handled during a complete test at various temperatures; the design of the instrument is such that the temperature of the specimen follows closely the temperature of the bath, so the data for the temperature vs. viscosity curve can be taken while the sample is cooling; the meter gives the viscosity of mixtures, such as paints, as well as for liquids that have been carefully filtered; there are no glass parts to break; the personal error is eliminated; and the meter can be made self-recording.

This viscosimeter operates in accordance with the principle that a solid body having a surface of revolution experiences, when suspended in a rotating liquid, a torque that is proportional to the viscosity of the liquid. The instrument is shown diagrammatically herewith. The specimen is contained within a cylindrical chamber that is caused to rotate uniformly by a motor *M* through a worm drive *R*. A cylinder *C* is suspended within the specimen by a thin steel wire *W* so that the axis of the rotating liquid coincides with the axis of the cylinder. The specimen chamber is provided with a cap *V*, so shaped that the excess liquid can overflow when the cap is seated and thus give constant conditions within the chamber.



THE NEW VISCOSIMETER

The specimen chamber is surrounded by an oil jacket *J*, in which a thermometer *T* is suspended. The jacket oil may be brought to any desired temperature by means of a heating coil or by a side coil not shown in the diagram. The cover *P* of the jacket chamber is provided with a scale which is marked in degrees or may be calibrated to read off directly, through the deflection of the pointer *P*, the viscosity in terms of a standard liquid. The specimen chamber and the suspended cylinder are both made of copper, to insure constant temperature throughout the specimen, and the outside of the specimen chamber is provided with blades that keep the jacket oil thoroughly mixed as the chamber revolves, thereby exposing the latter to a uniform temperature. This is an important factor toward insuring constant temperature throughout the specimen.

Machine-Shop Power Tests as an Aid to Economy

The difficulties surrounding power measurements by mechanical means are well known to those who have experienced the simplicity of the electrical measurements connected with similar processes. Thus the operations involved in the measurement of the mechanical-power output of an electric motor by means of a prony or strap brake and balances or scales may be contrasted with the exceedingly simple measurement of electrical-power input of the same motor, requiring, as the latter does, merely several indicating electrical instruments that are read at a glance.

Nor is the difficulty of the mechanical measurement, in contrast to the electrical observations, limited only to inconvenience, for there are many sources of probable error in the former that may be reduced practically to negligible proportions in the latter. Accuracy, therefore, is one of the greatest points favoring electrical measurements in comparison with former methods, and these two features—namely, convenience and accuracy—no doubt largely account for the widespread use of the electric current in some shop measurements at the present time.

With all the many advantages of the indicating electrical instruments, typified by the well-known voltmeter, ammeter and wattmeter, the more recent development of graphic electrical instruments has been a marked step forward toward still more highly specialized methods in the practice of measurement. In the graphic instrument we have the means for inscribing in a convenient form an indelible record of past operations, which may be used later for a study at length of the various steps of an operation or for analyzing the parts of a cycle of operations, for the purpose of locating, for example, time losses not readily discernible by an observer.

A striking example of the more modern methods of shop analysis is that of the graphic meter when applied to an electric motor that drives its individual machine tool. The power-input-time record resulting from a graphic meter on such a tool gives to the operator and foreman a most instructive chart of the cycles followed in the work on a given operation. It tells the number of minutes during which the machine has worked and during which it has been idle. If the crane service is poor and undue delays are experienced in getting the material for his machine, the operator has a proof, in the form of the graphic chart, on which to base suggestions.

Perhaps of equal importance, however, is the information of the exact power transmitted to a given machine tool, made possible by the graphic chart. With line-shaft drive and belt transmission there is no very convenient method for determining the exact quantity of power being imparted to the machine tool, save that of calculation on a more or less empirical basis. If an electric motor is employed to drive this same tool, a graphic meter arranged to record the electrical input to the motor furnishes an accurate record of exact power transmissions; and the proper size of the motor for driving the machine most economically is readily determined.

These advantages, however, do not apply so much to the determination of exact power requirements of the machine as to the effects of suitable power input on the time of production. As has often been pointed out, the power consumption of almost any machine tool represents an expense that is virtually negligible in comparison with the corresponding labor and overhead charges against this same machine. The economic effect of having adequate power available, on the ability of the operator to get out his work in the minimum practical time interval, is therefore of far more consequence than the mere determination of power input, and it is this function that is performed so conveniently by modern graphic meters.

There is but little doubt of the fact that the intelligent use of suitable measuring devices is capable of reducing much shopwork to a more highly systematic basis than was possible with former methods, where the foreman and operator were almost entirely at the mercy of line-shaft speeds of fixed values and given belt widths; and incidentally the electric motor comes in for a share of the credit in making such a method of measurement possible, because of the medium of electric rather than mechanical supply on which its operation depends.

Machine Tools in South America

Almost 40 per cent. of the machine tools in the shops in South America were made in the United States of North America. This may be a confounding statement to the alarmists who say that we never have had much machinery trade with our southern neighbors and are not likely to. We have been told that the demands for cash business have debarred North American manufacturers from selling in South American countries. The long credit has been held up as the only basis for South American business. But in spite of these facts and many others that have been held up as barriers against the northearn business man, 39.3 per cent. by number of the machine tools in South America machine shops were imported from the United States.

The statistics from Mr. Hood's report bearing on the nationality of the machine tools are as follows: "British machine tools, 43.2 per cent.; United States, 39.3 per cent.; German, 13.4 per cent.; French, 3.2 per cent.; Belgian, 0.5 per cent.; all others, 0.4 per cent."

As regards the nation of origin, Great Britain leads, with the United States a close second. The reason for the predominance of British-made machines is undoubtedly found in the financial arrangements that have existed between South American countries and English capitalists. British gold has financed South American

railroads, mines and other enterprises. Many of these projects have been organized and operated by British engineers. It was very natural, therefore, that they should buy British machinery.

Perhaps the second most surprising fact brought out by these percentages is the smallness of the German importation. Only about one-eighth of the machine tools in South America are German made.

It is evident that there is nothing disheartening to American machine-tool builders in these statistics. If the past lays a foundation for the future, the United States builders will surely reap their share of the coming South American business.

It is of interest to present some further figures in regard to the number and distribution of these machine tools. Quoting again from Mr. Hood's report, there are in the South American machine shops that were plotted on the map on page 652 of last week's issue a total of 11,681 machine tools. Distributed according to the size of the shops, the classification is: In shops employing up to 20 men each, 4,747 machines; from 21 to 50 men each, 1,361; from 51 to 150 men each, 862 machines; from 151 men upward, 4,711 machines.

The statistics referred to also divide these machine tools into eight classes according to kind. Of the 11,681 machines, 3,417 are lathes, 885 planers, 425 millers, 522 boring machines, 1,695 drilling machines, 997 grinders and 3,740 of various kinds, including woodworking machinery. It is interesting to calculate a few percentages from these figures. Thus, lathes comprise about 30 per cent. of the total, drilling machines about 15 per cent. and planers about 8 per cent. It is fair to assume that these figures indicate roughly some of the proportions in which various kinds of machine tools will be bought in South America in the immediate future.

Lobsters and Machine Tools

Necessity is said to make strange bedfellows, and it seems that war can reclassify both necessities and luxuries.

A recent announcement has been made of articles prohibited for importation into Germany. This act is taken as a war measure and is stated to be aimed at luxuries that the German people can do without. Here is the list: "Lobsters, caviare, liquors, champagne, fans, hats, caps, pineapples, raisins, silk, silk clothing, pictures, sculptures, jewelry, gold, silver, toys, artistic ironware and machine tools." The list begins with lobsters and ends with machine tools. Queer bedfellows, surely!

We have been wont to understand that machine tools are a humdrum product of industry, bought only because they are needed and used only because they have to be. In fact, we have always placed them at the bottom of the scale of everyday necessities to keep the world going. But this order shows that we were mistaken. Machine tools should properly be classed with champagne, caviare and lobsters—never mind if they are more indigestible than any of the others.

In a changed mood, is it worth while asking: Why this prohibition? Will it hold after the war is over? In connection with these questions it must be recalled that some three or four years ago an effort was made in Germany to prohibit the importation of machine tools from abroad. This movement had its inception in the minds of the leaders of some of the machinery builders' associations. The *American Machinist* was credibly informed at the time that the matter had been brought to the notice of Government officials, who might take action. However, nothing was done officially.

Let us hope that there is no basis or reason for being disturbed over this order. On its face, it is nothing but a war measure. May it be such in fact!

Belting Specifications

The purchase of leather belting has lagged behind the progress made in exact specification and testing now common in the many other shop materials and supplies. Even today, price is usually a controlling factor when a belting contract is let. Wherever specifications are used, more often than not they attempt to control the process of manufacture rather than to set up requirements that the belting must meet in use. The unsatisfactory situation is well outlined in the article on page 683.

This presentation of a new basis for writing leather-belting specifications is a definite challenge to both belting manufacturers and belting users. These suggestions turn the entire discussion from one that might be merely destructive to something that is definitely constructive. The *American Machinist* hopes that there will be full and free discussion of these new specifications, with the purpose of improving the basis upon which belting is bought.

Vital Factor of All Munitions

The more one sees of munitions the more evident it becomes that the designers and those who prepared the specifications know little or nothing of economical manufacturing methods. They do not realize how much easier it is to call for concentricity of shells within 0.003 in. than to secure this in actual manufacturing, nor how slight an error in the curve of the nose will affect the exact profile. Yet gages are called for that require almost absolute perfection of product to pass the inspection honestly.

If this perfection were necessary for the proper functioning of the shell, no objection could be made to its being demanded. But when one nation requires holes reamed glass smooth in high-explosive shells and another accepts them just as they come from the forging punch, the extreme smoothness cannot be absolutely necessary. One nation insists that the relieved surface on the shell be turned smooth or ground, while others consider the coarse thread left by the tool to be not only good enough, but better, as it affords a good painting surface.

The one vital consideration in preparing both designs and specifications for munitions, just as in all other mechanisms, is that the product shall function properly; all else should be secondary. All vital dimensions should be held within as close limits as necessary; all other dimensions should be given as large tolerances as possible without affecting the proper functioning of the shell. And so throughout the list. There can be no better form of preparedness than that which will eliminate useless expenditure of time, money and material and enable a larger supply to be made at short notice.

Some of the testing gages are fearfully and wonderfully ingenious; but were half the gray matter expended on these turned to making the designs and specifications simple and more easily complied with, all concerned would be far better off.

Shop Equipment News

A Single-Belt Automatic Screw Machine

The illustrations show a front and a back view of the latest form of automatic screw machine developed by the Chicago Automatic Screw Machine Co., Chicago, Ill., for the John Macnab Machinery Co., 90 West St., New York City.

The machine is operated by a single belt run directly from the lineshaft, making unnecessary any countershaft. A fast-and-loose pulley is arranged on the spindle head, the power being transmitted to the spindle through two trains of gears, one of which is changeable to obtain the spindle speed desired. The intermediate shaft is extended to the rear end of the machine, where it is connected to the feed bracket by a clutch that is operated by a hand lever conveniently located at the operator's right hand; the desired feeds are obtained by changing two gears on the feed bracket. The feed can be operated by a handwheel to assist the operator in setting up the machine.

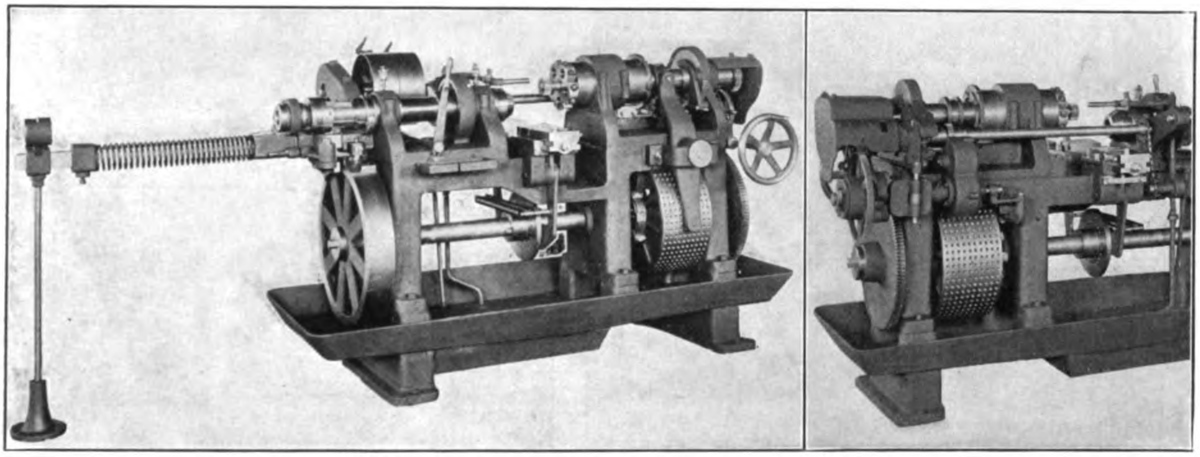
The turret is indexed by a clutch mechanism that is positive and can be arranged to skip any number of holes in the turret, when all the turret holes are not being used. The feed to the turret is transmitted from the cam drum by a lever which allows the turret tools to be brought up to their cutting position rapidly. A tool-steel plate, hardened and ground, is used to align the turret, provision for wear being made by a wedge under this plate.

The two cross-slides are operated independently of each other by two separate cams and levers. They have broad bearing surfaces that are scraped. A rapid method of adjustment is provided by a screw and nut which are locked in position when the desired adjustment is obtained.

As the spindle runs in a left-hand direction and is not reversed, right-hand threads are cut with a die or tap holder that runs slightly faster than the spindle. When the desired number of threads are cut, the turret returns; the driving gears for the die or tap holder are disconnected, the die or tap stops revolving and so runs itself off the work. Button or spring dies are used. Left-hand threads are cut by running the die or tap slightly slower than the spindle when cutting and faster when running the die or tap off the thread.

The die- or tap-holder gear is driven by a gear on a shaft that runs through the center of the turret. This shaft can be readily taken out when the machine is not being used for threading.

A fast and a slow motion for the feed mechanism are provided on the larger machines, thereby cutting idle-movement time down to a minimum. This feed is operated by dogs mounted on a disk on the camshaft, where they can be readily adjusted to their correct positions.



CHICAGO AUTOMATIC SCREW MACHINE DESIGNED FOR QUICK CHANGE OF WORK

Spindle capacity, 2 in.; width of belt, 4 in.; diameter of turret, 7½ in.; number of holes in turret, 4 or 5; diameter of holes in turret, 1¼ in.; milling distance, 6 in.; longitudinal adjustment of tools, 2 in.; floor space, 36x124 in.; approximate weight, 3,450 lb.

The stock feed and the chuck-operating mechanism are of the usual types, the stock feed being adjustable to feed any length up to the capacity of the machine. This arrangement eliminates wear on the feeding fingers in pushing back the stock to the correct length.

The oil pump is located at the rear of the machine and is driven by a silent-chain drive from the feedshaft. An oil pan and tank, allowing an ample supply of cutting lubricant, are provided with strainers so that chips cannot interfere with the pump or pipe fittings.

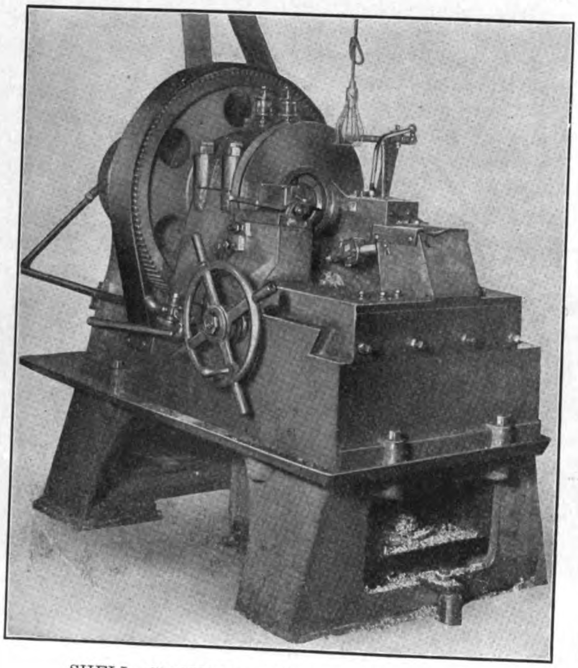
Frictions are used only to prevent breakage of parts but do not form a part of the driving train in that they cannot act until the load or stress greatly exceeds that due to normal operation.

In the design of this machine one of the chief aims was to provide simple construction throughout and to enable quick change from one job to another. In carrying out this purpose all the cams, tools, the spindle speed and the feed-charge gears were made readily accessible. The machine is made in a number of sizes.

Machine for Grooving and Waving 6-In. Shells

The shell-grooving and waving machine shown represents the latest development of the Traylor Engineering and Manufacturing Co., Allentown, Penn. It was designed for 6-in. shells, weighs approximately 9,000 lb. and occupies a floor space of 6x4 ft.; but other sizes have been designed and manufactured.

The machine is equipped with an air chuck (the piston being 9 in. in diameter) that holds the shell securely during the machining operations. The drive is by a belt 4 in. wide, operating through a quick-acting chuck. The tool is of rigid construction, the main spindle bearings



SHELL GROOVING AND WAVING LATHE

being 11 in. in diameter by 12 in. long and lined with a peened babbitt that is afterward bored and scraped. The spindle and the gears are made of semisteel, the teeth afterward being machine-cut.

The shell-holding chuck is a steel forging, which is split into six segments after being turned and bored to the correct size. The longitudinal traverse table is fitted with a take-up gib held and adjusted by four setscrews with check nuts. A chute cast on the machine carries the chips away from the tools and shell. Cutting lubricant is fed through a pipe and flows back by gravity through a screen into a tank in the bed of the machine.

In operation, after the shell has been slid into the chuck, the adjustable stop, shown at the forward end, is raised and the shell end brought up against it. The air pressure is then turned on, which not only grips the shell by means of the segmental chuck, but also pushes the shell against the stop. This insures precise positioning of each shell in relation to the tools. The channel or groove is machined by a tool held under the shell and fed across by the handwheel, shown in front. Thus the correct depth of groove is machined after the tool has been once properly set, as the operator does not have to depend on any gage measurement. The undercut surfaces are machined with the tools shown in front, the handle carrying them first to the right and then to the left against adjustable stops provided for the purpose.

The wave is formed with the tool at the rear, the operator drawing back the tool to the correct depth, determined by an indexed dial on the spindle on which the handwheel is mounted. The proper form of the wave is obtained by the large face cam, which may be seen on the outer surface of the chuck-holding flange. A roller presses against this face cam, which operates the tool, being held against it by a tension spring.

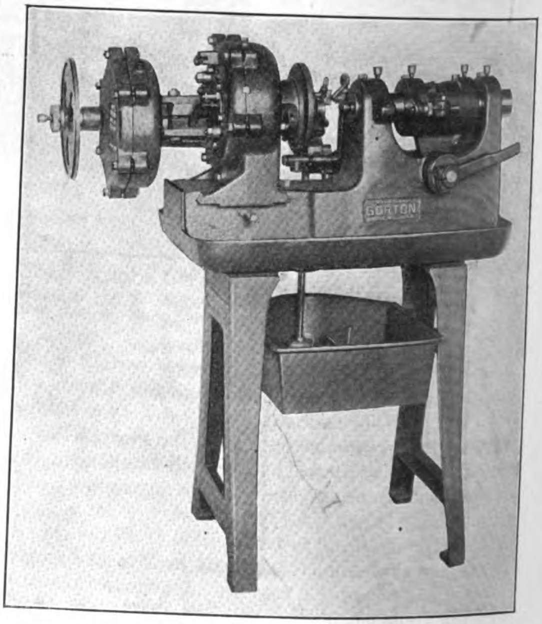
The average time required for machining the groove, undercutting and forming the wave of a 6-in. shell, from floor to floor, is $3\frac{1}{2}$ min.

Routing Machine for Fuse Rings

The illustration shows a machine designed and built by the George Gorton Machine Co., Racine, Wis., for the sole purpose of routing the rings of fuses for shells.

Ample adjustments are provided for, so that the powder groove can be milled any circle up to 4 in. in diameter. It may also be of any length from 0 to 360 deg. Gage holes on the rings may be in any position on top, bottom or side. The spindle of the machine runs approximately 3,200 r.p.m., but may be varied to suit the work.

The groove is finished smoothly and accurately in one cut, and a production of 25 to 30 rings per hour can be



HORIZONTAL ROUTING MACHINE FOR FUSE RINGS

maintained. The ring is clamped on a hardened and ground steel plate by means of a drop-forged fork and hardened cam.

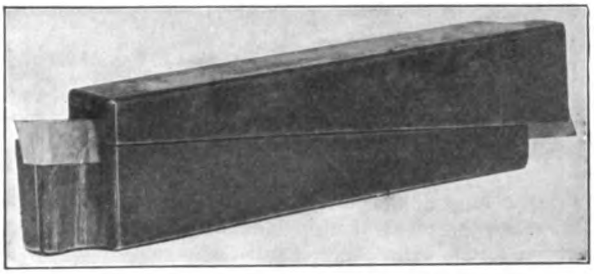
The stops are made of hardened tool steel and operate inside the work-holder case. The feed pulley is mounted on the rear case and operates the work holder by two pairs of reduction spur gears.

The spindle, pump and feed pulleys are all driven from a jackshaft that can be made long enough to drive a number of machines, eliminating the use of individual countershafts and being more practical.

A cutter-lubricating system, including pump tank, strainer, relief valve, piping and flexible nozzle, is provided with the machine, which is mounted on legs. It can be furnished as a bench machine, however, in which case no pump is supplied.

Lathe and Planer Tool Holder

With the type of tool holder shown, in which the cutter is supported directly under the cutting edge and throughout its entire length, it is calculated that cutter breakage will be reduced to the minimum. By the elimination of bosses and setscrews it is possible to bring the holder



LATHE AND PLANER TOOL HOLDER

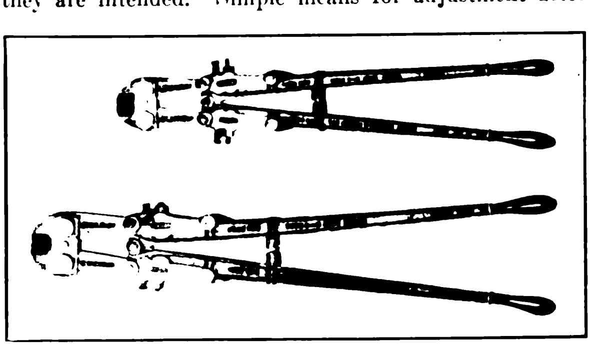
closer to the cutting edge, providing a rigid support and removing the possibility of breakage through setscrews playing on the tool steel.

The holder can be used either as a right- or a left-hand holder by simply reversing it in the tool post.

The tool holder illustrated is made in nine sizes, to take square cutters ranging from $\frac{3}{16}$ to $\frac{7}{8}$ in. It is a recent product of the Worcester Flexible Tubing Co., Worcester, Mass.

Bolt Clippers

The American Metal Products Co., Chicago, Ill., is making bolt clippers in several sizes, as shown. All castings are of the best malleable iron, and the knives are of special tool steel, tempered to meet the specific service for which they are intended. Simple means for adjustment after



BOLT CLIPPERS

Specifications—Made in four sizes: No. 300 cuts threaded bolts to $\frac{5}{16}$-in. diameter, soft steel to $\frac{1}{4}$-in. diameter, and weighs $3\frac{3}{4}$ lb.; No. 400 cuts bolts to $\frac{3}{8}$-in. diameter, soft steel to $\frac{5}{16}$-in. diameter, and weighs $5\frac{1}{2}$ lb.; No. 500 cuts bolts to $\frac{1}{2}$-in. diameter, soft steel to $\frac{3}{8}$-in. diameter, and weighs $9\frac{1}{2}$ lb.; No. 600 cuts threaded bolts to $\frac{5}{8}$-in. diameter, soft steel to $\frac{1}{2}$-in. diameter, and weighs 13 lb.

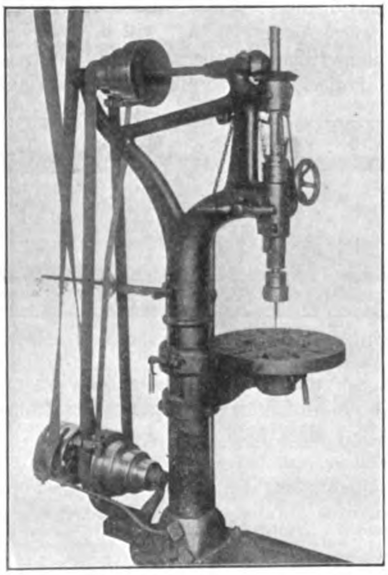
grinding are provided. All parts are interchangeable and can be easily replaced if necessary.

The nuts on the bolts that hold the blades are securely locked by a die-cut lock set in between the two nuts and so shaped as to allow twelve different positions for each hexagon locknut. The bumpers on the handles are designed to really act as such and are not useless parts, as is often the case. The castings are finished in black enamel noted for its wearing qualities.

Automatic Belt Shifter

The belt shifter shown on an upright drilling machine was designed to provide a quick means of shifting the belt from step to step of the cone pulley. The shifter is equally applicable to all classes of cone-driven machine tools. It is of simple construction, consisting of only five parts.

The vertical shifter rod and upper part of handle are a single unit; the pivot rod is screwed into the rear of the drilling-machine column; the belt loops are secured to the shifter rod by set-screws; the retaining strap is



AUTOMATIC BELT SHIFTER

secured to the column of the machine and limits the movement of the handle. The lower leg of the retaining strap is adapted to engage a notch cut in the lower portion of the handle or operating arm, thereby locking the belt in normal position on each step and so preventing the belt from slipping off under heavy drilling.

Viewed from the top of the machine the pivot rod is parallel with the corners of the cone-steps on the belt-entering side and by sliding the handle on this rod, the shifter loops are moved in a way that enables them to move the belt easily from one step of the pulley to another. It will be seen that the handle projects beyond the shifter rod and is there bent over to form a lug in which is drilled a hole to admit the pivot rod freely.

To operate, the handle is lifted slightly to disengage the notch and move the handle forward (or backward) to the next notch engaging the lower portion of the retaining strap and the belt has been moved from one cone-step to the next. When the belt is shifted on to the

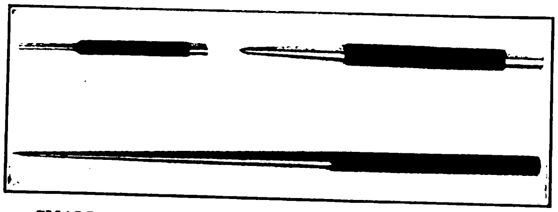
nearest cone-step (the one closest to the column) the operating handle would project in front of the machine column and probably interfere with some work. To overcome this difficulty the handle arm is hinged and can be swung to the side out of the way.

The device can be worked with one hand and is within convenient reach of the operator when he is in front of the machine. If it is desired to shift the belt from one end of the cone pulley to the other, it is unnecessary to shift it from step to step; in such a case the operator simply lifts the handle up to the limit of the retaining strap, pulls or pushes the handle to the limit of its movement in the proper direction, stops being provided so that the handle cannot be moved far enough to throw the belt off the pulley.

This belt shifter is made by Nils E. Larson, 3939 Park Ave., Chicago, Ill.

Scribers, Pin and Center Punches

The West Haven Manufacturing Co., New Haven, Conn., has brought out a line of scribers, center and pin punches, examples of which are shown in the illustration. These tools are manufactured of a good quality of steel, nicely knurled and finished. The pin



SMALL HAND PUNCHING AND SCRIBING TOOLS

punches are made with parallel driving ends from $\frac{1}{16}$ to $\frac{3}{8}$ in. in diameter and in lengths from $2\frac{1}{4}$ in. for the smallest sizes to 6 in. for the largest.

The center punches are furnished in three sizes—with body diameters of $\frac{3}{16}$, $\frac{1}{4}$ and $\frac{3}{32}$ in. The scribers are made in three diameters and lengths.

Measurement of Viscosity and New Form of Viscosimeter

(Continued from page 696)

The experimental work has shown that the temperature of the specimen is uniform to within a small fraction of a degree. Moreover, the temperature of the specimen follows the temperature of the jacket oil so closely that the temperature-viscosity curve can be taken while the temperature is slowly raised or lowered. This proves to be a great saving of time. It also saves labor, for one does not need to stand by the instrument continually. The deflection of the pointer is at any instant a measure of the viscosity, so all that is required it to take simultaneously readings of temperature and deflection at intervals during the heating or cooling process. The new viscosimeter of the nonflow type described has the following advantages:

1. It gives values for the viscosity which are in agreement with those given by the standard capillary-tube method.

2. During a series of tests at various temperatures the oil is not handled.

3. The sensitiveness of the instrument can be made anything desired by changing the speed of rotation of the specimen or by using suspension wires of various diameters.

4. The density or change in density is not a factor in computing the results; in fact, the instrument may be graduated to read off the viscosity directly.

5. The viscosity of liquids which contain particles in suspension can be measured, and the operation of the meter is independent of the color of the specimen.

6. The temperature-viscosity curve can be taken with a fair degree of accuracy while the temperature is rising or falling, as the temperature of the specimen closely follows the temperature of the jacket.

7. The personal error which arises in determining time intervals with a stop watch is removed.

8. The instrument is simple, rigid and self-contained. It has no separate parts to get lost or glass parts to get broken.

Plan for Classification of Technical Literature

The Joint Committee on Classification of Technical Literature, composed of representatives of the leading technical, engineering and industrial organizations of the country, met on Saturday, Apr. 1, in the Board room of the American Society of Engineers. Henry W. Peck, of Schenectady, presented a progress report, outlining the way in which the committee came into being and reviewing its work to date. W. P. Cutter, librarian of the Engineering Societies Library and secretary of the executive committee, presented a paper on "How To Make a Classification." After considerable discussion as to the relative merits of the plan recommended by the executive committee, of the proposal to assign the classification of various divisions of the subject to the societies dealing with those specialties and of the suggestion to employ a professional to prepare a tentative classification for later discussion and revision by the respective societies it was decided to adopt the recommendation of the executive committee as more in accord with the means at the disposal of the committee.

F. R. Low resigned the chairmanship of the executive committee in favor of Henry W. Peck, who has been actively identified with the movement from its inception.

NEW PUBLICATIONS

ELEVATORS—By John H. Jallings. Two hundred and seventeen 5½x8¼-in. pages; 172 illustrations; indexed; cloth bound. The American Technical Society, Chicago, Ill. Price, $1.50.

This book, written in rather popular style, describes and illustrates all the common forms of elevators. It is divided into three parts, of which the first takes up hand-power elevators, belt-power elevators and worm and gear elevators. The second part includes steam elevators and hydraulic elevators, while the third part takes up electric elevators.

The historical development of the elevator as a lifting device is quite fully covered and with a sketch of the early developments of the various common types of today fits the book for anyone who wishes to acquaint himself with the general features of construction and operation. However, but very little information is given which would be of value to the elevator designer or erector.

The illustrations have been drawn from commercial types, and generous credit has been given to the firms who have supplied the photographs, drawings and information.

AUTOGENOUS WELDING AND CUTTING—By Theodore Kautny. Translated from the German by the author and James F. Whiteford. One hundred and forty-two 5x7-in. pages; 133 illustrations; indexed; cloth bound. McGraw-Hill Book Co., New York City. Price, $1.

This is one of the most valuable books that has appeared in English, dealing with flame welding and cutting. Its author, Mr. Kautny, is a recognized expert in Germany and has been intrusted by the Prussian Government with the organization of a large number of welding schools throughout the empire.

The book is written entirely from a practical viewpoint and is intended to cover in a brief compass information of value to the works engineer, foreman and welder. Its scope is indicated by the headings of the 19 chapters, which are: Autogenous Welding Flames, Acetylene Manufacture and Apparatus, Oxygen Manufacture and Apparatus, Gas Mains and Fittings, Autogenous Welding Burners, Autogenous Cutting Burners, Autogenous Welding of Iron, Repairs on Gray Cast-Iron, Welding of Sheet Iron, Manufacture and Repairs on Boilers, Manufacture of Cylindrical Vessels, Manufacture of Rectangular Vessels and Miscellaneous Articles, Manufacture and Installation of Large Pipes and Conduits, Manufacture and Installation of Gas and Water Pipes, Construction of Pipe-Shaped Apparatus, Welding of Copper, Welding of Aluminum, Welding of Nickel and Other Metals, Conclusion.

The book should find a place in the hands of everyone who is interested in any way in the flame welding or cutting of metals, either for repair work or in manufacturing.

PERSONALS

P. J. Krentz, for sometime superintendent of the Buffalo Foundry and Machine Co., has become works manager.

G. Strom, formerly tool designer with the Titusville Iron Co., Titusville, Penn., has joined the ship-drafting force at the Brooklyn Navy Yard.

E. S. Cullen, for a number of years associated with the Niles-Bement-Pond company has established the E. S. Cullen Machinery Co., Cleveland, Ohio.

Clarence K. Prince, for over 25 years associated with the H. B. Smith Co., Westfield, Mass., has been appointed general superintendent to fill the vacancy caused by the death of George H. Cushing.

Fred. Kent, general manager of the Lodge & Shipley Machine Tool Co. made an address before the Engineering Society of Buffalo at a meeting on April 12 on the general subject of modernizing the shop.

Axel Malm, an occasional contributor to our columns, has resigned his position as superintendent of the Egry Register Co., Dayton, Ohio, in order to establish the Malm Machine Co., of which he has become vice-president and general manager.

W. V. Houck, for the past two years assistant superintendent of the King Sewing Machine Co., Buffalo, N. Y., and for ten years prior thereto associated with the Garvin Machine Co., has accepted the position of factory manager of the Sterling Engine Co., Buffalo, N. Y.

C. H. Halcomb and William P. Davidson, for many years executives of the International High Speed Steel Co. have organized the firm of Halcomb & Davidson, Inc., 149 Broadway, New York City. The new company will specialize in the manufacture and sale of alloy steels.

TRADE CATALOGS

CATALOGS WANTED

The Liberty Fuse and Arms Corp., Jackson Ave. and Crane St., Long Island City, N. Y., would like to receive catalogs of machinery and tools used in the manufacture of fuse parts and other brass work.

Count S. I. Shulenberg, Imperial Russian Railway Commission, 140 Broadway, New York City, requests catalogs of all kinds of machine shop equipment, and equipment for steel mills. Count Shulenberg does not wish such catalogs for himself or for the Russian Government, but wants them for many friends in Russia who continually send him inquiries in such lines.

BUSINESS ITEMS

The Desmond Stephan Mfg. Co., Urbana, Ohio, has bought the business of The Rupert Co., Indianapolis, Ind., manufacturers of Huntington dressers.

The Malm Machine Co., Dayton, Ohio, has been organized to take up the manufacture of the recently invented Malm rotary punch press. The following officers have been elected: A. G. Stevens, president; F. Kiefaber, vice-president; Axel Malm, vice-president and general manager; H. M. Estabrook, secretary and treasurer.

The Cyclops Steel Works, Titusville, Penn., operated for many years by Charles Burgess has been purchased by the Cyclops Steel Co., Carl F. Boker, president, and will be enlarged and developed. F. C. Kirkpatrick and Walter Bould, managers of the works under Mr. Burgess, will continue with the new company and the organization will remain unchanged. Carl F. Boker has parted with his interest in the H. Boker Co. The New York office of the Cyclops Steel Co. is at 115 Broadway, N. Y.

FORTHCOMING MEETINGS

National Metal Trades Association. Annual meeting, Apr. 27-28, New York, N. Y., Hotel Astor. H. D. Sayre, secretary, Peoples Gas Building, Chicago, Ill.

American Society for Testing Materials. Annual meeting June 27 to July 1, 1916, Hotel Traymore, Atlantic City, N. J. Edgar Warburg, secretary, University of Pennsylvania, Philadelphia, Penn.

American Society of Mechanical Engineers. Monthly meeting first Tuesday. Calvin W. Rice, secretary, 29 West Thirty-ninth St., New York City.

Boston Branch National Metal Trades Association. Monthly meeting on first Wednesday of each month, Young's Hotel. W. W. Poole, secretary, 40 Central St., Boston, Mass.

Providence Association of Mechanical Engineers. Monthly meeting fourth Wednesday each month. J. A. Brooks, secretary, Brown University, Providence, R. I.

New England Foundrymen's Association. Regular meeting second Wednesday of each month. Exchange Club, Boston, Mass. Fred F. Stockwell, 205 Broadway, Cambridgeport, Mass.

Engineers' Society of Western Pennsylvania. Monthly meeting third Tuesday; section meeting, first Tuesday. Elmer K. Hiles, secretary, Oliver Building, Pittsburgh, Penn.

Rochester Society of Technical Draftsmen. Monthly meeting, last Thursday. O. L. Angevine, Jr., secretary, 857 Genesee St., Rochester, N. Y.

Superintendents' and Foremen's Club of Cleveland. Monthly meeting third Saturday. Philip Frankel, secretary, 310 New England Building, Cleveland, Ohio.

Western Society of Engineers, Chicago, Ill. Regular meeting first Wednesday evening of each month, excepting July and August. J. H. Warder, secretary, 1785 Monadnock Block, Chicago, Ill.

Philadelphia Foundrymen's Association. Meetings first Wednesday of each month. Manufacturers' Club, Philadelphia, Penn. Howard Evans, secretary, Pier 45 North, Philadelphia, Penn.

Technical League of America. Regular meeting second Friday of each month. Oscar S. Teale, secretary, 35 Broadway, New York, N. Y.

Prices--Materials and Supplies

IRON AND STEEL

Pig Iron—Quotations were current as follows at the points indicated:

	Apr. 14, 1916	One Month Ago	One Year Ago

6	55.68	40.32	91.20	60.48

Bar Iron—Prices are as follows in cents per pound at the places named:

	Apr. 14, 1916	One Month Ago
Pittsburgh, mill	2.50	2.20@2.30
New York	2.75	2.40@2.45
Warehouse, New York	3.15	2.70
Warehouse, Cleveland	3.25	...
Warehouse, Chicago	3.10	...

Cold Drawn Steel Shafting—From warehouse to consumers requiring fair-size lots, the following quotations hold:

New York	15% above list price
Cleveland	20% above list price
Chicago	10% above list price

Boiler Tubes—From Pittsburgh, the following are the less-carload basing discounts for lap-welded boiler tubes:

1¾ and 2 in.	51%	3½ to 4½ in.	60%
2¼ in.	48%	5 and 6 in.	53%
2½ and 2¾	54%	7 to 13 in.	50%
3 and 3¼	59%		

These discounts apply to standard gages and to even gages not more than 4 gages heavier than standard. For long tubes charge 10% net extra as follows: 1¾ in. size over 18 ft. and not exceeding 22 ft.; 2 to 3 in. sizes over 22 ft. and not exceeding 24 ft.; 3¼ to 13 in. sizes over 22 ft. and not exceeding 25 ft.

Swedish Steel Sheets—To consumers requiring fair-sized quantities tool steel sheets sell at 16c. base and spring steel sheets at 12c. base. These prices are f.o.b. warehouse, New York.

Swedish (Norway) Iron—This material per 100 lb. sells as follows f.o.b. places named:

New York Today	New York One Year Ago	Cleveland	Chicago
$4.75	$3.75@4.00	$5.05	$4.10

In coils an advance of 50c. is usually charged.

High Speed Tool Steel containing from 10 to 18% tungsten sells as follows per pound in New York:

Billets .... $2.35 Bars $3.00

METALS

Miscellaneous Metals—The present quotations in cents per pound, with a comparison of practically a month and year ago, are as follows:

	New York Apr. 14, 1916	One Month Ago	One Year Ago
Copper, electrolytic (carload lots)	28.50	27.25	16.87½
Tin	54.00	42.00	55.00

The contract has been awarded for the construction of a 3-story, 100x300-ft. addition to the plant of the Lunkenheimer Co., manufacturer of brass, iron and engineering specialties, at Cincinnati, Ohio. Noted Jan. 20 and 27.

The American Steel and Wire Co. has awarded the contract for the construction of an addition to its plant at Cleveland, Ohio. Noted Mar. 30.

Plans are being prepared for construction of a 3-story garage at Cleveland, Ohio, for H. W. Clark, 608 Bolivar Rd., Cleveland. Estimated cost, $30,000. Noted Dec. 2.

Preliminary plans are being prepared for the construction of a 2-story, 87x110-ft. and 31x50-ft. addition to the factory of the D. G. Hutchcraft & Sons Co., 1318 West 78th St., Cleveland, Ohio, manufacturer of automobile bodies.

The contract has been awarded for the construction of the 1st unit of the plant on East 152nd St., Cleveland, Ohio, for the Jordan Motor Car Co. Estimated cost, $50,000.

Preliminary plans prepared for 1-story, 92x230-ft. garage at Cleveland, Ohio, for Henry P. Oster, 10550 Euclid Ave., Cleveland. Estimated cost, $30,000. Noted Mar. 9.

We have been informed that the Republic Structural Iron Works Co., 1270 East 53rd St., Cleveland, Ohio, does not plan to enlarge its plant on Lakeside Ave., Cleveland as stated in our issue of Apr. 6.

The contract has been awarded for the construction of a 5-story, 100x300-ft. garage and service station at Cleveland, Ohio, for the Willys-Overland Co. Estimated cost, $50,000. Noted Nov. 25 and Jan. 20.

Plans are being prepared for the construction of a 1-story addition to the plant of the Burke Machine and Tool Co. at Conneaut, Ohio.

The Safety Auto Light and Manufacturing Co. plans to build a plant at Erlin, Ohio (Fremont post office).

The contract has been awarded for the construction of a 2-story garage at Logan, Ohio, for the Main Motor Car Co. Estimated cost, $10,000. Noted Mar. 30.

Plans are being prepared for the construction of a 1-story, 120x200-ft. foundry and machine shop at Lorain, Ohio, for the American Shipbuilding Co. A. G. Smith is Gen. Mgr. Noted Apr. 6.

Plans are being prepared for the construction of a 1-story, 40x80-ft. addition to the plant of the Peerless Drawn Steel Co. on Sippo St., Massillon, Ohio.

The contract has been awarded for the construction of a 2-story factory on Washington St., Springfield, Ohio, for the Myers Auto Top Co.

The Griffith & Wedge Co., manufacturer of steam engines, boilers and clay machinery, plans to enlarge its plant at Zanesville, Ohio. C. B. Wedge is Pres.

Plans are being prepared for the construction of a 2-story, 66x113-ft. garage at Zanesville, Ohio, for Charles N. Harvey, Main and 2nd St., Zanesville. Estimated cost, $25,000. Noted Nov. 11.

The contract has been awarded for the construction of a 5-story factory at Ft. Wayne, Ind., for the General Electric Co. Estimated cost, $350,000. Noted Apr. 6.

Jnagy Bros. will construct a garage at Hamilton, Ind. Estimated cost, $10,000. Noted Jan. 20.

The Lima Locomotive Works, Lima, Ohio, plans to construct a foundry at Huntington, Ind. Estimated cost, $50,000. A. L. White, Lima, is Pres.

Plans have been prepared for the construction of an addition to the plant of the Link-Belt Co. on Addison St., Indianapolis, Ind. Estimated cost, $12,000. Noted Jan. 13.

The contract has been awarded for the construction of a 1-story, 50x327-ft. foundry at Kokomo, Ind., for the Kokomo Brass Works. J. W. Johnson, 1412 North Webster St., Kokomo, is Mgr. Noted Mar. 16.

The contract has been awarded for the construction of a factory at Detroit, Mich., for the Packard Motor Car Co. Estimated cost, $50,000.

The contract has been awarded for the construction of a 2-story, 300x350-ft. addition to the plant of the Buick Motor Co., Flint, Mich. Noted Feb. 24.

The Sparks-Withington Co., manufacturer of roller bearings and pressed metal products, is constructing an addition to its plant at Jackson, Mich., and is in the market for presses. Noted Mar. 23.

We have been advised that plans have been prepared for the construction of a 90x175-ft. machine shop at Chicago, Ill., for the Albaugh-Dover Co. Estimated cost, between $25,000 and $30,000.

We have been informed that the A. Finkel & Sons, 1322 Cortlandt St., Chicago, Ill., is constructing a 1-story, 25x110-ft. machine shop at Chicago. Estimated cost, $10,000. Noted Apr. 6.

The contract has been awarded for the construction of a 1-story addition to the garage at 39th St. and Wabash Ave., Chicago, Ill., for the U. S. Auto Supply Co., 3845 South Wabash Ave. Estimated cost, $12,000. Noted Feb. 17.

The contract has been awarded for the construction of a 1-story box shop at Granite City, Ill., for the National Enameling and Stamping Co. Estimated cost, $12,000.

The Claus Automatic Gas Cock Co. is constructing a 1-story foundry and machine shop on Kefe Ave., Milwaukee, Wis., and is in the market for turret lathes, hand miller and milling machinery. Estimated cost, $15,000. Noted Mar. 16 and 23.

T. Weinand contemplates constructing a 1-story garage and salesroom at West Bend, Wis. Estimated cost, $10,000.

WEST OF THE MISSISSIPPI

The Shrauge & Johnson Co., Atlantic, Iowa, manufacturer of lighting rods and hardware specialties, plans to construct an addition to its plant.

The Great Northern Ry. plans to construct shops in the Kendon Addition, Sioux City, Iowa. Estimated cost, $200,000. A. H. Hogeland, St. Paul, Minn., is Ch. Engr.

M. D. Prendergast, Port Huron, Mich., plans to construct a plant at Stillwater, Minn., for the manufacture of wire fencing.

The Chillicothe Gun Manufacturing Co. is constructing a plant at Chillicothe, Mo.

The Keys Piston Ring Co., St. Louis, Mo., plans to install new equipment.

Plans are being prepared for a 1-story, 70x90-ft. auto repair shop for the Old Line Carriage Works, Springfield, Mo. Estimated cost, $10,000. C. G. Levan is Mgr.

The Denver Boiler and Iron Works, Denver, Colo., is negotiating with the manufacturing committee of the Chamber of Commerce, El Paso, Tex., with the view to constructing a foundry at El Paso.

WESTERN STATES

The Ford Motor Co., Detroit, Mich., plans to construct an assemblying plant at Salt Lake City, Utah. Estimated cost, $400,000.

The Columbia Iron Works, Astoria, Ore., contemplates to construct an addition to its welding mill and will install new equipment.

The Electric Steel Foundry Co., 24th and York St., Portland, Ore., is constructing an addition to its plant at Portland. Estimated cost, $40,000. Noted Feb. 24 and Mar. 16.

The Cowels Investment Co. plans to construct a 60x100-ft. garage and machine shop at Spokane, Wash. Estimated cost, $20,000.

Plans are being prepared for the construction of a 3-story, 32x100-ft. factory at Tacoma, Wash., for the Atlas Foundry and Machine Co. Estimated cost, $10,000.

Henry Abrahamson plans to construct a garage at Broadway and 29th St., Oakland, Calif. Estimated cost, $20,000.

The contract has been awarded for the construction of a 3-story assembling plant at Oakland, Calif., for the Chevrolet Motor Co. Estimated cost, $200,000. Noted Dec. 9.

Edward Somarstrom, 202 East 12th St., Oakland, Calif., plans to construct a 1-story garage on Broadway, Oakland. Estimated cost, $25,000.

The J. D. and A. B. Spreckels Securities Co., Union Bldg., San Diego, Calif., will build a garage and machine shop at 409 Broadway, San Diego. Estimated cost, $10,000.

The contract has been awarded for the construction of a 1-story plant at Folsom and 11th St., San Francisco, Calif., for the manufacturer of auto trucks, for Kleiber & Co. Noted Feb. 10.

CANADA

The Hull Iron and Steel Co., Montcalm St., Hull, Que., plans to construct an addition to its plant at Hull. Estimated cost, $5,000.

The contract has been awarded for the construction of an addition to the plant of the Canadian Iron Corporation, Sherbrooke, Que.

The Canadian Foundries and Forgings Co. plans to construct an addition to its plant at Brockville, Ont.

The Canada Wire and Iron Goods Co., plans to build an addition to its plant on King William St., Hamilton, Ont. Estimated cost, $3,500.

The Hydro Electric Radiation, Ltd., contemplates constructing a factory at Listowel, Ont. G. E. Harrison, 704 Traders Bank Bldg., Toronto, Mgr.

The contract has been awarded for the construction of a machine shop for Whitfield & Co., 33 Sherbourne St., Toronto, Ont. Estimated cost, $12,000.

The Volta Manufacturing Co., manufacturer of specialties for electric furnaces, etc., plans to build a 2-story, 50x60-ft. factory at Welland, Ont.

GENERAL MANUFACTURING

NEW ENGLAND STATES

The contract has been awarded for the construction of a 1-story, 50x65-ft. addition to the plant of the Saunders Cotton Co., Saundersville, Mass. Estimated cost, $5,000.

The contract has been awarded for the construction of a 4-story, 84x220-ft. addition to the plant of the Baltic Mills Co., Baltic, Conn. Noted Jan. 13 and Mar. 23.

The contract has been awarded for the construction of a factory at Hope, R. I., for the Hope Mill, manufacturer of shirting. Noted Mar. 16 and 23.

The Sidney Worsted Co. has awarded the contract for the construction of a 2-story, 77x120-ft. mill at Woonsocket, R. I. Estimated cost, $30,000. Noted Mar. 23.

The Winchester Woolen Co. plans to construct a plant at Thamesville, Conn. Estimated cost, $200,000.

MIDDLE ATLANTIC STATES

The General Chemical Co. plans to construct a 1-story addition to its plant at 350 Abbott Rd., Buffalo, N. Y. Estimated cost, $14,000.

The Clayville Knitting Co., Clayville, N. Y., plans to enlarge its plant. Estimated cost, $200,000.

Bids are being received by the Isco Chemical Co., Niagara Falls, N. Y., for a plant at Royal and Union St. Estimated cost, $300,000. Noted Mar. 6.

The Arlington Co., Arlington, N. J., manufacturer of celluloid and pyroxlin specialties, will construct 2 additions to its plant.

The Carbo-Hydrogen Co. of America has acquired a site at Hobart Ave. and Oak St., Bayonne, N. J., and will construct a plant.

Thomas Oakes & Co., Bloomfield, N. J., manufacturer of woolens, will construct a 2-story addition to its plant.

The Martin Dennis Co., Newark, N. J., manufacturer of chemicals, has awarded the contract for the construction of a factory at Kearney, N. J. (Arlington post office).

The Central Dyestuff and Chemical Co., Newark, N. J., will improve and enlarge its plant on Plum Point Lane.

The Duratex Co., Newark, N. J., manufacturer of leather, will construct an addition to its plant on Frelinghuysen Ave. Estimated cost, $30,000.

The Heller & Merz Co., Newark, N. J., manufacturer of colors and dyes, will construct a 1-story factory on Hamburg Pl.

Felix C. Holmes, Newark, N. J., has acquired a site on Halsey St. and will establish a plant for the manufacture of automobile seat covers and tops.

The Imhoff-Berg Silk Dyeing Co., Paterson, N. J., will construct a dye and finishing plant at Paterson. Estimated cost, $40,000.

The Union Silk Co., Summit, N. J., recently incorporated, has had plans prepared for a silk mill on Morris Ave.

Preliminary plans are being prepared for a 1-story, 200x 250-ft. factory for the Sommer Co., Washington, N. J., manufacturer of pianos. Estimated cost, $50,000. John H. Sommer, Pres.

Bids are being received by the Lee Tire and Rubber Co., Conshohocken, Penn., for a 2-story fireproof mill construction building.

The Juniata Hosiery Mill, Mifflintown, Penn., is building an addition to its plant.

The contract has been awarded for the construction of an addition to the plant of the Cramps Shipbuilding Co., Philadelphia, Penn. Estimated cost, $6,000.

Bids are being received by Harry C. Eisenbise, Arch., Philadelphia, Penn., for a 3-story belting factory on Cottman St., Philadelphia, for L. H. Gilmer Co. Noted Mar. 30.

Plans have been prepared by Day & Zimmerman, Arch., 611 Chestnut St., Philadelphia, Penn., for reconstructing a 2-story factory at 37th and Tasker St., Philadelphia, for the Nitrogenous Chemical Manufacturing Co.

Bids will soon be received by F. A. Muhlenberg, Arch., 706 Colonial Trust Bldg., Reading, Penn., for a 100x229-ft. factory on South 8th St. for the Pennsylvania Optical Co., Reading. Noted Dec. 16.

Sheldon & Leach, Wilkes-Barre, Penn., plan to construct a silk mill at New Grove and Gilligan St., Wilkes-Barre. Andrew K. Leach is Pres.

The Chemical Products Co., Washington, D. C., has awarded the contract for the construction of a 1-story factory. Estimated cost, $24,000.

SOUTHERN STATES

The Davis Hosiery Mills, Chattanooga, Tenn., has awarded the contract for the construction of a plant at Bristol, Va. Estimated cost, $200,000.

State contemplates construction of lime-grinding plant at Tidewater, Va. Estimated cost, $25,000. H. C. Stuart, Governor.

R. J. Morrison plans to construct a knitting mill at Cherryville, N. C.

The Ware Shoals Manufacturing Co. plans to construct a 2-press cotton seed oil mill at Ware Shoals, S. C.

The Southern Cotton Oil Co. plans to improve its plant at Columbus, Ga. Estimated cost, $10,000.

Armour & Co., Chicago, Ill., plans to construct a cold-storage plant at Hattiesburg, Miss.

The plant of the Carcolite Chemical Co., Copper Hill, Tenn., recently destroyed by fire with a loss of $250,000, will be rebuilt. Noted Apr. 6.

MIDDLE WEST

The contract has been awarded for the construction of an addition to the plant of the Blumenstock & Reid Co., 3261 West 65th St., Cleveland, Ohio. Estimated cost, $20,000. Noted Apr. 6.

Plans are being prepared for the construction of a 1-story, 43x250-ft. addition to the factory of the Climax Cleaner Manufacturing Co. at Cleveland, Ohio.

The Champion Coated Paper Co. will construct an addition to its plant at Hamilton, Ohio. Estimated cost, $10,000. Noted Apr. 6.

The McKee & Bliven Button Works plans to construct a factory on 3rd St., Marietta, Ohio.

The Sullivan Packing Co., Detroit, Mich., has awarded the contract for the construction of a 2-story, 50x50-ft. addition to its plant at Toledo, Ohio. Estimated cost, $10,000.

The Starr Piano Co. will build a 6-story addition to its factory at Richmond, Ind. H. Gennett s Pres.

The Farmers Ground Limestone Co. plans to construct a plant at Vernon, Ind.

The contract has been awarded for the construction of an addition to the factory of Morgan & Wright, manufacturer of rubber goods, at Detroit, Mich.

Plans are being prepared by H. P. Henschien, Arch., 37 West Van Buren St., Chicago, Ill., for the construction of a 2-story, 76x166-ft. packing plant at Elgin, Ill., for the Kerber Packing Co.

Plans are being prepared for the construction of a packing plant at Quincy, Ill., for the Fair Abattoir Co. Estimated cost, $50,000. R. J. Connery, 20th St. and Broadway, Quincy, is interested. Noted Mar. 23.

The contract has been awarded for the construction of a cold-storage plant at Eau Claire, Wis., for H. Cary & Son, 407 Galloway St., Eau Claire.

Plans have been prepared for the construction of a 2-story, 50x100-ft. factory at 6th and State St., La Crosse, Wis., for the Fisk Rubber Co., Chicopee Falls, Mass. Noted Mar. 23.

The contract has been awarded for the construction of a 4-story, 60x200-ft. factory and a 55x70-ft. addition to the milling department of the La Crosse Rubber Mills Co. at La Crosse, Wis. A. P. Funk is Gen. Mgr. Noted Mar. 9.

Bids will soon be received for the construction of a 3-story, 50x120-ft. factory at Waupun, Wis., for the Paramount Knitting Co., Chicago, Ill. Estimated cost, $40,000. Noted Feb. 17.

WEST OF THE MISSISSIPPI

The Hugo Manufacturing Co., manufacturer of specialties, 310 West 2nd St., Duluth, Minn., will construct a 2-story factory. Estimated cost, $25,000.

P. J. Neel will build a box factory and lath mill at Ranier, Minn.

Henry Meinecke, Tomah, Wis., plans to construct a packing plant at Fairbury, Neb. Estimated cost, $250,000.

The Ohio Oil Co., Findlay, Ohio, plans to construct an oil refinery at Greybull, Wyo.

The American Manufacturing Co., manufacturer of cordage and bagging, 220 North 4th St., St. Louis, Mo., has awarded the contract for the construction of a 2-story factory. Estimated cost, $40,000. Noted Apr. 6.

J. S. Thompson, Grit, Tex., will build a cotton gin about 16 mi. south of Brady, Tex.

The Houston Packing Co., Houston, Tex., plans to enlarge its plant.

The Lockhart Oil Mill Co., Lockhart, Tex., has awarded the contract for the construction of a cotton seed oil mill. Estimated cost, $50,000. Noted Dec. 23.

The McKinney Compress Co., McKinney, Tex., will rebuild its plant recently destroyed by fire with a loss of $50,000.

The Texas Co. plans to enlarge its oil refinery at Port Neches, Tex.

The Sugarland Manufacturing Co., Sugarland, Tex., plans to construct a sulphuric acid plant at Sugarland. Estimated cost, $300,000.

The Texas City Handle Factory, Texas City, Tex., plans to enlarge its factory.

A tire manufacturing plant will be equipped by the White Springs Tire Co., Edmond, Okla., recently incorporated with $50,000 capital stock. J. W. White and M. J. O'Connor are interested.

J. C. Palmer, Orr., Okla., plans to construct a cotton gin at Ringling, Okla. Estimated cost, $12,000.

WESTERN STATES

The Malaga & Thompson Grape Growers Association plans to build a packing plant at Clovis, Calif.

The White Star Canning Co., San Pedro, Calif., will construct a canning plant in East San Pedro.

The California Bag and Paper Co. plans to equip a factory at Emeryville, Calif. Walter Mackey, Oakland, is interested.

The California Fruit Products Co. plans to construct a cotton gin at Holtville, Calif.

The Elderwood Packing Co. is constructing a packing plant at Lindsay, Calif. Estimated cost, $10,000. H. B. McClure is Pres.

The California Orange Jelly Co. plans to construct a factory at 9th and McGarry St., Los Angeles, Calif.

Work will soon be started on the construction of a plant at Oakland, Calif., for the Pacific Thread Tire Co. Estimated cost, $250,000. V. K. Sturges, 26th and Union St., is Pres.

The Orange County Valencia Association, recently incorporated, plans to build a packing plant at Orange, Calif.

Swift & Co., Chicago, Ill., has awarded the contract for the construction of a potash-manufacturing plant on the water front near E St., San Diego, Calif. Noted Feb. 17.

The Wheeler-Chase Canning Co. plans to build a fruit canning plant at San Diego, Calif.

Plans are being prepared by D. B. Day for the construction of a packing plant at Woodlake, Calif., for the Elderwood Packing Co.

Classified Advertising

The Classified Advertising section appears on pages 177, 178, 179, of this issue and will in future appear in the same relative position in the paper.

American Machinist

L. P. ALFORD, *Editor*

Published Weekly by HILL PUBLISHING COMPANY
Tenth Avenue at Thirty-sixth Street, New York, N. Y.

ARTHUR J. BALDWIN, President — CHESTER W. DIBBLE, Vice-President — ROBERT McKEAN, Secretary

Chicago, Monadnock Bldg. — Cable Address, "MACHINIST N. Y."

Correspondence on mechanical subjects solicited and paid for. Names and address must always be given—not necessarily for publication. Subscribers can have address changed at will. Give old and new addresses. Subscription price $4 per year, postage prepaid, to any postoffice in United States, United States possessions and Mexico; $5.50 to Canada; $7 in all foreign countries except Europe and British possessions in Eastern Hemisphere. Hill Publishing Co., Ltd., 6 Bouverie St., London, E. C., will serve all subscriptions for English Edition for Europe and British possessions in Eastern Hemisphere. Price 30 shillings for England; for all other countries in Eastern Hemisphere 35 shillings.
Entered at New York Postoffice as mail matter of the second class.

Advertising is the Great National Business Science

BY ARTHUR BRISBANE, *Editor N. Y. Journal*

Written for the Associated Advertising Clubs of the World.

ADVERTISING is the art of transferring an idea from your mind to the minds of others.

The advertiser's task is to see a thing clearly, DESCRIBE IT SIMPLY and convincingly:

The business man is the DYNAMO, the advertising man is the electric BULB that tells of the dynamo's work.

The bulb that thinks itself more important than the dynamo is foolish.

The big dynamo that thinks it can get along without any bulb and make a success of a lightning plant all by itself, is a foolish dynamo.

Advertising is an art of science important to all the nations and to every man in the nation.

Advertising is to business, industry, manufacture, WHAT PRINTING AND LANGUAGE ARE TO THE HUMAN RACE. Advertising is the SPEECH OF BUSINESS. Without it, business is dumb. Long since we enumerated four things that the advertiser must do or fail.

1—He must make the public SEE his advertisement.

2—He must make the public READ it.

3—He must make the public UNDERSTAND it.

4—He must make the public BELIEVE it.

Is advertising difficult? It is, indeed. It would be easier to start a new religion or a successful career in the United States THAN TO START A NEW BRAND OF SOAP.

Get the name of your client's product so thoroughly in the public brain that the product and the name you advertise become synonymous.

If in the United States you say "Tiffany" it means jewelry. If you say "Delmonico" it means food.

Advertising genius properly encouraged can actually take a meaning as old as the language, and transfer it to a new word, to a new name.

How is this done? First of all, BY REPETITION.

"Repetition is reputation."

The great French revolutionist said that success called forth "audacity, audacity, more audacity." Advertising success calls for REPETITION, REPETITION, MORE REPETITION.

There is advertising in every year of the human being's life. The new born baby advertises its need of food and a bath with pitiful squalling.

The little boy twisting his hat in his hand, asking for work, seeks to advertise his qualities as an office boy.

The young man in his courting is a tremendous advertising agent, hoping that he will favorably impress one who is the entire public to him, and persuade her to accept what he has to offer.

To every advertiser of every kind these things are of vital importance in bringing success.

Know exactly what it is that you have to say.

Know that you are telling a truth which is useful to the public.

Express yourself with SIMPLICITY, for that is the greatest of literary art.

You must avoid dryness, which discourages the reader.

You must avoid unnecessary words; everyone of them cost money; every surplus word discourages the reader and drives away from your advertisement.

You must know where to begin—just where your reader's interest begins. You must know where to stop, just where HE would stop if you did not.

You must avoid the appearance of preaching at the people, for the people get all the preaching they want on Sunday.

You must write exactly as though you were TALKING to the reader, for an advertisement writer is a salesman.

Many a man in business can wait patiently while a factory is going up brick by brick—knowing that the bricks must be bought and laid first. But he cannot wait patiently while his reputation is being built up brick by brick through advertising. He wants to get returns on the first load of bricks thrown on the vacant lot.

To keep him while he teaches the public is difficult—but difficulty is what makes advertising interesting.

Advertising is important, not only because it helps business, but because it increases the efficiency of labor.

Advertising renders public service, the great advertiser puts his fortune INTO HIS REPUTATION, and if he dies the successor cannot AFFORD TO DAMAGE THAT REPUTATION.

No man sets fire to a factory that has cost millions.

No man sets fire to an advertising reputation that has cost millions and injures the quality of the advertised goods. That would destroy the reputation.

Every man excepting the fool, knows that the foundation of advertising success is honesty. And the higher you hope to build THE MORE POWERFUL YOUR FOUNDATION MUST BE.

Theory of Economic Milling

By Reginald Trautschold

SYNOPSIS—The theoretical factors affecting the economy of milling operations analyzed and differentiated. Milling-cutter charasteristics taken up and their co-relationship explained. "Revolution factors" established and the question of speed resolved to a "basic speed." Feed requirements considered and a system of milling-cutter classification described, together with the relative economy of the system proposed.

But three factors affect the efficiency of milling operations—the depth of cut, the feed and the cutting speed of the milling cutter—yet their co-relationship is not generally understood, so that the economic operation of a miller is today largely a matter of chance, and rarely are two pieces of work cut with the same degree of efficiency or with equal economy. Particularly is this true when the milling cutters are of different diameters. High cutting speeds are aimed at and the use of milling cutters of large diameters recommended, in order that the speed of revolution may be at a minimum for a maximum cutting speed. Further than this, milling operations, as practiced today, call for a more or less definite cutting speed for a cut of certain depth on a particular piece or kind of work; that is, a piece of soft cast iron, for instance, is now cut at quite a different speed from that at which a piece of hard tool steel is cut, the depth of cut being the same in the two cases. The feed for the harder machined work would also be reduced, so from the point of view of work done but one of the three variables remains the same—the depth of cut. Obviously then, with only one of the three factors affecting the efficiency of the operation considered constant, any standardization of milling operations is well-nigh impossible, and a satisfactory standard for one shop would not necessarily represent the best practice in another. If two of the three variables could be taken as constant, on the other hand, standardization would be greatly simplified and equally efficient milling of various materials and in different shops would be much more nearly realized.

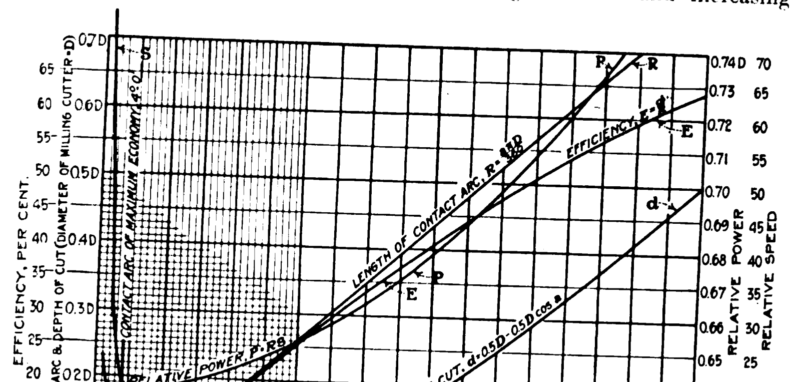

CHART 1. MILLING-CUTTER CHARACTERISTICS

Fig. 1 diagrammatically shows a milling cutter engaging a piece of work. A study of this illustration sheds considerable light on the characteristics of milling operations. Disregarding for the time being the question of feed, it is quite evident that both the depth of cut and the length of arc contact between the cutter and the work are dependent upon the diameter of the milling cutter and the angle of contact, so that a definite relationship must exist between the depth of cut taken and the length of the arc of contact. As the action of a milling cutter, after the work has passed the center line of the cutter, is to shear off material normal to the arc of contact, the length of this arc accurately measures the resistance of the work for a given feed; and also the product of the depth of cut and the feed measures the amount of work accomplished. Evidently, then, the efficiency of the operation is the ratio of the depth of cut to the length of contact arc—the work accomplished to the resistance overcome.

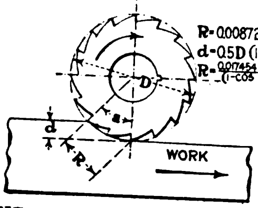

FIG. 1. DIAGRAM OF MILLING CUTTER AND WORK

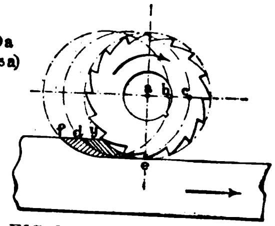

FIG. 2. DIAGRAM OF ACTION OF MILLING CUTTER

The same amount of work could be accomplished by decreasing the feed and increasing the depth of cut. Increasing the depth of cut would increase the arc of contact—in a somewhat lesser ratio, it is true, but nevertheless increase it. The relationship existing between the depth of cut and the arc of contact is such that the resistance does not increase as rapidly as does the depth of cut; therefore, a deeper cut and a finer feed would result in more efficient operation, permitting a corresponding reduction in the cutting speed. Theoretically, the increase in efficiency would continue at a somewhat diminishing rate until the arc of contact was 90 deg., at which value the depth of cut would also be at a maximum.

With maximum efficiency the cutting speed would be at a minimum for accomplishing a specified amount of work and would be proportionally greater for any reduction in efficiency, if an equivalent amount of material be removed by the milling cutter. If a speed of unity is

then arbitrarily adopted for the maximum depth of cut—that is, the depth the cut could be taken under the most efficient conditions, the contact angle equal to 90 deg. and the depth of cut equal to half the diameter of the milling cutter—the "relative speeds" for any lesser depth of cut and corresponding smaller angle of contact can easily be arrived at, being inversely proportional to the efficiency of operation.

Since the resistance overcome and the speed of cutting measure the power consumed in the operation, the product of the "relative speed" and the length of contact arc is proportional to the amount of power required to make the cut, and this "relative power" measures the economy of the operation.

The angle of contact, length of contact arc, depth of cut, efficiency of the operation of milling, "relative speed" and "relative power" are then the characteristics of milling-cutter operation, and such data are listed in Table 1, per degree of contact arc, in terms of the diameter of the milling cutter. The same data are also graphically depicted on Chart 1, from which it is evident that the most economic arc of contact is one of about 4 deg. The efficiency of operation with such a small arc of contact would be quite low, about 3½ per cent., and the depth of cut extremely shallow unless a milling cutter of very large diameter were employed. A cutter nearly 9 in. in diameter would have to be used before a cut 0.01 in. deep could be taken at this most economic arc of contact. As the efficiency of the milling operation increases materially with but a comparatively slight increase in the power requirements, with the increase of the arc of contact, there is really little sacrifice contracted by the inability of making practical use of "the most economic arc of contact." A considerably larger arc of contact may therefore be employed to advantage, as an actual gain is so realized on account of the better efficiency.

Table 2 presents the milling-cutter characteristics of a cutter 1 in. in diameter for cuts from 0.01 to 0.25 in. in depth, a range that covers all practical workable require-

* In terms of the diameter of the milling cutter.

ments; and though such a cutter would rarely be used on account of its small diameter, it serves as an excellent basis of comparison for cutters of greater diameter. Arbitrarily designating the "relative speed" for such a cutter when taking a cut 0.01 in. deep as a "proportional speed" of 100, the "proportional speeds" for other depths of cut are listed in Table 2. The relationships existing between the depth of cut and the "proportional speed" of cutters from 1 in. to 8 in. in diameter are graphically depicted upon Chart 2, which representation really illustrates the complete requirements for efficient and economic milling operations. The "proportional speeds" are directly proportional to the best cutting speeds for the respective depths of cuts at the feeds best suited for the character of the work machined.

TABLE 2. CHARACTERISTICS OF 1-IN. MILLING CUTTER

0.25	60	0	0.5240	47.70	1.34	21

From a practical point of view, however, the data depicted upon Chart 2 are not satisfactory, for the machinist

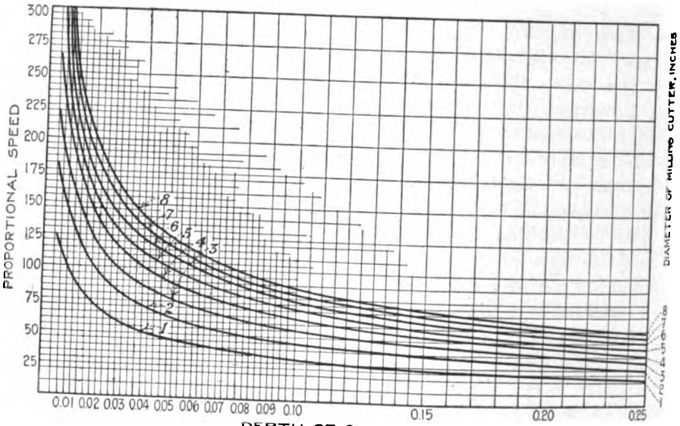

CHART 2. PROPORTIONAL SPEED OF MILLING CUTTERS AND RELATIONSHIP OF DEPTH OF CUT

would have to convert the "proportional speeds" into the true cutting speeds and then calculate the required revolutions per minute for each diameter of cutter. These tedious computations are avoided by transforming the "proportional speeds" into what may be termed "revolution factors," which when multiplied by the most economic cutting speed for a milling cutter 1 in. in diameter will give directly the revolutions per minute for the particular cutter. Such "revolution factors" are depicted upon Chart 3 in a manner that permits easy and accurate reading, the curves being resolved into straight lines by making the horizontal scale of the chart proportional to the variations in speed due to the diameter of the cutter. For instance, Table 3 lists the correct revolutions per minute for milling cutters from 1 to 8 in. in diameter, taking a cut 0.075 in. deep on the basis of a cutting speed of 75 ft. per min. for a cutter 1 in. in diameter removing 0.01 in. of material.

A "basic speed" of 75 ft. per min. cannot be taken as a definite standard, however, for this very important consideration is governed not by the requirement of advisable speed for a cutter 1 in. in diameter, though arbitrarily adopted for such tool in order to facilitate computations, but by the speed limitations of the largest milling cutter employed. A cutting speed of 75 ft. per min. for a cutter 1 in. in diameter would call for a cutting speed of over

200 ft. per min. for a cutter 8 in. in diameter, in order to maintain the same relative economy in milling, the "proportional speed" for a milling cutter 8 in. in diameter being 2.83 times as great as for a cutter 1 in. in diameter. Should the 8-in. cutter be larger than any employed in the particular shop, a higher "basic speed" could safely be employed so as to secure the better efficiency of higher speed milling and vice versa.

Feed Factor in Milling Operations

Theoretically there is no limit but the question of feed to the cutting speed that may be employed for a milling cutter, other than the limit fixed by centrifugal force. No matter how difficult the machining of a piece of work, the cutting speed need not vary, provided the feed is adjusted to conform to the difficulty of cutting. The cutting capacity, upon which the feed depends, is affected

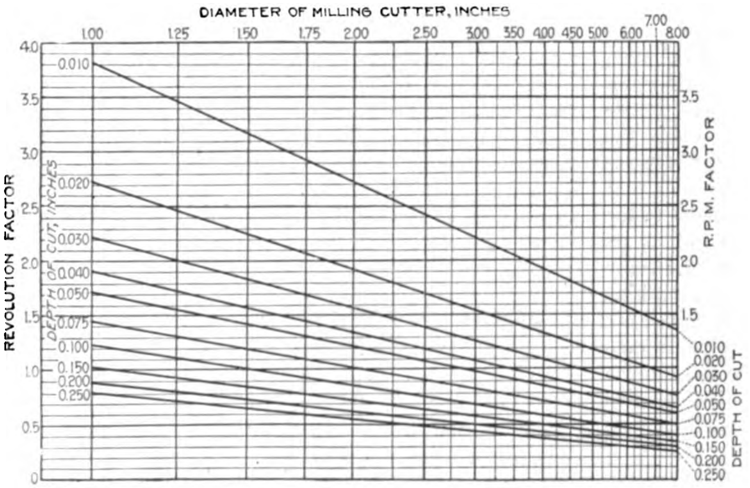

CHART 3. REVOLUTION FACTORS FOR MILLING CUTTERS. DEPTH OF CUT: 0.01 TO 0.25 IN.

by a number of conditions that are individual with each miller, each milling cutter and the difficulty with which the material machined can be cut. First, there is the power capacity of the machine to be considered. This

TABLE 3. REVOLUTIONS PER MINUTE OF MILLING CUTTERS

4.50	0.685	51.0			
4.75	0.670	50.0			

must be ample, if the best efficiency of the machine is to be realized; that is, there should be a plentiful supply of power to meet possible increase in requirements. The number of teeth of the milling cutter materially affects the allowable feed in low-speed operations; but the variations are largely overcome in high-speed work, so that the number of cutting edges to a cutter usually need not be taken into consideration. The relative ease with which a particular piece of work can be machined cannot be controlled, however, and should therefore be the governing condition upon which the feed should be based.

With the speed fixed, the economy of operation for a definite depth of cut by a milling cutter of certain diameter is dependent upon a definite feed, and a control based on this fact is preferable to one calling for a variation in speed as well as in feed. The definite feed should of course be the maximum for the speed employed, so an increased feed—one greater than can be maintained with the constant speed—would necessitate a reduction in cutting speed, which in itself would tend to reduce the efficiency of the operation. Furthermore, an increased feed increases the resistance against which the cutter works and so also reduces the efficiency of the operation.

TABLE 4. REVOLUTIONS PER MINUTE OF 4-IN. MILLING CUTTER

("Basic Speed," 75 Ft. per Min.)

0.050	0.87	55.0	0.250	0.39	29.0

Fig. 2 illustrates the increased resistance caused by an increase in feed. With the milling cutter in the position indicated, first consider the work having advanced in a certain time a distance equal to *ab*. During such progress the resistance encountered would be proportional to the curve *de*, the material represented by the area *yed* having been removed. Increasing the feed so that the work advanced during the same period of time a distance equal to *ac* would increase the resistance encountered to an amount proportional to the curve *fe*, the material represented by the area *yef* measuring that removed. The difference in resistance encountered—the difference in the length of the curves *de* and *fe*—would be directly measured by the increase in feed and would be quite an appreciable proportion of the total resistance encountered with the shorter feed. The increase in percentage would depend upon the diameter of the milling cutter and therefore upon the arc of contact.

Selection of "Basic Speed."

Accurate adjustment of feed and also of cutting speed is not always possible, so certain variations from the best practice must be resorted to in even well-equipped shops. The "basic speed"—the best speed for a milling cutter 1 in. in diameter taking a cut 0.01 in. deep—should be accurately established, however; and departure from this base should be as slight and as infrequent as possible, in order to maintain an equally high degree of efficiency and economy in various milling operations. Accuracy in establishing the "basic speed" is best secured by experiment with several different sizes of milling cutters taking cuts of various depths as efficiently as possible, averaging the "basic speeds" computed from such data and adopting the mean value as the base from which to vary as little as possible. For instance, the best speed for a cutter 3 in. in diameter taking a cut 0.04 in. deep is 1.1 times the "basic speed"; the best for a cutter 4¼ in. in

diameter when removing material 0.10 in. in thickness is equal to 0.59 times the "basic speed"; etc. (see Chart 3). The multiple of the "basic speed" is the "revolution factor" for the depth of cut taken by the milling cutter of specified diameter. The greater the number of such experiments performed with cutters of appreciable difference in diameter and their results averaged the more accurate the established "basic speed." Once this has been established to the best ability, it should be used exclusively for ascertaining the best speed for milling cutters of other diameters and for the various depths of cuts which may be taken—the necessary computations being simply the multiplication of the "basic speed" adopted by the proper "revolution factor" from Chart 3.

Variations from the Best Cutting Speed

When the limitations of the miller make it impossible to secure the most economic cutting speed for some particular depth of cut, it is preferable to use a higher speed and reduce the feed than to employ a lower cutting speed and increase the feed—the economic balance always being in favor of the speedier operation, as the increased resistance encountered by the more rapid feed discounts the heavier work accomplished per revolution. Better practice still is to use a milling cutter of a diameter such that the capabilities of the miller permit the attainment of the best cutting speed for the desired depth of cut at its suitable feed, as by such balance the best overall economy can be realized and the full capacity of the machine developed. This may necessitate the use of a milling cutter of slightly greater diameter than the smallest cutter which might be employed, thereby departing from the old dictum, "Always use the cutter of smallest possible diameter," but such departure from this excellent rule will result beneficially.

Classification of Milling Cutters

A system for a shop to employ might be to list the milling cutters according to the best speed for a specified depth of cut and also to list the best speeds for various depths of cuts by cutters of a certain diameter. The shop should then adopt the exclusive use of only such cutters as its equipment will permit to be operated under the best conditions. Investigations should be made for each depth of cut usually taken, to ascertain the desirable feed, and the proper speeds for each diameter of cutter should be filed in the stockroom for ready reference by the machinist.

A typical record for milling cutters of various diameters when employed to take a cut 0.075 in. deep is given as Table 3. For such a record and for all milling-cutter records the "basic speed" adopted for the particular shop should be used in the computations. This may be greater or less than the speed of 75 ft. per min., upon which speed the tables presented are computed. Table 4 illustrates a record for a milling cutter of particular diameter. Similar records should be made for all usual depths of cut and for all sizes of cutters, the data applying to cutters of diameter suited to the equipment of the shop tabulated or presented in convenient chart form, a copy of the record being attached to the miller or placed in a position suitable for ready reference by the machinist.

To summarize, efficient and economic milling is possible only when the proper relationships of the factors affecting the operation are recognized and differentiated. The speed factor is dependent upon the depth of cut and vice versa, both of which factors are quite independent of the feed for the best overall results. The feed factor, on the other hand, is dependent upon the ease with which a piece of work can be cut and is quite independent of the question of speed, although affected by the depth of cut. The speed factor can be accurately calculated for any diameter of cutter and depth of cut, once the "basic speed" has been carefully ascertained by experiment, and should not be varied from to any great extent if economy in milling is to be realized. The feed factor, on the contrary, can only be ascertained by experiment and will be affected by any variation in the hardness of the work or other condition affecting the ease with which the material is cut. The feed should always be the maximum that can be maintained with satisfactory results.

Once such a system has been installed in a shop, the only variable factor requiring the attention of the machinist is that of feed, and even this becomes pretty well standardized if the quality of the material worked is reasonably uniform.

Varying both the speed and the feed to conform to the requirements of the work undertaken, as is the usual practice, not only makes the attainment of economic milling largely a matter of chance, but is productive of much wasted time, as the machinist has two factors instead of only one to adjust and balance in order to produce satisfactory work.

Some Methods of Measuring Screw Threads

By William Ferguson

This article deals primarily with the measuring of Whitworth screw threads, but the methods are applicable to any form of V-thread. They apply more particularly in testing screw gages or master taps, the dimensions of which must be very accurate.

Three dimensions are involved in measuring a screw—the outside diameter, the effective diameter and the root diameter. The outside diameter is of course quite easily

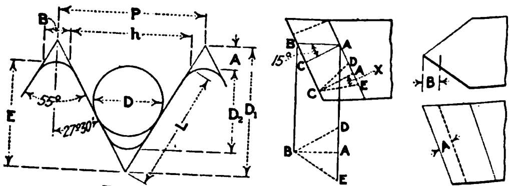

FIG. 1 FIG. 2 FIG. 3

METHODS OF MEASURING AND GRINDING MASTER TOOLS FOR WHITWORTH GAGES

measured by means of a micrometer and must be accurate when this method of gaging is employed. The depth to which the tool should be fed in chasing the screw is gaged by a piece of round wire, the diameter of which is equal to the diameter of the inscribed circle in a triangle of thread section, as shown in Fig. 1. The diameter of wire used may be made 0.0001 in. above or below the calculated size of wire, thus giving a very fine limit gage, yet a difference which is quite easily felt. The wire is best applied under the face of a micrometer that has been closed on the outside diameter of the thread, but a straight-edge may be used, held upon the top of

the threads. To obtain the diameter of wire, the following calculations must be made, in which

P = Pitch (threads per inch);
D_1 = Depth of thread with sharp top and bottom;
D_2 = Actual depth = $\frac{2}{3} D_1$;
A = Amount cut off = $\frac{1}{6} D_1$;
B = Base of triangle of which A is perpendicular;
E = Perpendicular of triangle of which H is base;
$H = P - B$;
L = Length of side of triangle of which H is base;
D = Diameter of inscribed circle.

D_1 may be found from

$$D_1 = \frac{P}{2} \cot 27 \text{ deg. } 30 \text{ min.}$$

or from

$$D_1 = \frac{D_2}{4} \times 6$$

(D_2 being taken from tables)

$$A = \frac{D_1}{6} \text{ or } \frac{D}{4}; \quad B = 2A \tan 27 \text{ deg. } 30 \text{ min.}$$

$$P - B = H$$

or

$$H = \frac{5}{6P}$$

by similar triangles.

$$E = \frac{5}{6D_1}; \quad L = \sqrt{\left(\frac{H}{2}\right)^2 + (E)^2}$$

The radius of the inscribed circle in the triangle of which H is the base given by

$$r = \frac{area}{semiperim} = \frac{\Delta}{S}$$

$$S = \frac{H + 2L}{2}$$

or

$$Area = \frac{H}{2} \times E$$

$$r = \frac{\frac{HE}{2}}{\frac{H + 2L}{2}} = \frac{HE}{H + 2L}$$

$$D = 2 \frac{HE}{H + 2L}$$

If the values are found for E, H and L in terms of P, a formula of the nature of $D = \frac{C}{N}$ is obtained, where C is a constant for a particular form of thread and N is the number of threads per inch (single thread). Thus:

$$D = \frac{0.5054}{N}$$

for the Whitworth form of thread.

The accompanying table of values gives the diameter of wire required for different numbers of Whitworth threads per inch.

Lathe tools for accurate thread chasing must have a cutting face that is flat and that lies in a plane containing the axis of the screw to be cut. The front rake of a tool of this description is usually made 15 deg. To obtain the angle that the tool should be ground, so that section AB is the correct thread angle, assuming 15 deg. front rake (see Fig. 2), let $AB = 1$. Then

$$AD = AB \tan 27 \text{ deg. } 30 \text{ min.}$$
$$AC = AB \cos 15 \text{ deg.}$$
$$\frac{AD}{AC} = \tan \frac{X}{2}; \quad X = \text{angle required}$$

If the tool is ground to a sharp edge, an amount A, indicated in Fig. 3, must be ground off and the square edges rounded to the required radius for the number of threads per inch to be cut. This amount A is usually ground off in a direction as shown at B. The amount to be ground off is therefore equal to $A \times \cos 15$ deg. If this is ground off the nose of the tool and a groove is cut on a piece of round steel of diameter D, of a depth such that the wire gage just fits between the micrometer face and the sides of the groove, the diameter D_2—that is, the root diameter of the groove—should just be the correct root diameter corresponding to D. This root diameter may be found to be large, owing to the fact that in grinding the tool a sharp edge is not really obtained. A little less than A_1 is next ground off and a

groove cut as before, the root diameter accurately measured and the error noted. If the groove root diameter is too small, an amount equal to half the error should be ground off the nose of the tool. This should give the correct root diameter when the thread is cut to suit the wire gage.

The tool should now be honed to the correct radius, and a female tool for rounding the tops of the threads should be made from this prepared tool. To measure the diameter at the bottom of these grooves, two conical thimbles may be fitted to an ordinary micrometer, the angle of cone being of course less than the thread angle. If a thread is cut with a tool thus prepared and gaged with a wire gage for effective diameter, it will also be correct for the root diameter.

Considerations in Good Furnace Practice—It is pointed out in the "Brass World" that in avoiding the ever-present danger of oxidation, good manipulative furnace practice consists in minimizing exposure of molten metal to atmospheric contact and the intelligent understanding and judicious use of fluxes and deoxidizing agents, whether neutral or active. Of the two considerations the former is the more valuable. It is better not to do a bad thing than to try to undo it.

Foolish Regulations

An intelligent and observant mechanic who has had access to a number of the manufactories in the United States where ammunition for the Allies is made has noticed a number of foolish regulations and restrictions imposed by the governments whose contracts are being filled. One of the most outstanding idiocies is the requirement covering heat numbers.

All steel is required to pass a rigid chemical and physical test before it is accepted as suitable for the manufacture of shells. Having passed the tests, it is given a heat number. The government requires that this heat number be stamped on each bar of rolled steel and on each forging blank cut from a cast ingot. When the rolled bars are cut into machining blanks for shells made from bar stock (such as the 18-pounder British high-explosive shell), each blank must be stamped with the heat number.

The shell blanks are shipped to the manufacturers from the steel mills in large lots, usually carload lots. The steel mills, as a usual thing, do not seem to pay any attention to the heat numbers which go to make up a shipment, beyond taking care of course that the blanks shipped are properly tallied and from heats that have passed inspection. In other words, they do not seem to exert themselves to send large numbers of shell blanks of any one heat number, but take them as they come, sending to a manufacturer often as few as one single shell blank of a heat number. For this reason a shipment of shell blanks as received from the steel mill would run something like the following:

Heat No.	No of Blanks
23	3
31	1
43	15
58	4
137	24
269	7
648	1
964	21
averaging 8½ per heat number.	

At present a series (of shells) consists of 250 shells, each of which carries a series mark. For instance, the first series will be marked with the series symbol A, the next B and so on till the alphabet is exhausted. The next series is AA, then AB, AC, etc.

Heats in Series Restricted to Fifteen

The government requires that the series shall be made up from steel that has passed inspection, but it restricts the number of heats represented in a series to 15. This requirement would not be difficult to follow if the shell blanks were shipped from the steel mill in sufficient quantities of each heat number. But as previously stated, there is often only a single shell blank from a certain heat. To be made up from 15 heat numbers, a series of 250 shells requires that the average number of shell blanks for each heat number in the series be nearly 17. But many heat numbers are represented by a single shell blank. And for each such number in a series some other number must be represented by 33 shell blanks.

This rule results in an accumulation of finished shells that cannot be marked with the series symbol, because there are so few of each heat number that the series would represent more than 15 heat numbers. And yet the steel used in the shells has passed the government inspection and has been declared suitable for the use to which it has been put. There are at present many thousands of shells held up by this senseless restriction. That there is no sense to it is proved by the fact that in some shops the accumulation of very large lots of shells representing a great variety of heat numbers (but only a few shells of any one heat number) has led the manufacturers to petition the government to permit making up some series from shells representing a large number of heats. These requests have in a number of instances been granted. In one case a series (250) was made up from shells representing nearly 200 heat numbers. If it is permissible that one such series should be made up, then it is permissible that any series should go through in the same way.

Besides the cost of storage of these large numbers of shells till a place can be found for them in series that are to go out of the shop, there is another element of cost directly chargeable to the heat-number foolishness. In the course of manufacture it is necessary to efface the heat number; that is to say, the part of the metal which bears the heat number is cut away. Whenever this happens, the heat number must on the completion of the operation be again stamped on the work.

In a certain shop with a capacity of 5,000 shells per day, where the system of keeping track of heat numbers is nearly perfect, the cost of sorting (to make series that contain 15 heat numbers) and transferring heat numbers from base to side, from side to base and back to the nose again is estimated at $50 per day. In this same plant before the present system was installed the cost of this work was $250 per day.

Another proof, if further proof is necessary, that the heat-number requirements are foolish lies in the fact that after the series has been made up, packed in 41 boxes containing six shells each (in the case of the 18-pounder high-explosive) or in 125 boxes containing two shells (in the case of the 4.5 high-explosive shell) and shipped to the loading station, no further notice is taken either of heat numbers or of the series symbol. In the process of loading, the series from the various manufacturers are apt to be mixed. When a series is shipped from the loading station, it will contain 41 boxes (in the case of the 18-pounder high-explosive shell), but the 41 boxes may contain shells from 41 different manufacturers; and further, it is within the range of possibility that each box may contain shells representing six different heat numbers.

There is no doubt that a series symbol is of use, as by means of it shells which prove to be in one way or another objectionable may be traced to their original source. There is, however, no good reason why a series should contain any arbitrary number of shells.

It has been suggested by men well posted in the manufacture of shells that it would be much more sensible to make the daily output of a factory determine the size of a series and have it contain all the shells made at the factory on a given date. The date stamps are changed daily in the marking machine. The series stamp could also be changed at the same time and not, as now, with every 250 shells.

Useless Work and Unnecessary Accuracy

Another government requirement is that test pieces from base plates shall be pulled to destruction. When the gun is fired, the base plate is under compression, not tension; and while the strength of the metal under compression may bear some relation to its strength under tension, in the case of the base plate there is a difference, because the base plate is surrounded and supported by the

metal in the shell body itself. Wasted work and material! The undercut in the 18-pounder British shell at the inner end of the thread in the fuse hole is optional, and yet the government inspectors are required to see that the recess is absolutely clean. There must be no varnish in it. This requirement means that the recess must be scraped out with a bent scraper. When the screw gage is run in the fuse hole, any particles of varnish in the thread are carried down by the end of the gage and deposited in the undercut. The government requirements are that this varnish shall be removed. Useless work!

Another foolish requirement with regard to varnishing is that, should a drop of varnish adhere to the varnished surface at the bottom of the shell, it must be removed. The same rule also applies to the accidental adherence of a bristle from a varnish brush to the bottom or walls of a shell. Useless work!

When the wave ribs are formed on the bottom of the driving-band groove, there are three or more points—little moon-shaped ribs or burrs—left by the tool. These burrs would not in any way interfere with the pressing on of the band. They would, however, assist in holding it more securely when pressed on. The government requires that these burrs be removed, which is done with hammer and chisel and file. Useless work!

The angle of the fuse hole in the nose of the 18-pounder shell is required to be "dead" smooth. This surface forms a seat for the leather washer, which in turn seats the fuse, and there is no reason for making this seat smooth.

The diameter of the check on the nose of the same shell on the outside is required to be held within 0.005 in. There is no reason why the tolerance should be anywhere near so small as this. Needless accuracy!

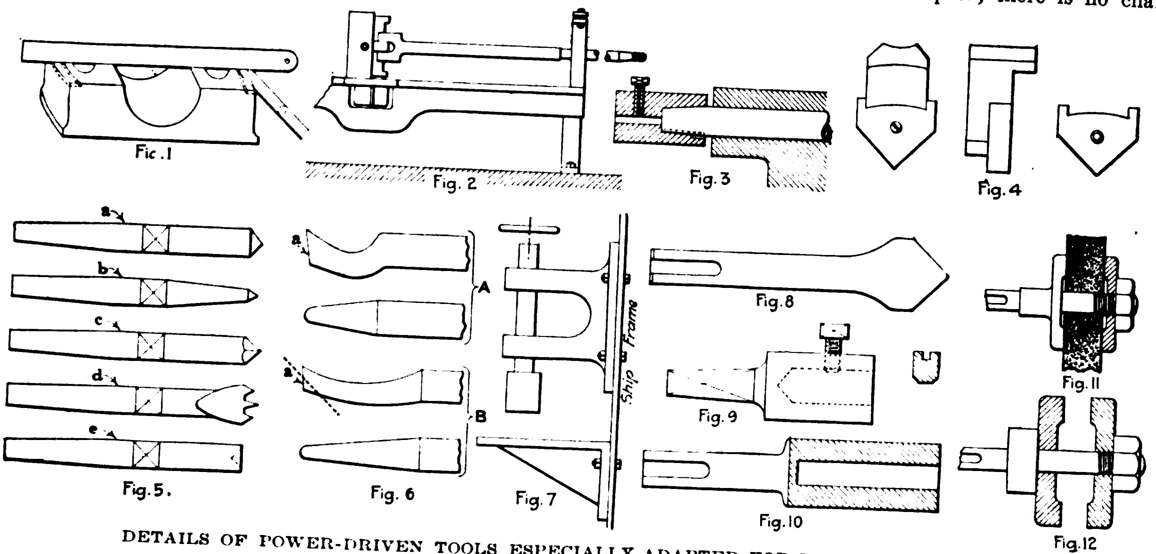
Shells are painted before they leave the factory where they are made. There are many instances where government inspectors have ordered shells repainted because the color has been slightly darker at one part of the shell surface than at another. The shells were not merely given another coat of paint on top of the paint already there; but they had to be sandpapered before the new coat could be applied, as the painted shells must pass through a ring gage, which the extra coat would prevent.

Power-Driven Tools on Ships*

By J. H. Thomson

It might be thought that in the present age of machinery there would be little need to plead for uptodate power-driven tools for executing the everyday mechanical work on board a modern steamship; yet the majority of ships will be found deficient in this respect, many possessing no power tools whatever, others only a nondescript lathe put on board with considerable disregard of the probable requirements, size of ship, etc., and of the large range of work which can be economically carried out, given suitable and suitably equipped tools.

Any repair that can be efficiently performed on board ship by the ordinary staff, without entailing the neglect of other duties and without entailing any overtime work, will cost anything from 75 per cent. and upward less than such repair would cost ashore. For there are no extra wages to pay for such repair; there is no charge



DETAILS OF POWER-DRIVEN TOOLS ESPECIALLY ADAPTED FOR DUTY ON BOARD SHIP

for the use of shore machinery; the profit required by the shore firm is saved; much scrap material that usually goes ashore for a very small return can be profitably worked up on board; there is an enormous saving in the time taken to execute the repair, a saving which in some cases would keep the ship from being detained in port; owing to the quickness and ease with which the work can be done, the machinery will be kept in better repair, as the ship's staff will have more time to devote to it; there will be a saving in the bill for files and other hand tools used on board; and last, but not least, it will tend to minimize discontent from overtime.

To take a simple illustration of everyday routine work: Suppose a 3-in. diameter by 2-in. wide bearing wants stripping, the amount of metal to be removed—ascertained in the usual way by leads—is 0.025 in. The bearing could be put in the lathe, the amount required taken off to within 0.001 in., a true plane surface left, parallel with the opposite plane surface of the bearing or parallel with the bearing itself, as may be required, sharp edges and rags removed—all in well under half an hour, with a

*Condensed from paper presented to Institute of Marine Engineers

minimum of physical labor, by anyone with a slight knowledge of turning. In the vise, with a good file, the same job would take from 1 to 1½ hr., and a good tradesman might have the required amount off to within 0.002 in. and in that time have an approximately plane surface, nearly parallel with the other surface of the bearing. With a poor tradesman there might be 0.005 in. or more of error in the parallelism of the two surfaces, and the new surface might resemble the Bay of Biscay on a rough day more than a true plane. In contrasting these two methods of doing the same job remember that such work often has to be carried out in an engine room at a high temperature, particularly so in the tropics. Doing the job in the lathe has been a pleasure to the engineer, and he is practically as fresh after its completion as he was before he started. Doing it in the vise is mere mechanical drudgery, and the engineer is wet with perspiration and has lost a considerable amount of energy. In passing, a simple method of taking off exactly the right amount of metal in the lathe may be given: Face up only about a quarter or less of the surface to be stripped, until when laying a good straight-edge across the old surface, the required feeler will just slip in between the straight-edge and the new surface, after which the remainder of the old surface can be faced down to the same plane (see Fig. 1).

An illustration of common repair: The valve spindle of a steam stop-valve is broken on the day of sailing. With a power-driven lathe on board and a small stock of various sizes of brass rod, such a spindle could be replaced in about 4 hr., possibly less if it so happened that there were on board any old valve spindles that could be worked up for the job. Without a lathe and with the necessity of sending the spindle ashore to be made good, the time lost may be anything from a half day upward.

Arrangement of Machine-Tool Equipment

The minimum power-driven tools advocated on board a ship are a lathe, a drilling machine and a high-speed grinder. These tools should be so arranged that each can be used independently of the others, or so that all three can be in use simultaneously. It will be most convenient if the three machines are grouped together, so that all may be driven off the one countershaft, fitted in the usual way with driving and loose pulleys. For driving the countershaft an electric motor complete with starting switch, etc., will be required, the power of the motor depending upon the size of the tools that it is proposed to install; one of 2½ hp. should be ample for all ordinary requirements. A point which might be considered is whether the motor might not be fitted so as to be capable of assisting the lathe gearing in getting the required slowness of speed for turning a job of large diameter; such a job being of infrequent occurrence, there would be no objection to running the countershaft temporarily at a reduced speed. Getting the lathe to revolve slowly enough is sometimes a bit of a problem on board; it can occasionally be solved by running the dynamo at a reduced voltage.

It is difficult to fix definitely the size of the lathe that should be fitted on board ship, and the point is one that will bear discussion. The suggestion is put forward that the aim should be to have a lathe which, with the gap removed, would be capable of dealing with the high-pressure junk-ring, the high-pressure piston being the one which usually gives the most trouble from wear. In length the lathe should be capable of dealing with any of the main-engine valve spindles, not that it is thereby implied that the valve spindle should be accommodated between the lathe centers; it will be sufficient if by the aid of a fixed stay, Fig. 2, that part of the spindle which works through the neck bush, stuffing-box, gland and guide can be efficiently dealt with. Space in a ship for a lathe of such size is not always obtainable; but with a little contriving it should be managed, except in very small boats, where the length may require consideration. A suitable position in a turbine-driven ship is often found in the shafting space, which usually extends right across the engine space. There the lathe, drilling machine and grinder can be ranged along the ship's side, using the ship's frames for the purpose of attaching countershaft brackets, motor, etc. The forward starboard side is usually the more suitable, thus leaving the ends of the shears clear for any extra long job to overhang. This point should also be kept in mind if the lathe is placed in the engine room, as one often sees the end of the shears close up against the ship's skin, which renders the turning of a long job impossible. If the space is so limited that the end of the shears cannot be left clear, then they may abut on a hold or bunker bulkhead, which can have a circular hole cut in it in line with the lathe centers, such hole being made water-tight with a covering plate. This means that for doing any job which is extra long, a time must be selected when the bunker is clear of coal or the hold of cargo. It may be mentioned that such a hole, by bolting a suitably shaped piece of wood to it, may be utilized as a fixed stay.

Pointers on Tools for Ship-Board Duty

There is one point that must on no account be lost sight of in selecting a position for these tools. The space selected must be well ventilated and cool enough at all times, even with steam on the main engines and the ship in the tropics, for a man to work in comparative comfort. The speed at which the ship's lathe can be driven requires more consideration than it usually gets; for seeing that there is only the one machine, one would think it stands to reason that it is necessary to have it capable of a very much larger range of speed than would be the case in shop practice. Thus if the suggestion that the lathe should be capable of dealing with the junk-ring be accepted, then it follows that the lathe spindle should be capable of being driven from a speed suitable for such ring up to the speed suitable for turning a small-diameter brass pin; and if the suggestion made later on regarding the supplying of one or two emery wheels for use in the lathe be carried out, then the lathe spindle should be capable of a higher speed still—say 1,500 r.p.m.—which is suitable for a 14-in. diameter wheel.

The ship lathe must be capable of cutting screws of all the standard pitches, and it may need to have one or two odd wheels for bastard pitches, if the engine builder happens to be one of those who use bastard threads—a practice resorted to in order to compel the user to come back to the maker for renewals. The usual compound saddle rest is required with crossfeed, etc. The quadrant should be marked off in degrees. The moving headstock should have a cross-adjustment for purposes of alignment or turning up tapers. A suggested fitting for the moving headstock—one that would be of great use—is a drill

chuck. It would be attached to the moving cylinder of the headstock, the boring of holes in work attached to the running spindle being of much more frequent occurrence than that in which the drill is attached to the running spindle. Drills are sometimes supplied capable of being placed in the taper hole that holds the fixed center or a special drill holder; but the practice is not good, as the hole gets damaged and so renders the fixed center shaky or out of alignment. A suggestion for a holder is given in Fig. 3. It is self-centering, free from shake and can be detached by drawing in the cylinder by means of its screws, when the holder will abut on the barrel and be forced off; a sunk feather is fitted to the holder, engaging in a keyway on the under side of the cylinder end. The attachments for the running spindle will consist of one large faceplate for use with gap removed; one faceplate for use with gap in place; one driver plate for driving work held between the centers; one chuck with four independent dogs, each having three steps and capable of being reversed to hold circular work securely. A shortcoming of most dogs is that they will not readily catch small work, say of 1/4-in. diameter.

In Fig. 4 is shown an attachment which will be found useful in this connection. Anyone wishing to use it should make a wooden pattern a neat fit for the dog and get four forged off it in tool steel. True up one flat surface of the forgings and fit them to the dogs. Make sure when boring the holes and fitting the pins that the strain in screwing up the job will not come on the set-pins; the set-pins will last better if they are also made of tool steel. After the forgings have been fitted to the dogs, true up the sides of the V-shaped portion until the four points meet in the center of the plate. The dogs are lying in a true circle, and the sides of the V-shaped portions form true radii of a circle. The front faces of the segments may be faced up with the chuck running on the lathe spindle. The V-shaped portions should not come to absolute points, but be left about 1/16 in. wide. A small rack, consisting of a piece of 1/8-in plate with four tapped holes to take the set-pins, is desirable to hold pins and segments when not in use.

A Few Special Devices

There should also be supplied one drill chuck which will hold the drills supplied to the ship (this may be one of the numerous small self-centering grip chucks or a chuck with a plain parallel hole, say 5/8 in. in diameter, if the drills are, as is very common, forged from 5/8-in. round tool-steel bar); one fixed stay, which can be bolted down to the lathe shears; one running stay, which can be attached to the saddle (those with adjustable metal dogs are more useful than those requiring the fitting of various-sized wooden blocks); one hand rest for wood-turning tools.

Fig. 5 shows the lathe centers required: Two ordinary pointed centers, one ordinary pointed center with end of reduced diameter for small work, one cutting center, two or more driving centers for wood-turning, one hollow center (optional). A list of tools is given of the ordinary form, 1/2-in. or 5/8-in. square-section common tool steel, this steel being selected as the many special self-hardening steels require an experienced toolsmith to deal with them. While tools made of such steel could be dressed ashore, there is always the possibility of their getting broken when away from port.

The tool list comprises three ball-point roughing tools—two for iron, one for brass; two right-hand side-cutting tools—one for iron, one for brass; two left-hand side-cutting tools—one for iron, one for brass; one spring scraper; one right-hand knife tool; one left-hand knife tool; two Whitworth standard-thread screw-cutting tools—one medium, one small and both to be dressed as right-hand tools; three parting or square thread-cutting tools, of widths 1/12 in., 1/8 in., 1/6 in.; five inside screw-cutting tools, to correspond with outside screw-cutting tools, the smaller size V-thread and the 1/12-in. square thread to be capable of cutting a thread in a 1/2-in. hole. In the event of the shifting headstock not being fitted to hold drills one drill holder suitable for fixing in the tool rest should be provided, and there should be a set of inside and outside combs.

Finishing Tools Principally Used

Other tools may be added from time to time as may be required, but with the foregoing outfit any ordinary job can be tackled. In getting tools made or dressed for ship's use, it should be remembered that they will be principally used for light duty—that is, taking a light cut or skimming off work that has been previously machined—and they can therefore be dressed of lighter shape than would be the case for shopwork. Further, the facilities for grinding tools on board being usually of the most crude description, the under side of the tools should be cut well back, so that there may be as small a surface of steel to grind as possible. Fig. 6 shows a ball-point roughing-tool *A* as used in the shop; *B* is a similar tool for light duty in a ship's lathe. It will be noticed that the surface to be ground *a* when the tool requires sharpening is only about one-third in tool *B* of what it is in tool *A*.

For shipwork a drilling machine that will bore holes from 1/32 in. up to 1 1/2 in. is required, and it must therefore have the range of speeds and power required for such sizes. It will not matter if the speed is not quite so high as boring a hole of 1/32 in. permits, but it must be able to revolve slowly enough and have the requisite power and rigidity for the 1 1/2-in. hole. A speed ranging from 30 revolutions per inch to 300 revolutions per inch per minute should be obtainable. When space can be had, a useful type of machine is the one which has the drilling spindle and its driving and feed gear mounted on a short cast-iron pedestal or column, a double bracket capable of swinging round, being raised or lowered and clamped in position on the column. One end of the bracket supports a round table capable of revolving on its axis and of being clamped; the other end consists of small shears, on which slides a parallel vise. This is a well-known type of machine, familiar to all engineers and made by practically all the well-known tool makers. It has the further advantage that the brackets, when swung at right angles to the spindle, leave the floor space clear for putting any extra-large job under the spindle.

Devices for Saving Space

When space is not available, various modifications can be made. Thus instead of a double-swing bracket a single one can be used, allowing the machine to go close against a bulkhead or the ship's side, when the flat revolving table should be retained and a parallel vise supplied, which can be bolted on top of the table. The advantage

of the vise fitted on the shears is the clearance which is available under the vise, the limit to the length of the work which may be held being the floor underneath. A ship's frame can be utilized instead of the cast-iron column, the drilling spindle and its gears being secured to the frame at a suitable height. The table could consist of an ordinary good-sized cast-iron knee plate, capable of being bolted to the frame at various heights or of being removed to allow the job to sit upon the floor. A parallel vise should be supplied, which will be suitable to attach to the table. Fig. 7 is a rough sketch of a drilling machine attached to the ship's frames; in both instances all driving, feed gear, etc., are omitted.

The Forms of Drills Used

The drills for the machine are the next consideration. Should they be twist, flute or common? Should they have parallel round shanks, taper round shanks or taper square shanks? The ideal would be to have two complete sets of drills—the twist or flute for use in the machines and the common drills for use in the ratchets or machines. Failing this, choice must be made of the one kind for all purposes. The drill which can be most easily made, repaired and ground is the common drill forged from plain $\frac{5}{8}$-in. round-bar tool steel, with a flat at the one end to take the point of the set-pin, Fig. 8. The sockets of the ship's ratchets should suit this or a loose socket with square tapered male end, Fig. 9, and round $\frac{5}{8}$-in. parallel female end be supplied. Such sockets are not very difficult to make, and two or three of various lengths are most useful for ratchet work and will often save a lot of time being spent in hunting up and fixing packing. The set-pins for these sockets should be of tool steel, with the cheese points slightly tempered, each socket having two set-pins—one with a square head, the other of a grub-screw shape. The latter is only for use when there is not clearance room for the one with the square head. If flute or twist drills are to be supplied, the flute shape will be the more useful. They are more easily ground, and they are more efficient for use in reaming out a hole parallel and true to size, at which class of work a twist drill has a great tendency to draw itself into the work, seize and snap. In attempting to ream a hole with a twist drill it usually pays to plug up the original hole first with hardwood or brass.

Drill Sizes Generally Required

The sizes of drills should range at least from $\frac{3}{16}$ in. to $1\frac{1}{2}$ in., advancing by $\frac{1}{16}$ in., with four extra drills for $\frac{3}{8}$-in., $\frac{1}{2}$-in., $\frac{5}{8}$-in. and $\frac{7}{8}$-in. tapping sizes and one good large countersink point, making 27 drills in all. It would be better still if the sizes ranged from $\frac{1}{16}$ in. to 1 in. by $\frac{1}{32}$ in. and from 1 in. to $1\frac{1}{2}$ in. by $\frac{3}{16}$ in., with countersink point, making 36 drills in all. There remains the question of sizes smaller than $\frac{3}{16}$ in. For this purpose a good method is to have them forged from $\frac{1}{16}$-in., $\frac{3}{32}$-in. and $\frac{1}{8}$-in. square tool-steel rod, a short length, say 2 ft. of each size, being also supplied to provide for any breakage or odd-length drill that may be required. Steel rod of this size and section requires the minimum of forging, and the square section provides a most efficient grip for the ordinary shark-jaw chuck with which the American brace is usually fitted. For use in the power-driven drilling machine a chuck should be supplied. A useful chuck for the drilling machine and lathe can be made by making a male part, as shown in Fig. 10, to suit the shark jaws and outer nut removed from either the American or the wood brace.

Why, it may be asked, should the engine room of a modern ship—a space full of intricate machinery—have placed in it a dirty, inefficient, manual-power grindstone? The most suitable grinder for a ship should open up some discussion and suggestion from those who have expert knowledge of the subject. A machine with a 12-in. to 14-in. by $1\frac{1}{2}$-in. wet wheel on one end of the spindle and a similar-sized emery facer on the other end, with suitable rests, etc., should prove a useful and satisfactory machine for ship use. An attachment should be supplied for grinding twist or flute drills. Those who have to contend with the old-fashioned grindstone will find the expedient of getting an emery wheel and using it in the lathe a welcome help. A sketch of such a wheel fitted on a suitable spindle to fit the drill chuck is given in Fig. 11. In ordering a wheel for this purpose get as large a diameter wheel as the lathe will accommodate with the gap in place, in order to get a good peripheral speed; a small wheel at the usual fastest lathe speed is not of much utility. It should be possible to provide a lathe with a sufficiently high speed for driving an efficient wheel of medium size, and this might be done when, for reasons of want of space, a grinder could not be installed. The drawbacks to the emery wheel being used in the lathe are the difficulty of keeping the wheel running true and the grit that tends to get into the spindle bearings and under the saddle. With due care the latter can be much minimized. As the spindle in Fig. 11 requires a special forging, a sketch is given in Fig. 12 of a construction that can be carried out on board ship. The spindle is turned out of a good-sized piece of steel, in order to get as large a collar as possible. The washers are made of $\frac{1}{4}$-in. plate, one-third the diameter of the wheel, faced on one side sufficient for a collar and nut respectively and recessed on the other side in order that they may grip the wheel at their edges; or instead of recessing, a ring of $\frac{1}{16}$ in. of paper or fiber on either side will give the same result.

Forge Considerations on Board Ship

The forge may not be, strictly speaking, a power-driven tool, unless the term may be permitted if the blast is supplied from a power-driven fan. Why it should not be so is difficult to understand, as the cost would be not much greater than supplying the usual hand forge, with which machinists on ships are doubtless familiar, possibly painfully so. Seeing that the average steamer is provided with power-driven fans for the boiler furnaces, it should not be a difficult matter to provide a forge with an air pipe led to it from a convenient fan trunk. The following are details of an expedient that was carried out: The cyclone part of the forge was removed and the remaining cast-iron pan and tuyere on its stand were bolted down in a corner of the stokehold, immediately under a fan trunk. Some old 3-in. iron pipes, flanges and elbows that happened to be on board were utilized to make a connection from the bottom of the fan trunk to the tuyere. A thick asbestos millboard joint was put between two of the flanges, with a portion of the joint cut away and one bolt left out. In the space thus provided a bit of sheet iron of U-shape was inserted, which acted as a valve. The result was an excellent forge,

capable of melting cast iron, as was conclusively proved by the prompt disappearance of the tuyere. However, a new one protected by firebrick and fireclay lasted better and gave most efficient service. A water-cooled tuyere of the usual type would of course be better still.

Still, a coal forge is not the ideal fitting for a steamer. One is required that is smokeless or nearly so, able to be put in operation on short notice and capable of heating up ¾-in. square tool steel to white heat in a reasonable time—say 5 min. It is seldom that any larger job than this turns up on board; and if it did, it could probably be dealt with in one of the boiler furnaces.

This paper has not covered the whole ground of power tools for a ship. There are many other tools which could be suggested, which would be most useful and not very costly, such as an arrangement for driving a hacksaw, a small shaping machine (both of which could be arranged as lathe attachments), a portable electrically driven driller that can be used in any part of the ship, the current being obtained from the nearest lamp socket, etc. It is hoped that enough has been said to initiate a good discussion, and to induce others to give details of any useful contrivance they may have seen or evolved. It is suggested that such details should refer to power-driven contrivances only; otherwise so large a subject is opened up as to be unwieldy. Possibly at some future time the author or someone else will take up the subject of the outfit of hand tools for a ship. Such an article should render available a large store of personal experience, both for the use of those who go to sea and have to use the tools and for those who have to do with putting a suitable outfit on board.

Making and Testing a V-Block

By Gustave A. Remacle

An accurate V-block is a valuable aid in manufacturing precision gages. The block may be pronounced accurate when it proves true under the following tests: Clamping a ground and lapped cylindrical rod in the V, as in Fig. 1, the ends of the rod should be tested with a good indicator. When the side of the block *A* is on the surface plate, points *B* of the rod should register alike on the indicator. Reversing the block so that the side *C* rests on the surface plate, points *D* of the rod should register the same as the points *B*. Testing in the same manner to ascertain the truth of the V to the bottom of the block, the rod is clamped as in Fig. 2 and tested at points of the rod *A*. However, as the block is often used for holding cylindrical pieces on the magnetic chuck of the grinder in squaring the ends, the test in Fig. 3 may be applied to determine further the accuracy of the block by strapping it to the faceplate of the bench lathe, which has been carefully tested for truth. The block is adjusted so that the point *A* of the rod runs true. If points *B* also run true, the block may be pronounced satisfactory for use in manufacturing gages.

An interesting feature in the making of the V-block was the use of the sine bar for obtaining the angle. A piece of ¼-in. flat stock was sawed off to about the desired size and angle (45 deg.) and two sides were ground at

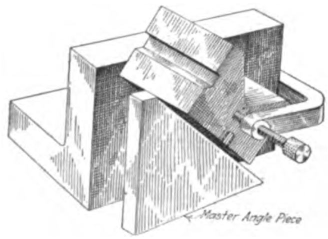


FIG. 6. SET-UP FOR GRINDING THE V

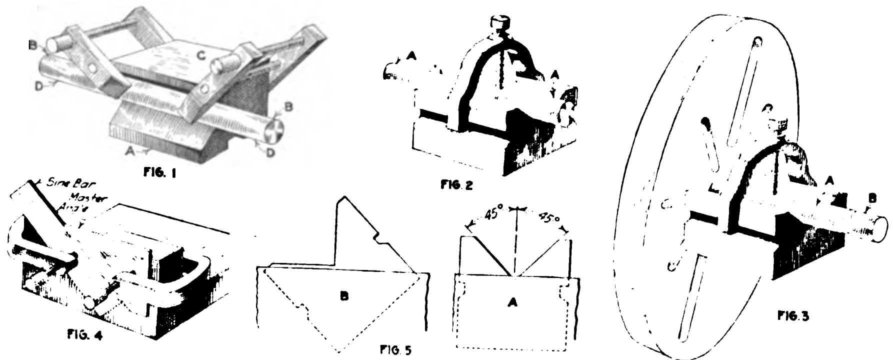
right angles. A sine bar was easily and accurately set to 45 deg. and clamped on an angle plate, to which the flat stock was also clamped, Fig. 4, properly located by the sine bar. Removing the sine bar, the third side was ground and later used as a master angle for obtaining the angle in the V.

While the V in a job of this kind is generally machined in the shaper, as at *A*, Fig. 5, the work was accomplished most rapidly in the manner shown at *B*. In machining the block it was unnecessary to disturb the head of the shaper. The block was inclined at the angle of 45 deg. by allowing it to rest upon the master piece. The set-up for grinding the V is shown in Fig. 6. Both angle plate and master piece are held firmly in place by the magnetic chuck. After one side of the V was ground, the block was reversed, the pin in the master piece locating it at the same height and angle. The remaining side was ground so nearly central and true to the rest of the block that a minimum amount of lapping was necessary to complete the job.



FIGS. 1 TO 5. DETAILS OF TESTING DEVICES FOR ACCURATE V-BLOCKS

The Physician in Industry

Apart from the medical aspect, enlightened employers are beginning to see clearly the value of a physician as a staff member. This conclusion is reached by W. W. Alexander in *American Industries,* and he is also of the opinion that employers have learned to appreciate that a physician's peculiar relationship to employees as a friendly medical adviser enables him to exert a wholesome influence upon their mental attitude as well as upon their physical welfare. It should therefore not be surprising to find physicians in future regularly attached even to small plants.

Punches and Dies for a Door-Hanger Carriage

By Robert Mawson

SYNOPSIS—In this article are described the tools for the last four operations in manufacturing a door-hanger carriage. This includes countersinking in the punch press, drawing out metal for riveting and upsetting the drawn portion to fasten the two parts together, so that assembling as well as stamping and riveting is handled in these dies. A testing fixture is also shown, which is used to determine whether the width between the rollers is to the prescribed limits.

On page 622 were illustrated some of the punches and dies used by the McCabe Hanger Manufacturing Co., New York City, in making the carriage that is part of the equipment on various types of door hangers. Other punches and dies are here given. These tools, as well as those shown in the previous article, are of good design and produce accurate results quickly.

The first operation described in this article is countersinking. The plate is placed on the die, and the punch, guided through a stripper plate, is fed down to the piece and the operation performed. The countersinking is done on only one hole on a plate. The other end of the plate has the hole drawn out in a similar manner.

The plates are placed in the die, shown in Fig. 8, located by stop surfaces at the rear and the ends. The punch is fed down by the press and the plate bent to the desired contour. Two of the plates are then placed together, the drawn surface around one hole being placed into the countersunk hole of another unit. The two plates are put on the die bed, shown in Fig. 8. The punch, which is fitted with a pilot, is placed in position as shown and, being fed down with the press, upsets or rivets the projecting metal. The operation is repeated at the other end of the plates, thus uniting them. The assembled plates are tested to see if they come within the prescribed limit of 0.005 in.

These tools have been so well designed that very little variation is found, and practically all the pieces are accepted as being correct in form and to the required dimensions.

The cups and ball bearings are placed in the plates afterward. The rollers, either steel or fiber, as the design demands, are assembled and riveted in position. The carriage is then ready for either placing in service or stock, as desired.

The cups are made of pressed steel by means of punches and dies but it is thought that the tools shown for manufacturing the side plates are of greater interest. The company also made other types of door-hanger carriages with the side plates of other shapes. One of these has the plates straight instead of being bent as described in this article, but this makes no material difference in the manufacturing methods here employed.

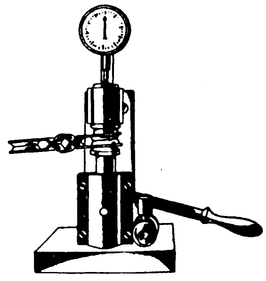


FIG. 9. TESTING DEVICE FOR HANGER

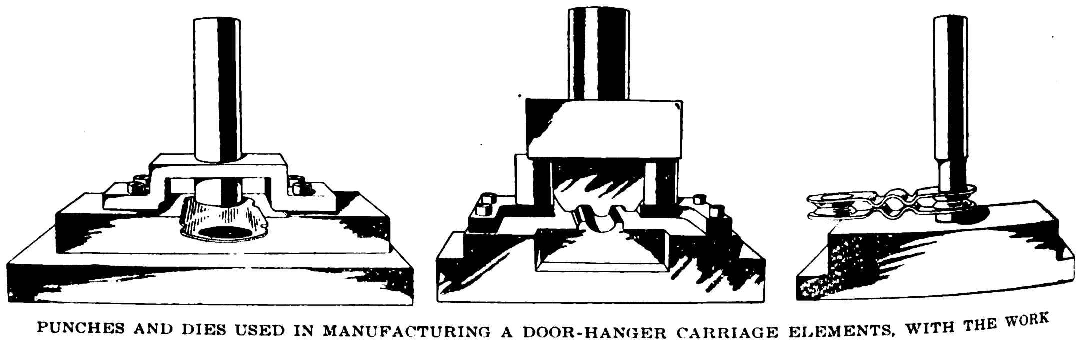

PUNCHES AND DIES USED IN MANUFACTURING A DOOR-HANGER CARRIAGE ELEMENTS, WITH THE WORK SHOWN IN POSITION ON THE DIES

FIGS. 2 AND 2-A

Operation—Countersinking the plate, as shown in Fig. 1. The blank is placed in the die, being located in a steel bushing in which the embossed head rests. The punch, when made to descend, produces the countersunk hole.

FIG. 4-A

Operation—Drawing the hole to the contour shown in Fig. 3. The piece is located in a manner similar to that described in the previous operation, and the punch, by descending through the stripper, produces the desired drawn lip.

FIGS. 6 AND 6-A

Operation—Bending to the contour, Fig. 5. The pieces are located in the die by means of the stop plates at the ends and the rear. The contour is produced by the punch as shown in the illustration.

FIGS. 8 AND 8-A

Operation—Riveting two plates together to form the assembled part illustrated in Fig. 7. One of the plates produced up to this operation is being countersunk, and the other plate having the drawn lip is placed on the die. The punch, which is made with a pilot, is then fed to the plates, and the two are riveted together. In Fig. 9 is shown a complete door-hanger carriage being tested to see if it will pass under the required limits.

Drilling Suggestions for Munition Work

SPECIAL CORRESPONDENCE

The manufacture of munitions of various kinds has brought out many interesting problems, the methods and results obtained in drilling being of especial interest. This work may be divided into two classes—the heavy drilling, as in shell manufacture, and the light drilling of the fuses and gaine tubes.

The making of small shells, particularly the 3-in. or thereabouts, is handled in two ways—by using forgings with the hole drawn approximately to size and shape and by drilling from the solid. The latter method is in the minority, but is used in some shops and has developed several drilling problems. One of the difficulties was to secure a hole that was straight and fairly true with the outside. Drills and reamers have been condemned when in reality the trouble was in the method.

As with most things in life, success depends upon what kind of start you make. The truth of the first 2 in. of the hole is very important. If this is straight, no trouble is likely to develop. For this reason the hole should be started with a short, stiff drill, through a fixture with a hardened bushing. Then the piece can be passed to the long drill and the hole finished without difficulty and without a guide bushing. This practice has the further advantage of affording a means of using up drills that have become too short for drilling the full depth of the hole, and in these days of high steel prices this point counts considerably.

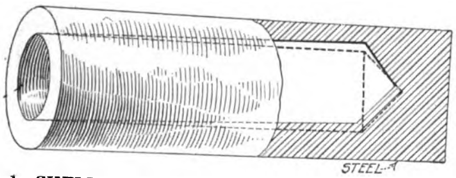

FIG. 1. SHELL DRILLED OFF CENTER; DOTTED LINES SHOW PATH OF REAMER

Many shells were rejected on account of the reamer not cleaning out the hole at the bottom, the reason being that the drilled hole was off center, as is shown somewhat exaggerated in Fig. 1. The reamer in trying to cut straight would clean out only part of the hole, leaving a portion of one side rough as it came from the drill.

Actual Drilling Performances

One large shell shop, well equipped with heavy machinery, is drilling holes $2\frac{1}{16}$ in. in diameter at the rate of 166 r.p.m., or 90 ft. per min., with a feed of 0.024 in. per revolution. These shells are 20- to 25-point carbon, and a hole 8 in. deep is obtained in 2 min. Lighter drilling machines will not stand this feed, and in some cases they will not give the desired speeds.

In another shop on slightly smaller work $1\frac{3}{4}$-in. holes are drilled at 146 r.p.m., or 65 ft. per min., with a feed of 0.018 in. per revolution. These shells are harder and take about 3 min. each. A good working average for drills of this size would be 150 r.p.m. with 0.018-in. feed.

Best results are obtained by heating the cutting compound to about 150 deg. F. before starting to drill. The drills for this work have to be tempered harder than for ordinary work, and they are tougher (and so less likely to break) when warmed up to 150 deg. After they have drilled a few holes, the heat of drilling keeps the lubricant warm enough.

In drilling small holes speed is the main requisite, to which may be added sensitiveness in the spindle, so that the operator can feel the cut. Drilling the small holes in the gaine tube with No. 68 or 69 drills was difficult until high speeds were used. Now that this hole has been enlarged to $\frac{1}{16}$ in. the problem is not so difficult, although that is not a very large drill.

Success in Drilling Small Holes

Special machines have been made in many cases, whereby the work and the drill revolve in opposite directions. Others, with equal experience, advocate the less complicated method of revolving only the drill in a simple machine. One successful fuse maker has used simple drilling heads, Fig. 2, holding the work in V-blocks. The spindle A is of $\frac{1}{4}$-in. or $\frac{3}{8}$-in. drill rod, ground and polished. It is mounted in a head with two bearings B, this being a heavy iron casting, and the holes are drilled and reamed straight and true. The bearings should be six diameters long.

The drill is held in the end of the spindle by a small screw D, a similar screw E being put in at the opposite side for balancing, as perfect balance is essential. The pulley F is small—about $\frac{3}{4}$ in.—and the spindle is driven by a rubber band $\frac{1}{8}$ in. wide. The button G is loose on the spindle and allows the operator, usually a girl, to feel the cut of the drill perfectly. The head must be heavy to absorb vibration and to take care of heat, very litle lubrication being used and a light oil of high quality being necessary.

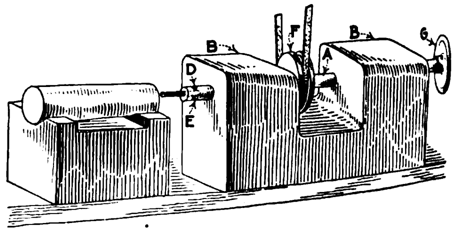

FIG. 2. SIMPLE AND CHEAP DRILLING RIG FOR SMALL HOLES IN GAINE TUBES

The girl wipes the drill with a brush dipped in lard oil, clears away the chips and lubricates the drill at the same time. When sharp, the drill rolls tiny chips out of the hole; when dull, it is restored by stoning, taking care to keep the center sharp. The spindle is so sensitive that the slightest dullness is easily detected, which also prevents snapping the drills, many hundred holes being drilled with no breakage. One No. 69 drill that had been used for 2,300 holes, each $\frac{7}{16}$ in. long, was in fine condition and good for many more.

Invar and Related Nickel Steels—The Bureau of Standards, Department of Commerce, proposes to issue a series of circulars of information on the properties of the more interesting or technically important metals and alloys. The first of the series, describing the properties of the nonexpansible alloy Invar and other nickel steels, has been published. The magnetic, electrical, thermal and mechanical properties are given with numerous illustrations, together with statements concerning microstructure, constitution and applications.

Forge Shop at Naval Station, Pearl Harbor, Hawaii

By J. A. Furer*

SYNOPSIS—The forge shop at the new naval station, Pearl Harbor, is a steel structure 200 ft. long by 100 ft. wide, consisting of a main bay 50 ft. wide and two side bays each 25 ft. wide. The height of the main bay under the 15-ton traveling crane is 31 ft. 9 in.; and of the side bays under the roof-truss chord, 15 ft. 8 in. The building has three open sides. This unusual feature in the construction of a shop building was rendered possible by the remarkably favorable climatic conditions at Pearl Harbor. Only the north side of the shop is closed—this to a height of 12 ft.—so as to break the force of the wind which blows almost constantly from that direction and to protect the oil fires from the strong breeze.

The naval station is located on the leeward side of the Island of Oahu. A mountain range on the windward side of the island precipitates the moisture carried by the northeast trade winds before they reach Pearl Harbor. It therefore seldom rains at the naval station, except in times of southerly storms. Bad weather from that direction is, however, infrequent and not of long duration.

As the Hawaiian Islands are situated in the tropics, sides for the buildings are not necessary to make them habitable in winter. Although the climate of the islands is described as tropical, it is nevertheless remarkably cool at Pearl Harbor even during the summer months. The range in temperature is in fact so unusual that it is worth mentioning.

The maximum temperature during 1914 was 86 deg. F. This temperature was registered only a few hours during the month of August. The usual maximum at the middle of the day in the summer months is 82 or 83 deg. F. By comparison many of the large cities in the northern part of the United States are more tropical in summer than Pearl Harbor.

The only objections to open sides for the buildings at Pearl Harbor are the occasional southerly rainstorms already mentioned and the dust that is blown up by the trade winds. These are not, however, vital considerations for a forge shop, as compared with the advantages of better light and better ventilation resulting from this construction. Buildings in which more delicate tools are housed, such as the machine shop, pattern shop and woodworking shop, are inclosed. In order to prevent pilfering outside of working hours the forge shop and other open buildings are fitted with wire-mesh sides.

MONTHLY TEMPERATURE AVERAGES FOR THE PAST THREE YEARS AT THE NAVAL STATION, PEARL HARBOR

Month	1912, Deg. F.	1913, Deg. F.	1914, Deg. F.
January	70.0	71.8	69.1
February	69.8	70.4	71.4
March	71.4	72.2	70.9
April	73.3	72.8	72.5
May	74.3	74.8	74.3
June	75.3	76.2	76.6
July	76.4	77.4	78.2
August	78.1	78.2	79.2
September	76.8	78.2	78.7
October	75.2	77.6	77.7
November	74.7	74.6	75.0
December	72.4	74.0	72.5

The usual smithing work will be done in this shop and also the plate and angle furnace work that at shipyards is ordinarily carried on in a separate building.

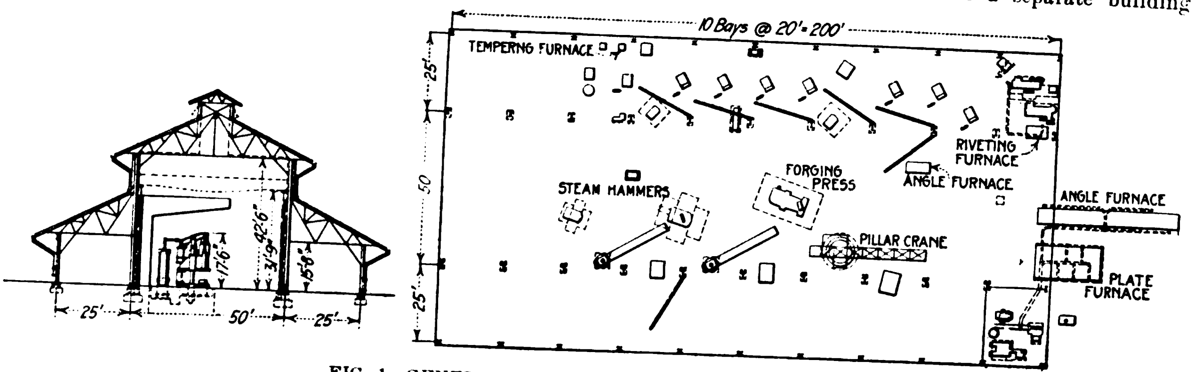

FIG. 1. GENERAL ARRANGEMENT OF FORGE SHOP

The advantages of combining the latter class of work with that ordinarily done in a forge shop are obvious, as the trades are allied and lend themselves well to supervision by one foreman. Moreover, duplications of equipment, such as blowers, pipe lines, cranes, etc., are avoided by having the angle smiths also in the forge shop. The plate and angle furnaces are located at one end of the shop, as will be seen from the layout plan of the building, Fig. 1. Only the working ends of these furnaces are under the roof of the shop. Corrugated-iron hoods are fitted over the parts of the furnaces that project beyond the building, so as to protect the brickwork from the occasional rains. In Fig. 2 the outside of the building is shown.

All the furnaces and forges are oil burning. The burners and collateral equipment were purchased, and the installation was made by the Government. The burners are of the combination type, using air at a pressure of 30 lb. for atomizing the oil and low-pressure air at 6 oz. for combustion. The blowers and pumps are installed in one corner of the shop and are illustrated in Fig. 3.

*Naval constructor.

The outfit consists of a blower having a capacity of 7,500 cu.ft. of air per minute, driven by a 50-hp. motor—two rotary pressure pumps each driven by a 2-hp. motor delivering oil at 30 lb. pressure—and a small individually driven air compressor for providing the atomizing air. Only one pump is actually in service at a time for delivering oil to the distribution system. The duplicate is provided as a relief in case of breakdown or choking of the working pump. An air receiver is installed in the compressed-air line, to equalize the pressure in the main and to separate the entrained moisture.

The most satisfactory combustion results are obtained by keeping the air pressure on the atomizing line the same or slightly higher than the oil pressure—in this case approximately 30 lb. If the air pressure is allowed to fall below the oil pressure, the oil is apt to be forced into the high-pressure line by way of the burners.

Various methods of leading the blast and oil piping to the forges and furnaces were considered. A concrete conduit of sufficient size to accommodate all the pipe lines was finally adopted as providing the most satisfactory arrangement. The conduit, with the pipes in place, is shown in Fig. 4. Openings were left in the walls for the branch piping to the forges and furnaces. The top is covered by plates, flush with the floor, thus providing ready access to the piping.

This conduit runs along two sides and across one end of the shop. It contains the low-pressure blast main, the high-pressure air line, the oil main and a steam pipe, close to the oil pipe, for heating purposes. This was

Fig. 2—View of forge shop from outside. Fig. 3—Blower and oil-pump equipment. Fig. 4—Concrete-pipe conduit. Fig. 5—Split-tile conduit for oil and steam piping beyond the concrete conduit. Fig. 6—Hand forge and tool-dressing equipment. Fig. 7—Rivet-making and power forging machines. Fig. 8—Steam hydraulic forging press. Fig. 9—Plate and angle furnaces

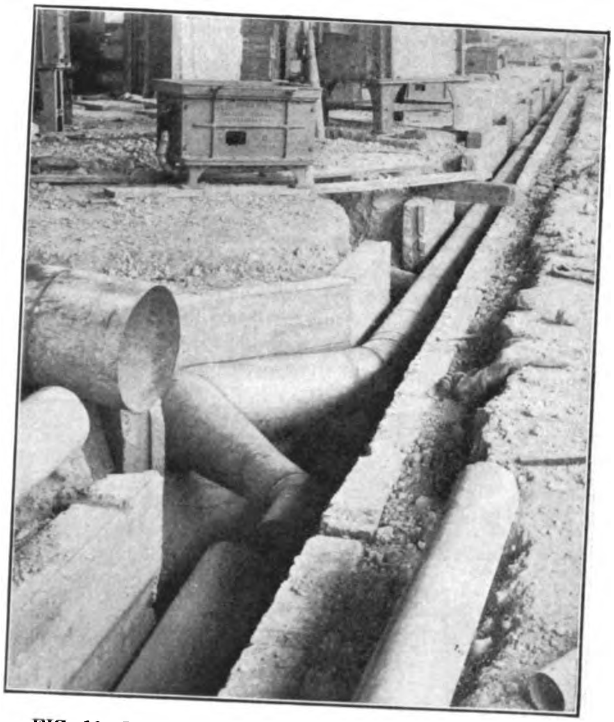

FIG. 10. PIPE CONDUIT. SHOWING OPENINGS FOR BRANCHES TO FORGES AND FURNACES

found to be a desirable part of the equipment, because the oil used is of the heavy California variety and must be brought to a temperature of about 130 deg. F., if entirely satisfactory combustion is to be obtained. The improvement in combustion when using warm thin oil as against cold thick oil is particularly noticeable at the open forge burners.

The oil and the steam lines form a complete loop around the shop. Oil in excess of what is consumed at the burners is pumped back into the loop and is kept from returning to the supply main by check valves. The oil consumption is measured by a meter in the supply main. The oil and steam lines are laid in hollow split tiles as illustrated in Fig. 5, where these lines cross the far end of the shop to complete the loop.

The blast piping is made of galvanized sheet steel ranging in thickness from 20 gage to 24 gage, depending on the diameter of the pipes. Such light metal could hardly have been used had the main been buried or installed overhead in accordance with customary practice. The joints in the blast piping were made tight by wrapping them with canvas soaked in red lead. The pipes were also given a heavy coat of asphaltum after having been placed in the conduit. While the first cost of this installation may be somewhat higher than the construction usually adopted, the upkeep cost should be small.

Russia's Industrial Requirements—After agricultural machinery and farming implements, Russia's greatest needs, according to "American Industries," are machinery in general, industrial machinery, both hand and power, machine tools and ordinary tools of all kinds, gas and petrol motors, steam engines, stationary and portable, electric-power machinery and electric motors, ironmongery, files, saws and cutlery. All sorts of hardware are needed, including tin-plate, enameled ware and all kinds of sheet-iron manufactures. Excluding the trade in munitions, the buying done by direct purchases here is insignificant in comparison with the enormous sales now effected by American representatives and salesmen now in Russia.

Safety Instructions for Guidance of Machine Operators

By C. B. Hayward

Many different plans have been worked out by various employers of labor to inculcate individual care and thoughtfulness among workmen in matters of safety for themselves or their neighbors. It is realized by all interested in the safety movement that, in order to blot out many of the trivial accidents, especially around machinery, it is necessary to make the employee think of safety and avoid dangerous points and practices. Hence, we try to get at the root of the trouble and, instead of caging a machine and endeavoring to operate it from the outside, give to the operator personal instructions in safety. He has always been taught the requirements needed to turn the wheel and give out the product. Now we are adding another important phase—get out the work, but do it safely.

When a new man is introduced to an unfamiliar piece of mechanism, he is apt to give more thought to the production than to the safe procedure. He will listen to the foreman's discourse on what to do and what not to do and then start to work, forgetting safety in his endeavors to satisfy the "boss" as to his efficiency. It is in this way that some, if not all, of the cautions that go with the first lessons are forgotten until an accident occurs.

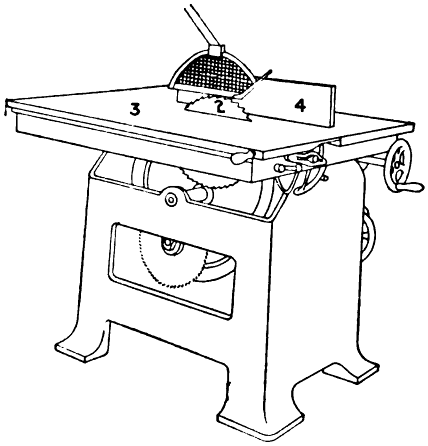

FIG. 1. CIRCULAR SAW

The views and text herewith present a method of pointing out to the workmen the dangers connected with the machines. This way of presenting the subject has a tendency to keep the matter of safety ever before them. It is a descriptive method of educating employees in the importance of caution and personal responsibility in the prevention of accidents and ought to leave a lasting impression, causing each man to think and act with careful consideration for his own and others' safety.

These illustrations and worded cautions give only an example of what may be done with all types of machinery in use in any industry. The drawings are made by outlining a sepia photograph and then washing the silver coating of the photograph off with a bichloride of mercury solution. This leaves the paper white with only the india ink outline and from this the ordinary zinc cut is made.

The warning paragraphs in connection with the illustration of the circular saw are as follows:

Torn parts or loose ends of wearing apparel should not be worn by employees while working around moving machinery.

Before oiling or cleaning machine and before adjusting any part of machine, shut off all power and wait until moving parts come to a standstill.

Keep hands away from revolving saw (2).

Always wear leather protection apron when using saw.

Do not push work away from back of saw with fingers—use stick.

Before removing work from table (3), be sure to push it beyond back of saw.

When sawing narrow stock, always use stick.

Where practicable, do not stand directly in line of revolving saw.

All guards should be kept in place.

Treat all uncovered gears as being dangerous.

Shut off power when it is necessary to put any belts on pulleys with hands.

When sawing lumber, keep straight edge of lumber against guide (4).

Be careful at all times not to expose yourself or your fellow-workmen to accidents.

Report all dangerous conditions to the foreman.

All injuries, however slight, should be cared for immediately, to prevent infection.

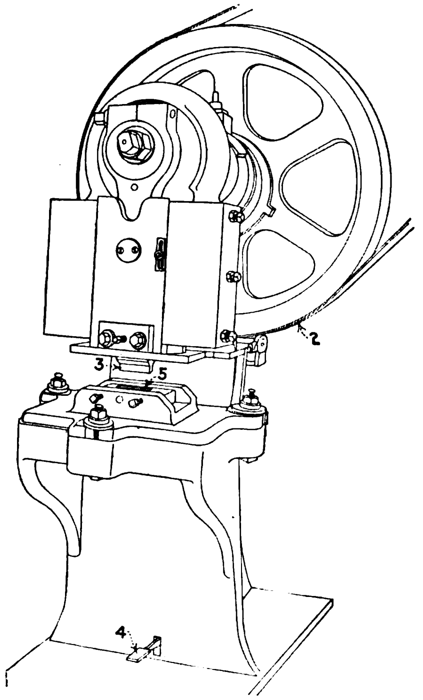

FIG. 2. PUNCH PRESS

The text accompanying the view of the punch press repeats the general cautions already given and adds some especially needed in the operation of this machine:

Torn parts or loose ends of wearing apparel should not be worn by employees while working around moving machinery.

Before oiling or cleaning machine and before adjusting any part of machine, shut off all power and wait until moving parts come to a standstill.

See that no person is working on or about machine, before setting flywheel (2) in motion.

Be sure the hands are out of the path of punch (3) when treadle (4) is operated by the foot.

Shut off power when it is necessary to put any belts on pulleys with hands.

All guards should be kept in place.

Treat all uncovered gears as being dangerous.

When putting work into die (5), keep mind and eyes on the operation and foot off treadle (4).

Do not adjust punch (3) or die (5) while flywheel (2) is in motion.

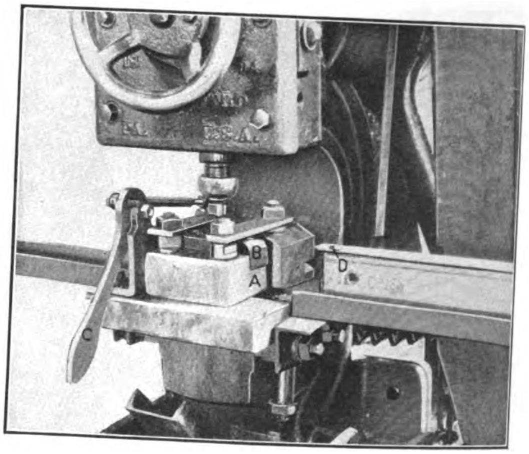
Be careful at all times not to expose yourself or your fellow-workmen to accidents.

Report all dangerous conditions to the foreman.

All injuries, however slight, should be cared for immediately, to prevent infection.

Punching Channel Sides

To punch holes in the bottoms of structural-iron channels is easy, but to punch holes in the sides is not so simple. As a rule, these holes are drilled; but if many parts are used and the channels are not too large, punching is much quicker. The Standard Dry Kiln Co., Indianapolis, Ind., requires a large number of short pieces of channel iron for



PUNCHING HOLES IN CHANNEL SIDES

making small trucks. Holes in the sides of these pieces are punched out in a press fitted as illustrated.

The die block is shown at *A*. This is so made that the lower side of the channel will fit in under its edge. The die may be seen at *B*. The channel is shoved in through the opening until it is in the correct position for the hole. The lever *C* is then pulled down. It operates a lever at the back and forces a pin in toward the channel, pressing it firmly to the die block. By pushing up on the lever the channel is released and may be shoved along or removed altogether. The hole punched in this particular piece is indicated at *D*.

In a South American Office

A Northern salesman was in the office of a South American business man and was waiting for an earlier caller to finish his interview. From the place where the second visitor was sitting, the desk of the South American was in view. Suddenly a small panel behind this desk, but in view of both visitors, glowed with the words *Sea breve.* Translated, the legend is, "Be brief."

Shortly after this little occurrence the first visitor left, and the North American was ushered to the desk of the man upon whom he had called. Following the usual cordial greetings, the Northerner laughingly said to the man who was receiving him, "Please don't light that sign for me." The South American then explained that he had a push button concealed under his desk and within reach of his foot, so that a polite warning could be flashed for the benefit of the caller who was outstaying his welcome. Perhaps a similar device might be a time-saver elsewhere.

War Problems of the German Machine-Tool Industry

Special Correspondence

SYNOPSIS—At the outbreak of war the machine-tool industry of Germany was prostrated, owing to the cutting off of foreign trade. Later on came an enormous demand for machines to produce war material. Meanwhile many workmen had been mobilized. Women were then taken into the machine-tool building shops. All stocks of partly built machines and parts have long since been exhausted. Today, plans are being made for the rebuilding of foreign trade when the war ends. The solutions of the problems have been largely due to the control of the industry exercised by the Ministry of War through two committees—one for war raw material, the other for industry. All distribution of material and product and the direction of the manufacturing capacity are in the hands of these committees.

The interruption of the commercial and economic intercourse between Germany and other countries did not take place at the beginning of the war, but was the result of a slow development that gave the German manufacturer time to accommodate his work to the new conditions. Further, the commercial isolation of Germany is not entirely the result of the so-called British blockade, but is also due to a self-imposed restraint having as its final object the withholding of goods necessary for the conduct of the war. So one of the first steps taken by the German Government after the declaration of war was an edict, published on Aug. 3, 1914, prohibiting the exportation of all goods and wares necessary for the defense of the country, or likely to be of assistance to the enemy. This edict, general in its first wording and merely intended to stop commercial intercourse for the first days of the war when all Europe was preparing for the ensuing great struggle, was soon followed by more explicit orders. Machines of all descriptions were included in the list of those goods not to be exported without special permission; but not all classes of metal-working machines were originally excluded from foreign trade, although most classes of machine tools were covered by the general description, "necessary for the defense of the country."

Initial Surplus of Production

Germany until then had exported yearly about $20,000,000 worth of metal-working machines of all kinds, while the import value given in the statistics of the Government was only $2,000,000. As it has been shown, however, that the estimated value of the imports of machine tools into Germany is much too low, one may take it that the real commercial value of those machines was some $5,000,000 to $6,000,000. Even so, there remains the fact that Germany, being a machine-tool exporting country, had left at the beginning of the war an uncalled-for yearly productive capacity of at least $14,000,000 worth of machine tools.

The first and initial difficulty arising out of the war was therefore a surplus of production. This difficulty existed for some time, until it found its solution in the natural progress of events. Outside of a few men who were especially able to judge the importance of the struggle, most people in Europe were still under the impression that the war would be a short one and that its economic results might be insignificant, owing to the firm economic position of the countries engaged. So it seemed to be a disadvantage for the German machine-tool industry to have on hand material and half-finished stock for an output far above the needs of Germany's own consumption and manufacturers were rather inclined to complain about the orders curtailing their export business. Losses occurred during the first months of the war, and the Association of Machine-Tool Manufacturers, at its first meeting after the declaration of war—early in 1915—complained mostly about the accumulation of half-finished stock that could not be sold, while the manufacturers seemed to be unable to finish it, owing to lack of labor.

A great number of the machine-tool plants of Germany belong to the middle-sized industries, having a comparatively small number of workmen. Unfortunately, just those smaller plants were most hurt in the beginning, owing to the withdrawal of workmen for military service. On the other hand, experience shows that in later months all those plants of medium size lying outside the congested industrial districts of Germany had a better chance of securing experienced labor than those in the so-called industrial districts. This fact proves again the correctness of the rule that, generally speaking, industrial decentralization will be more elastic in times of need than the accumulation of large industries in over-populated industrial centers.

Changes Wrought by the War

With the progress of the war and the realization of its possible long duration, reorganization began to take place. Some of the smaller plants ceased to operate entirely; others changed over to the manufacture of more important goods than those made before the war, allowing a redistribution of labor, which brought about a fair solution of the labor problem.

As we are now in the midst of the event itself, when the economic forces created by the war have not run their full course and new developments have to be expected, it is of course extremely difficult to give anything like a complete and coherent picture of all that happened. From the mass of information and experiences collected from time to time only certain tendencies seem to stand out, and it is practically impossible to concentrate the whole into anything like a system of industrial organization directed by one will. Much had to be done according to circumstances and convenience, and it must be left to the observer to extricate all those movements especially descriptive of the situation as a whole.

Therefore, in discussing the question of labor in the German machine-tool industry during the first 18 months

of the war no hard and fast rules can be laid down. The individual manufacturer had to deal with the local problem as it arose, and the solution has not been uniform. Excluding from the inquiry all those plants which either ceased to work or changed over to other fields of production, it appears that during the first months of the war the lack of labor in all the larger machine-tool plants of Germany had rather a beneficial influence, as it relieved the owners of the necessity of dismissing workmen. This step would otherwise have been unavoidable, owing to the disarrangement of the foreign trade. Later, when conditions began to change, the industry had to accommodate itself to the lack of man-labor, and several of the largest metal-working plants of Germany resorted to the expedient of hiring women. The actual figures of the woman-labor employed in the production of machine tools cannot be given now, but they are certainly very large; and it is only too possible that woman-labor will have gained more than a casual foothold in this industry. The employment of woman-labor seems to have been particularly large in the more populated industrial districts, as in the Rhineland. Here, the necessity of finding labor, as well as the need of furnishing employment so as to eliminate as much as possible the effects of the war upon the poorer classes, assisted very much in this development.

Later in the war the industrial conditions in the machine-tool building industry in Germany began to settle down to a routine. It would be incorrect to say that they became normal, but a state of normality was reached by a natural process of accommodation to circumstances and by becoming familiar with the conditions of war and the limitations it imposed upon German economic life.

Germany in the meantime had become a fortress surrounded by enemies, with few means of communication with the outside world. German economic life therefore was thrown back on its own resources. Out of the common danger and privation there sprang a new sense of entity and common purpose, which was ably directed by the Government. It is quite natural that the German machine-tool industry could not separate itself from this uniformity, but that, on the contrary, it had to become a subservient and important part of it. While the powers on the outside of the ring were able to replenish their diminishing stocks of industrial material by buying abroad, Germany was prevented from doing so; and its industry had to take up the battle, backed solely by the resources existing in Germany, Austria and the Balkans or that had been preserved during the first months of the struggle. Not only did the German machine-tool industry have to supply the great number of machines wanted owing to the expansion of the internal activity, but part of its energy was directed into other channels—mostly in the manufacture of war material, such as ammunition, guns, etc.

Significance of Change of Industrial Purpose

It is difficult to understand the significance of this great change of industrial purpose in Germany and its effect upon the German machine-tool industry without understanding as well the forces that brought it about. Thirteen per cent. of all the imports into Germany had consisted of manufactured goods, while 63 per cent. of the exports were manufactured articles. With the cessation of the exports, therefore, there was set free an enormous surplus of manufacturing energy, which only had to be regulated to be useful. This transformation, even now only partly carried through, needed time, and even with all the statistical data in the hands of the Government it could be effected only step by step, so as not to disarrange and endanger the industries affected. Certain industries, as the textile, toy making and ceramic, which suffered especially from the loss of exporting and from the reduction of labor by the mobilization, could not overcome the depression. In those industries women had taken a prominent position before the war.

The machine business soon began to feel the lack of orders coming from the other industries. On the other hand, the decrease in the output of machines for general purposes began to liberate the productive energy of the machine builders, including the machine-tool makers, for the immediate and growing military needs, which came rapidly into prominence. Large quantities of iron and steel otherwise used in industrial production were now also free for Government purposes.

How large this military demand has grown can only be guessed. It is, however, interesting to observe that the Verein der Eisen- und Stahlindustriellen (Association of Iron and Steel Industries) reports in 245 of the associated plants an increase of persons employed from 417,000 during August, 1914, to 447,000 during August, 1915. This record is probably a good guide for all the industries employed in defensive work. Another example worth mentioning is the increase of the profits of the Krupp works from $9,000,000 in 1914 to $22,000,000 in 1915, which figure is especially significant if viewed in connection with the higher cost of raw materials and production resulting from the war.

Activity of Metal-Working Industry

The activity in the metal-working machine industry, which became more and more prevalent during the early part of 1915 and continued throughout the whole year, was influenced by a number of things, of which the large demand for machines for the armament industries was the most outstanding. Outside of that there was an apparent tendency to replace human labor more and more by that of machines. Not only was this action necessitated by the lack of skilled labor, but the employment of woman-labor made desirable the use of automatic machines for all possible purposes. So it will probably be seen that the German machine-tool industry has taken up the manufacture of certain types of automatic machines formerly bought abroad, which may affect materially the German machine-tool business both at home and abroad after the war.

The lack of machine tools for special purposes was much felt at the beginning of the war. Before the war America supplied a large percentage of the automatic machines imported into Germany. Further, Germany and America were strong competitors in many of the European countries, Germany furnishing the more simple machines, while it fell to the lot of America to supply the complicated types. There is no information to indicate how far Germany may have been able to make use of stocks of American machines of that class in the hands of German firms in neutral countries at the outbreak of the war. It is, however, said that those stocks were not large; and even if there have been loop-

holes through which German manufacturers were able to secure American machine tools for some time, this practice has become increasingly difficult with the progress of the war. Consequently, German industry has been compelled either to go along as well as possible with the machines on hand or to build such machines in her own plants.

To prevent Germany from spending her industrial strength in the beginning of the conflict and also to conserve her economic energies, measures were soon taken to put a brake on the waste of energy and material wherever such existed. A careful preservation of resources was inaugurated, which possibly forms one of the most noteworthy economic and industrial features of the present war. The machine-tool industry was affected by those measures in several ways, both with regard to the supply of raw material and in its own production.

Industrial Department of the Ministry of War

Early in the war there was formed an economic and industrial department of the War Ministry. This department apparently has not been copied by any of the other nations at war, but has its counterpart in some degree in England in the Ministry of Munitions, which is intrusted with arbitrary powers in every direction. The method of precedure of the War Ministry is not to apply for legal powers from the Reichstag, but to issue edicts that become effective immediately. So there stands nothing in the way of that body, which can proceed without loss of time and can enforce compliance with its orders. This industrial and economic department is divided into a number of different committees, the members of which have been selected from among the leading German experts.

The machine-tool industry has to deal especially with two of those committees—the War Raw-Material Committee and the Industrial Committee. Bodies of the same sort have been formed in Austria. The working of those departments in their relation to the machine-tool industry is best explained by several examples. As previously explained, it has become necessary to close the frontiers for the export of certain machine tools, in fact for any trade that might benefit the enemy. Such an arrangement, however, might prove detrimental to the home industries if carried out too strictly. Relief had to be given in some way—mainly where it was necessary to keep up good commercial relations with neutral countries. So a special commission was formed for the purposes of passing export permits to manufacturers who could prove to the department the necessity of such licenses. To facilitate this work, it was soon necessary to form subcommittees in larger industrial centers. The machine-tool industry by those permits has been able to keep up necessary connections.

Machine Tools and Raw Materials

It may be mentioned that German machine tools had apparently been obtained through some loophole by manufacturers in countries at war with Germany and that in consequence a close observation of buyers from neutral countries had to be kept, which was a continual source of inconvenience to both the German manufacturer and the bona fide neutral buyer.

The enormous consumption of iron, steel and raw materials for manufacturing purposes was also felt seriously in machine-tool building, and the steps taken to relieve the shortage are of more than a passing interest. These relief steps were of different kinds. Germany was able to produce sufficient steel for her own purposes, but there was a cessation of the movement of other metals. A close investigation by the War Raw-Material Committee disclosed the fact that the difficulty was not so much a shortage of the materials in question as insufficient elasticity in the existing means of distribution. It was therefore necessary to bring about changes. Already in the first months of the war this lack of elasticity had shown itself, and there had been attempts to corner the market for the benefit of certain users. So the Government stepped in and decreed highest prices for the more important materials.

It would take too much space to cover the whole field of those preventive measures, but the following prices (for 100 kg., equivalent to 220 lb.) may be of interest: Electrolytic copper, 200 marks ($50); best old brass, 145 marks ($36.25); old bronze, 175 marks ($43.75); aluminum, 325 marks ($81.25); nickel, 450 marks ($112.50); antimony, 150 marks ($37.50); tin, 475 marks ($118.75). The mark price is given without reference to the present exchange rate, but at its former value, which was about four marks to the dollar.

It became evident, however, that the schedule of maximum prices was not sufficient to keep the market supplied. More serious steps had to be taken, and a general disclosure of all the stocks of metals was enforced by a system of registration. Other materials were included later in the list of raw materials to be reported. But the registration was intended not only to secure an unhampered supply of raw materials necessary for the defense of the country, but to collect as well all data affecting the industrial resources of Germany. Further edicts made compulsory the registration of unused electrical and power machinery, and this system has been slowly extended into other fields.

Organization for Scrap Recovery

Again, to give an example, this time from the Austrian system, a special Old-Iron Commission was formed to take charge of the scrap-iron resources of the country. Owners of scrap were compelled to disclose their stocks, which were registered and taken charge of by the commission. No removal from the holder took place and no interference with sales between merchants of old metals, as long as the stock itself was not decreased. But such sales had to be reported, so that the commission might know where stocks could be found. All transactions between the holders of the stock and consumers, however, must pass through the hands of the commission. The same system applies to all disclosed stocks of raw materials held in Germany, where special holding companies have been formed for the distribution of such holdings to consumers.

The registration of electrical material, machines, transformers and dynamos was ordered for a twofold purpose: First, it became necessary to collect as much copper as possible, and for this reason the committee that had in hand this section of the organization of German reserves had powers to order the destruction or reconstruction of the registered machines in such a way as to exclude the use of copper wherever possible; second, there is the desire not to expand unnecessarily the productive

energy of the electrical industry in Germany during the war, owing to the lack of raw material. By registering all unused machines, however, there are possibilities for employing all existing machines where there is need for them. A manufacturer desiring a motor for his plant can be put in touch with one who has a power plant, but is unable at present to use it. The feared shortage of leather for belts was overcome in a similar way.

To facilitate the distribution of materials, a special organization was set up. As in the case of export permits, special offices distributed over Germany have the right to issue permits for the sale and consumption of raw materials, machines and so on.

Compensating for Economic Disarrangements

The industrial department of the War Ministry has been especially useful for the purposes of the machine-tool industry. As mentioned, at the beginning of the war the conditions seemed to be rather disadvantageous for the industry, and overproduction was feared by the manufacturers. The progress of events brought a change, and for some time there was every conceivable difficulty in filling all the incoming orders for new machines. The industrial department was able to spread information that relieved the situation, making it possible for manufacturers to organize their production according to the needs of the market. In this connection there must be mentioned the Kriegswirtschafts A. G., which has done much to equalize demand and supply.

It is only too natural that, during a war like the present one, considerable economic disarrangement must take place, depressing industries of one class or in one part of the country while bringing about excessive demands in others. So it becomes necessary to curtail the output in any certain direction, while in others an immediate increase is imperative. This event has of course occurred in Germany, resulting in the slowing down of machinery of certain sorts and doubling the work of others. Very much as in the case of electrical machinery, steps have been taken to facilitate the exchange of industrial machines from places where not wanted to others where there is a demand. Machines can be registered for exchange, and manufacturers desiring to buy can register their needs. The Kriegswirtschafts A. G. has taken in hand the sales of machines and material found in conquered territory. This applies to machine tools and other kinds.

Importance of Machine-Tool Industry

The part played by the German machine-tool industry in the present struggle is a very important one. The war has shown that only strict coördination of all interests for the benefit of the whole can obtain results in a time when all the known rules of ordinary economic life have ceased to operate. While it is therefore impossible to view the German machine-tool industry during the last 18 months independently from all the other German industries, it is, however, useful to enumerate briefly the special effects of the war on that industry. In doing so we see early in the war a short but very heavy depression, owing to the sudden stoppage of export facilities. With the progress of the war the cessation of foreign imports of machine tools, in combination with the large demands for machine tools from all the industries having war orders, begins to create a contrary tendency. The machine-tool industry therefore is compelled to resort to the use of woman-labor. It is further called upon to construct certain classes of machines formerly largely imported. To relieve the shortage in machine tools in certain districts, it becomes necessary to organize machinery to facilitate exchange and sale. Shortage of raw materials makes necessary changes in constructive methods and in the employment of certain metals. The fact seems to be established that a modern war must invariably increase the demand for machine tools.

Machine Tools After the War

The fact was mentioned that the import as well as the export of metal-working machines has been greatly curtailed, in fact almost entirely interrupted. Except for the small number of machines exported under special permits, none have left the country, and the import has been small in comparison with what it was. The German statistical office has ceased to publish any foreign trade figures since the outbreak of the war, and the full history of the foreign business of Germany during the war most likely will never be written. So no figures are obtainable with regard to foreign sales of metal-working machines. Germany, however, has ceased to trouble about the export business of today. She is now preparing for the future, and there is no doubt that the machine-tool industry will try to regain at least a large part of the market lost. It is doubtful whether the industry will be able to start exporting at once after the cessation of hostilities.

Probable Future Requirements

The lack of raw material naturally has restricted ordinary manufacturing, and consequently only those machines have been constructed for which there was most urgent need. Further, the mobilization of all machine resources will have used up all the hidden reserves. Many a machine that had done quite satisfactory service before the war has been scrapped, and the machine-building industries have been living from the fat of the prosperous years. When the war is over, it will take some time before the previous comfortable state is reached again. Consequently, there will be a great demand for machines. Many will have to be imported, many will have to be built in German plants, and consequently German machine-tool builders most likely will prefer to supply the home market at first before entering the foreign field. On the other hand, even with these restrictions there must take place a certain amount of export. Stocks in the whole world have become low. For a while the surplus manufactured in the United States and still under order will help to overcome the shortage, which, however, will become more pronounced when normal conditions return.

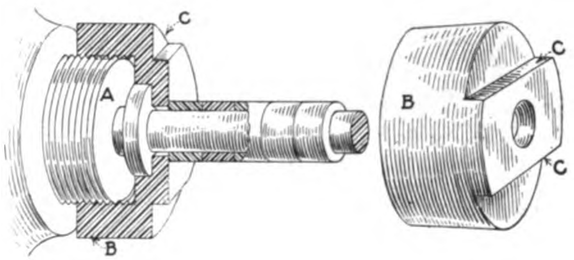
The German economic war committees have taken precautions for that event, and for several months there has existed a special department for the reëstablishment of German foreign trade after the war, conducted by one of Germany's most prominent experts.

German machine-tool construction has also undergone considerable changes during the war. It will be interesting to see how those changes will ultimately affect the sale of German-made machine-tools in foreign markets after the war.

Letters from Practical Men

Holding an Arbor in the Miller

The illustration shows a method of securing a miller arbor in the taper of the spindle, thereby preventing



HOLDING THE ARBOR TO PREVENT TWISTING OFF THE TANG

the twisting off of the tang, when it is necessary to take heavy cuts.

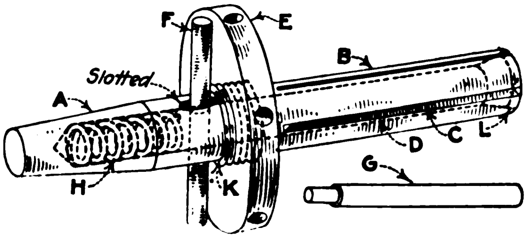
The spindle *A* was removed from the machine and an ordinary 8-pitch right-hand U. S. F. thread cut on its nose. A shouldered nut *B*, with flats *C* fitted to a standard wrench, was employed to draw the arbor into the spindle hole. CHARLES G. KAELIN.

Buffalo, N. Y.

Expanding Arbor

A satisfactory arbor is made with a taper shank *A* to fit the lathe spindle and is turned to the desired size at *B* for the work. It is splined in the usual way with any desired number of slots *C*. We have found four to work well.

The draw rod *D* is made of soft steel fitting loosely in the bore and seating against the taper *L* and the



AN EXPANDING ARBOR

heavy spring *H*. The disk *E* is made of soft steel and is about ¾ in. thick, 4 in. diameter. It is threaded 12 pitch and fits the arbor at *K*. There are four holes equally spaced around it to receive the handle *G*, which is a ¾-in. rod 12 in. long.

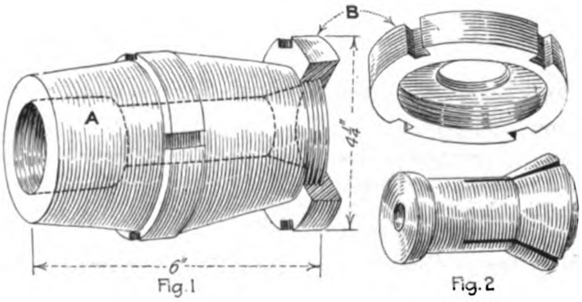
The $\frac{5}{8}$-in. tool-steel rod *F* is a driving fit through the hole in the draw rod *D*. The disk *E* is screwed on and against the rod *F*, drawing the tapered end against the taper *L*. The arbor is slotted to allow the rod *F* to travel and draw the expander rod *D* inward. A spring forces the rod *D* out and releases the work. P. S. SMITH.

St. Louis, Mo.

Adapter for Spring Collets

The adapter, Fig. 1, was designed for lathes that did not have a draw-collet attachment, but had the style of collet shown in Fig. 2.

The body *A*, Fig. 1, is made of cast iron, threaded to fit the nose of the spindle of a 16-in. lathe. The casting is screwed to the spindle and bored in position to receive



SPRING-COLLET ADAPTER FOR THE LATHE

the collet. The outer end is threaded to fit the nut *B*, which is made of machinery steel and pack-hardened.

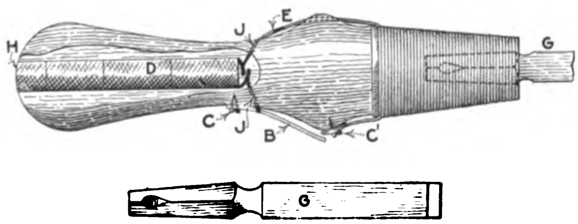
In use, the nut *B* is screwed up against the face of the collet, which forces it back into the casting and against the taper, squeezing it down on the work.

Of course, this contrivance was not as handy as the draw-collet arrangement on the modern toolroom lathes; but it was very convenient around a shop where most of the machines were old-timers, and it enabled us to use collets which we already had on hand. H. M. DARLING.

Greenfield, Mass.

Magnetic Screwdriver

I arranged a Clark patent screwdriver as shown, making it magnetic. I drilled an $\frac{11}{16}$-in. hole 4 in. long in the wooden handle of the screwdriver and in it placed a "fountain-pen flashlight" battery *D*, which is a little over



A MAGNETIC SCREWDRIVER

3 in. long by ⅝ in. in diameter. Previously, a 5-in. length of No. 22 double cotton-covered wire had been soldered to each pole.

These pieces of wire must be at least 5 in. long, as it is necessary to solder them on the battery with the wires coming through the two holes *J* and through the $\frac{11}{16}$-in.

hole. After the soldering the battery is drawn into the hole by the wires. Each wire is cut off, leaving about 1 in. projecting outside the holes *J*.

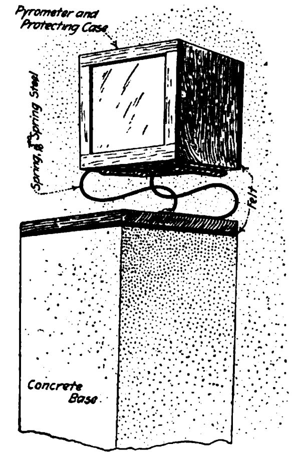
One wire is soldered to the brass spring *B*, $1 \times \frac{1}{4} \times \frac{1}{32}$ in., which is held by a wooden screw *C*. Six layers of No. 22 double cotton-covered wire are now wound on the front end of the steel nose piece. One end is soldered to the wire *E* and the other end to the $\frac{3}{8}$-in. brass washer held by the wooden screw C^1. A wooden plug *H* keeps the battery in place.

Normally, the spring *B* is not in contact with the washer *A*; but when pressed into contact with it, the current passes to the coil around the nose piece. As the nose piece is of steel, it becomes magnetized. When the blade *G* is inserted in its socket, it also becomes magnetized and will hold steel screws. JAMES MCINTYRE.

Bridgeport, Conn.

Spring Support for Pyrometers

The illustration shows a spring mounting for pyrometers, to counteract shocks and protect the instruments. Pyrometers in the blacksmith shop, while not very close to any of the large heavy steam hammers, gave a lot of trouble, as the operation of the large hammers interfered with the readings. Several different things were tried, among them alternate layers of felt and wood. The method shown proved satisfactory, and there is now no quivering of the indicator when hammers are working. On top of the concrete base *C* are a layer of felt, a board and then the springs, made of $\frac{3}{16}$-in. round spring steel. These support the pyrometer and protect the case and the board that forms a back for the device.



PYROMETER SPRING SUPPORT

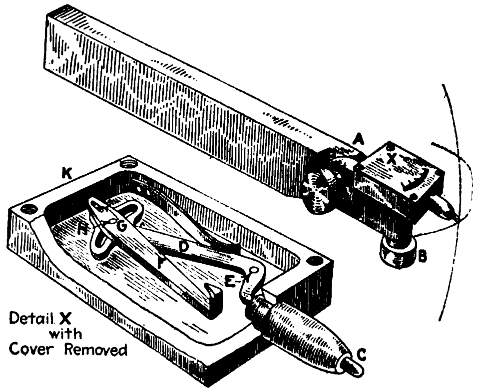
Renovo, Penn. JOSEPH K. LONG.

Multiplying Lever Test Indicator

The accompanying illustration shows a test indicator which has proved satisfactory in the toolroom. The working parts are simple, compact and well protected from dust and injury. The joints *A* and *B* give a wide range without additional change of position in the tool post. When the indicator is removed from the holder, it is so small ($\frac{3}{4} \times 1\frac{1}{8}$ in.) that it can easily be clamped to a surface gage for button work.

An enlarged view of the mechanism, which consists of two levers and a flat spring, is given. The plunger *C* moves the lever *D*, which pivots at *E*. This lever in turn moves *F* by means of the pin *G*, which is riveted to the lower lever and is a free fit in *F*. The lever *F* pivots on the pin *H*, and its extremity *J* has been pointed and bent so as to act as a pointer for the graduation on the cover. A simple scheme to get the correct spacing for these graduations is as follows:

Take a 2-in. micrometer and caliper the indicator at the points *C* and *K*. For each 0.001-in. movement of



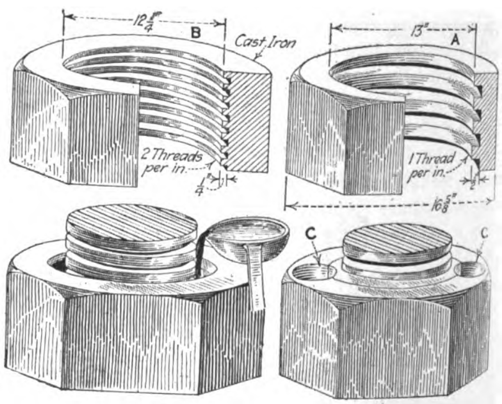
DETAILS OF TEST INDICATOR

C, lay out the corresponding spaces on the cover, as shown by *J*, the pointer. LAWRENCE E. OLSEN.

Schenectady, N. Y.

An Emergency Repair on a Stone Crusher

The sketch shows a cast-iron adjusting nut for a stone crusher. The nut has two square threads per inch, some of which broke off at the root. There was no extra nut



EMERGENCY JOB ON A STONE CRUSHER

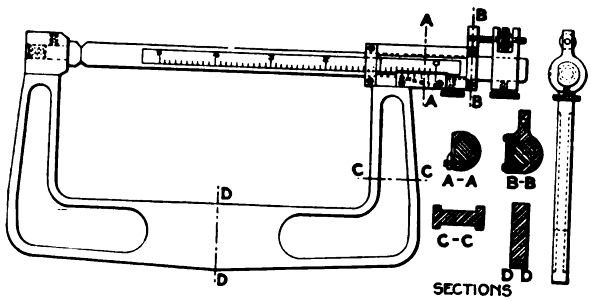
on hand, so the damaged one was bored to the dimensions shown at *A*. The original dimensions are given at *B*. After the nut was bored, the shaft was placed where it belonged, which is in a vertical position. Babbitt was poured in the nut and around the threaded shaft.

In about six months it was necessary to adjust the shaft, to get the proper size of stone going through the crusher. A new nut was on hand, so two $1\frac{1}{2}$-in. holes were drilled at *C*, and a punch was driven in to break the nut. The babbitt threads were found to be in good shape. W. F. JOHNSON.

Howes Cave, N. Y.

Adjustable Vernier Gage

The illustration shows the combination of a vernier and a micrometer into one tool. To get the graduations accurate on the sliding rod, I inserted a scale from a B. & S. depth gage. I found that, after this tool is once



AN ADJUSTABLE VERNIER GAGE

set, its accuracy can be relied upon without the use of a standard test rod. It will measure from 0 to 5 in. by thousandths.

This is an original idea with me, and I have one tool that has given good service. I should have made this tool to measure 6 in., but I did not have any way to graduate the rod, so I hit upon the idea of inserting a scale. Unfortunately, the scale was graduated for only 5 in.

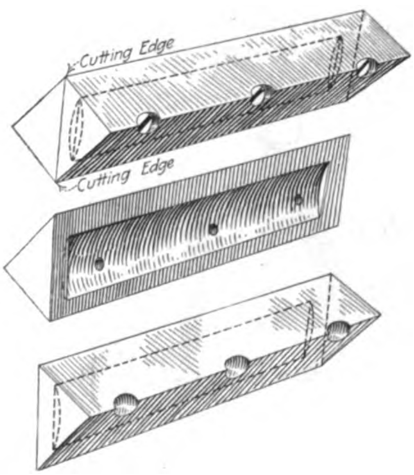
KARL J. FENNELL.

Davenport, Iowa.

Lap for Square Corners

The illustration shows a useful lap for finishing sharp square female corners. I had some difficulty in getting good results in making molds of tool steel hardened and ground to sizes within a limit of 0.0002 in.

I designed the tool shown, which proved satisfactory. Diamond dust, mixed with oil to suit, was applied be-



LAP FOR SQUARE CORNERS

tween the two halves, which were then screwed together, allowing the mixture to press out between the two thin edges.

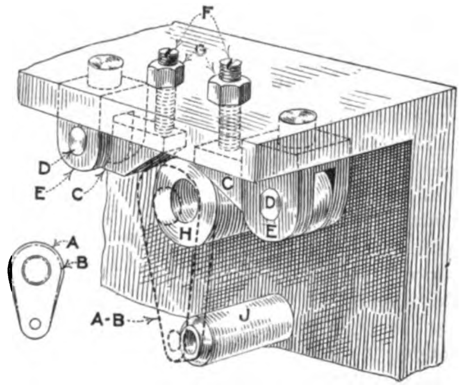
In lapping, the mixture will soon appear in the corner of the work. The tool should be made of tool steel, left soft and ground square on the surface grinder. The center should be hollow about 0.005 in., to receive the diamond and oil mixture.

ALFRED ERICSON.

Chicago, Ill.

Jig for Drilling Cranks

In two cranks A and B the center distances between the holes are the same, but the large diameter and the large holes vary about $\frac{1}{16}$ in. in diameter. The work is blanked and pierced and then placed in a jig, the large hole to be reamed and the small hole drilled. As the output is not very great, it was decided to change



ADJUSTABLE JIG FOR DRILLING CRANKS

the jig used on the large crank so that it would handle both cranks. The illustration shows how this plan was carried out.

The solid V-block is taken off and the adjustable one put on. The parts C are made of tool steel and beveled off to have the shape of a V-block. The parts C pivot on pins D in the slotted studs E. The adjustment is made by the setscrews F, locked by the nuts G. The same resting blocks H and J are used, as well as the bushing for the small hole and the method of bringing the work into the V-block and holding it. Slip bushings are put in the jig in place of the solid one for reaming the large holes.

Dayton, Ohio.

Balancing the Machines in a Trade-School Course

One common error in purchasing machines for a trade-school machine shop is to follow the established precedent of buying one planer, one shaper, one universal miller, one upright drill, one universal grinder and a varying number of lathes. This practice tends toward giving an unbalanced course, because the course is made to fit the machines. This is decidedly wrong; the machines should fit the course absolutely. The right thing to do is to decide the number of hours that should be devoted to each unit, find what relation each unit bears to the total number of required hours and buy enough machines to give an adequate balanced training to each boy.

A trade-school course, as a matter of time economy, must be condensed. The training must be continually progressive, with very little repetition of unit training.

Classroom work infringes so much on the shop end of the teaching, as compared with a commercial apprenticeship, that every minute of a boy's time in the shop must be utilized to his advantage. To do this, the course must be carefully predetermined and well balanced.

An apprentice in a machine shop generally receives three years of training, 52 weeks in the year, for 54 hr. each week, or 8,424 hr. Sometimes this total is greater, sometimes less. In trade-school work the hours required in the machine shop range from 2,000 to 4,000, according to the school. Some technical high schools demand only 250 hr. in the whole course. So it may be seen that this condensation of time required for the stipulated work must be met by well-studied methods in the presentation of the subjects.

Taking into consideration the fact that in a commercial machine shop the apprentices are carefully selected from a number of applicants, whereas in a trade school the boys are generally taken as they come (dumped down a chute into the machine shop, so to speak), the problem of properly balancing a course to suit conditions has difficulties all its own.

It makes no difference whether the boys are to spend each alternate week in the machine shop, each alternate hour or only 1½ hr. each day; the training on each machine should be properly proportioned. This is true whether the work is under the project system or mass production.

Let us take a machine shop for 30 boys. It is equipped in the usual way with one miller, one planer, one shaper, one upright drill and one grinder. Let us see the number of hours each boy can spend on any one machine, assuming that there are 25 lathes to accommodate the pupils who are not assigned to these five machines mentioned and also assuming that 4,000 hr. are required for a complete course, as that seems to be the maximum number of hours among trade schools. In 4,000 hr. each one of the 30 boys must get his turn at the miller, for instance, or 133⅓ hr. Now, 133⅓ hr. on the miller for any boy, however bright, is far from being sufficient, as all must admit, and naturally more time should be given to such work. This is how things stand among a great number of trade schools, and the condition should be corrected. The courses are made to fit the equipment.

The proper way to purchase machines for a trade school is to come to a decision regarding the length of time that is going to be assigned to the different units of a trade and then to purchase the machines accordingly. This practice gives a balanced course and makes the machines harmonize with it. For example, many commercial machine shops divide the apprentice's 3-yr. course into three months of milling, three months of planing, three months of shaper work, three months of grinding, etc.; that is, one-twelfth of the apprenticeship period is devoted to each of these five things. Now, if in the commercial shop experience has taught that one-twelfth of the boy's time on the miller gives him a sufficient working knowledge of that machine to suit the demands, then it is safe to accept this proportion as a beginning for use in the trade-school machine shop.

If one-twelfth of the pupil's time is set aside for milling, each boy will receive 366⅔ hr. of this branch of the trade. In order for each one of 30 boys to get 366⅔ hr. of milling, the number of millers to be purchased would be found by multiplying the number of boys by the number of hours of each unit and dividing by the number of hours in the course. For instance, $30 \times 366\frac{2}{3} = 11{,}000$ hr.; $11{,}000 \div 4{,}000 = 2\frac{3}{4}$ millers. Buying three millers, three planers, three shapers, three upright drills and three grinders would be a fraction over the required number of machines and would allow for a little future growth.

The criticism of this plan would be that it is much easier for a trade school to secure lathe work than it is for it to get milling, planing, drilling and grinding, but a little more scouting on the part of the shop superintendent can accomplish the desired end. It is much better to give the shop superintendent a part of his time exclusively for the purpose of going about among the factories looking for their superfluous planing, milling, drilling and grinding than to let the pupils fail to receive sufficient training in five of the fundamental machines of the trade.

The boring mill, radial drill, gear cutter, turret lathe, etc., should have as many hours assigned to them as seems proper to their local importance.

As the attention of the shop instructor should be devoted entirely to the supervision of the operation of the different machines under his charge, all such things as the teaching of the lacing of belts, chipping, filing, scraping, tapping, assembling, etc., should be treated as shop-instruction subjects under the head of classroom work. I fail to see where a trade-school shop with its already limited number of hours can provide time in the shop for these essential things without encroaching on the hours set aside for the operation of machines. If left to the discretion of the machine-shop instructor, the attention given them might be of a haphazard nature, whereas if assigned a definite number of hours in a certain classroom, they would be given the methodical attention due their importance in a well-balanced course.

Discussion of Previous Question

Straight and Taper Forced and Shrunk Fits

The three papers on the subject of forced and shrunk fits, published in *Engineering News*, Mar. 17, 1910, and in *American Machinist*, page 377, Vol. 42, and page 275, Vol. 44, are a valuable contribution to the subject of force fits, since they give us a much needed coördination and selection of the large amount of information supplied by many experimenters.

The alignment charts given by Professor Jenkins in the last two papers are clear and simple enough, but they do not readily show the comparative difference between the results obtained by using the formulas for straight fits and those for taper fits and do not show how the theoretical formulas published in *Engineering News* differ from the empirical formulas for either straight or taper fits.

I have plotted in a different way the fundamental equations and the empirical formulas derived by Professor Jenkins. I believe that this method is more handy and gives a more comprehensive idea of the relative meaning of the three sets of formulas. My results are shown graphically by means of the curves on the charts, Figs. 1 to 4, from which it will be noted that all four combinations of cast iron and steel are covered.

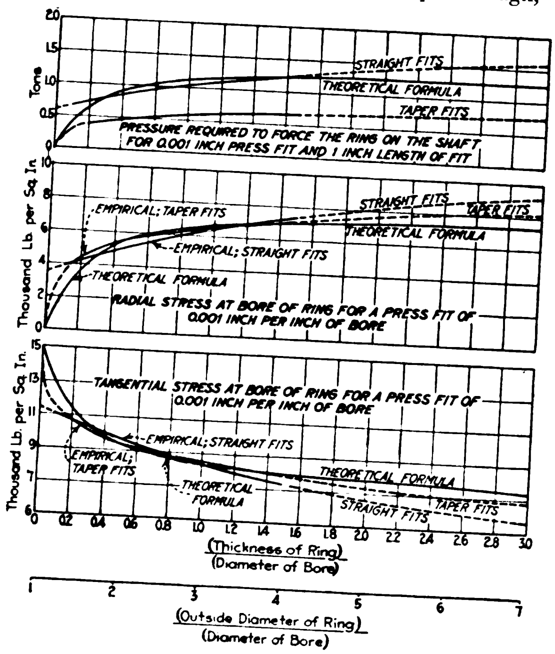

FIG. 1. CAST-IRON RING FORCED ON A STEEL SHAFT
